Nitro blue tetrazolium (NBT, N6495) is the most commonly used electron-transfer agent and co-precipitant for the BCIP reaction, forming a dark blue, precisely localized precipitate in the presence of alkaline phosphatase^{53,54} (Figure 10.3.15, Figure 10.3.16).

Kits for Detecting Phosphatases, Polymerases and Nucleases

We have developed some unique products for following the activity of phosphatases, polymerases and nucleases. Our P_i Per™ Phosphate and P_i Per™ Pyrophosphate Assay Kits provide ultrasensitive assays for free phosphate and pyrophosphate, respectively, through the formation of resorufin, which can be detected either fluorometrically or spectrophotometrically. Our EnzChek® Phosphate and EnzChek® Pyrophosphate Assay Kits provide spectrophotometric assays for inorganic phosphate and pyrophosphate, respectively. Both the P_i Per™ and the EnzChek® Phosphate Assay Kits permit continuous measurement of the activity of ATPases, GTPases, phosphatases, nucleotidases and a number of enzymes that produce or consume inorganic phosphate. Moreover, these enzyme assay kits utilize the natural substrate for the enzyme rather than a synthetic analog and detect the inorganic phosphate produced using enzyme-coupled reactions. The P_i Per™ Kit is more sensitive and better suited for high-throughput studies in microplates, but requires an additional enzymatic step, whereas the EnzChek® Kit is less sensitive but has a simpler protocol. In both the P_i Per™ and the EnzChek® Pyrophosphate Assay Kits, the phosphate assay is coupled with the enzyme, pyrophosphatase, in order to monitor the activity of pyrophosphate-producing enzymes such as DNA and RNA polymerases, adenylate cyclase and guanylate cyclase.^{55,56}

In addition to these kits, our RediPlate™ 96 EnzChek® Tyrosine Phosphatase Assay Kit (R22067) and RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit (R33700) utilize DiFMUP for assaying tyrosine phosphatase activity and serine/threonine phosphatase

Figure 10.3.15 Principle of enzyme-linked detection using the reagents in our NBT/BCIP Reagent Kit (N6547). Phosphatase hydrolysis of BCIP is coupled to reduction of NBT, yielding a formazan and an indigo dye that together form a black-purple-colored precipitate.

activity, respectively, as well as for screening phosphatase inhibitors in a convenient high-throughput format.

P_iPer™ Phosphate Assay Kit

The P_iPer™ Phosphate Assay Kit (P22061) provides an ultrasensitive assay that detects free phosphate in solution through formation of the fluorescent product resorufin. Because resorufin also has strong absorption, the assay can be performed either fluorometrically or spectrophotometrically. This kit can be used to detect inorganic phosphate (P_i) in a variety of samples or to monitor the kinetics of phosphate release by a variety of enzymes, including ATPases, GTPases, 5'-nucleotidase, protein phosphatases, acid and alkaline phosphatases and phosphorylase kinase. Furthermore, the assay can be modified to detect virtually any naturally occurring organic phosphate molecule by including an enzyme that can specifically digest the organic phosphate to liberate inorganic phosphate.

In the P_iPer™ phosphate assay (Figure 10.3.17), maltose phosphorylase converts maltose (in the presence of P_i) to glucose 1-phosphate and glucose. Then, glucose oxidase converts the glucose to gluconolactone and H₂O₂. Finally, with horseradish peroxidase as a catalyst, the H₂O₂ reacts with the Amplex® Red reagent (10-acetyl-3,7-dihydroxyphenoxazine) to generate resorufin, which has absorption/emission maxima of ~571/585 nm.^{57,58} The resulting increase in fluorescence or absorption is proportional to the amount of P_i in the sample. This kit can be used to detect as little as 0.2 μM P_i by fluorescence (Figure 10.3.18) or 0.4 μM P_i by absorption.

Each P_iPer™ Phosphate Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Concentrated reaction buffer
- Recombinant maltose phosphorylase from *Escherichia coli*
- Maltose
- Glucose oxidase from *Aspergillus niger*
- Horseradish peroxidase
- Phosphate standard
- Hydrogen peroxide
- Detailed protocols for detecting phosphatase activity

Sufficient reagents are provided for approximately 1000 assays using a reaction volume of 100 μL per assay and either a fluorescence or absorbance microplate reader.

Figure 10.3.18 Detection of inorganic phosphate using the P_iPer™ Phosphate Assay Kit (P22061). Each reaction contained 50 μM Amplex® Red reagent, 2 U/mL maltose phosphorylase, 1 mM maltose, 1 U/mL glucose oxidase and 0.2 U/mL HRP in 1X reaction buffer. Reactions were incubated at 37°C. After 60 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. Data points represent the average of duplicate reactions, and a background value of 43 (arbitrary units) was subtracted from each reading.

Figure 10.3.17 Principle of the P_iPer™ Phosphate Assay Kit (P22061). In the presence of inorganic phosphate, maltose phosphorylase converts maltose to glucose 1-phosphate and glucose. Then, glucose oxidase converts the glucose to gluconolactone and H₂O₂. Finally, with horseradish peroxidase (HRP) as a catalyst, the H₂O₂ reacts with the Amplex® Red reagent to generate the highly fluorescent resorufin. The resulting increase in fluorescence or absorption is proportional to the amount of P_i in the sample.

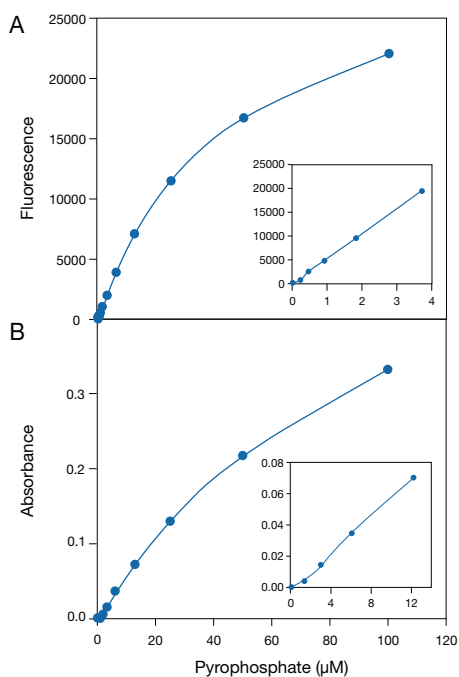

Figure 10.3.19 Detection of pyrophosphate using the P_i Per™ Pyrophosphate Assay Kit (P22062). Each reaction contained 50 μ M Amplex Red reagent, 0.01 U/mL inorganic pyrophosphatase, 2 U/mL maltose phosphorylase, 0.2 mM maltose, 1 U/mL glucose oxidase and 0.2 U/mL HRP in 1X reaction buffer. Reactions were incubated at 37°C. After 60 minutes, **A**) fluorescence was measured in a fluorescence-based microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm or **B**) absorbance was measured in an absorption-based microplate reader at 576 ± 5 nm. Data points represent the average of duplicate reactions. In panel A, a background value of 78 (arbitrary units) was subtracted from each reading; in panel B, a background absorbance of 0.011 was subtracted from each reading.

P_i Per™ Pyrophosphate Assay Kit

The P_i Per™ Pyrophosphate Assay Kit (P22062) provides a sensitive fluorometric or colorimetric method for measuring the inorganic pyrophosphate (PP_i) in experimental samples or for monitoring the kinetics of PP_i release by a variety of enzymes, including DNA and RNA polymerases, adenylate cyclase and S-acetyl coenzyme A synthetase. In the P_i Per™ pyrophosphate assay, inorganic pyrophosphatase hydrolyzes PP_i to two molecules of inorganic phosphate (P_i). The P_i then enters into the same cascade of reactions as it does in the P_i Per™ Phosphate Assay Kit (Figure 10.3.17). In this case, the resulting increase in fluorescence or absorption is proportional to the amount of PP_i in the sample. This kit can be used to detect as little as 0.1 μ M PP_i by fluorescence or 0.2 μ M PP_i by absorption (Figure 10.3.19). Each P_i Per™ Pyrophosphate Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Concentrated reaction buffer
- Recombinant maltose phosphorylase from *Escherichia coli*
- Maltose
- Glucose oxidase from *Aspergillus niger*
- Horseradish peroxidase
- Inorganic pyrophosphatase from baker's yeast
- Pyrophosphate standard
- Detailed protocols for detecting pyrophosphatase activity

Sufficient reagents are provided for approximately 1000 assays using a reaction volume of 100 μ L per assay and either a fluorescence or absorbance microplate reader.

EnzChek® Phosphate Assay Kit

The EnzChek® Phosphate Assay Kit (E6646), which is based on a method originally described by Webb,^{59,60} provides an easy enzymatic assay for detecting P_i from multiple sources through formation of a chromophoric product (Figure 10.3.20). Although this kit is usually used to determine the P_i produced by a wide variety of enzymes such as ATPases, kinases and phosphatases, it can also be used to specifically quantitate P_i with a sensitivity of ~ 2 μ M P_i (~ 0.2 μ g/mL) (Figure 10.3.21). Moreover, this spectrophotometric assay has proven useful for determining the level of P_i contamination in the presence of high concentrations of acid-labile phosphates using a microplate reader.⁶¹ Because the sulfate anion competes with P_i for binding to purine nucleoside phosphorylase (PNP), this kit can be adapted for measurement of sulfate concentrations between 0.1 and 10 mM in the presence of a low (<100 μ M) fixed P_i concentration.⁶² Each EnzChek® Phosphate Assay Kit contains:

- 2-Amino-6-mercapto-7-methylpurine riboside (MESG)
- Purine nucleoside phosphorylase (PNP)
- Concentrated reaction buffer
- KH_2PO_4 standard
- Detailed protocols for detecting and quantitating P_i

In the presence of P_i , MESG is enzymatically converted by PNP to ribose 1-phosphate and the chromophoric product 2-amino-6-mercapto-7-methylpurine (Figure 10.3.20). This kit contains sufficient reagents for about 100 phosphate assays using 1 mL assay volumes and standard cuvettes. The substrate MESG and the enzyme PNP included in our EnzChek® Phosphate Assay Kit have been adapted for monitoring the kinetics of phosphate release by:

- Actin-activated myosin ATPase^{60,63}
- Actin polymerization⁶⁴
- Aminoacyl-tRNA synthetase⁶⁵
- Aspartate transcarbamylase^{59,66}
- ArsA ATPase, the catalytic subunit of the arsenite pump⁶⁷
- Dethiobiotin synthetase⁶⁸
- Glycerol kinase⁶⁰
- Glycogen phosphorylase⁶⁹
- GTPases⁷⁰⁻⁷⁵

- ATPases^{66,76,77}
- *myo*-Inositol monophosphatase⁷⁸
- Phospholysine and phosphohistidine phosphatases^{79,80}
- Phosphorylase *a* phosphatase⁸¹
- Phosphorylase kinase⁸²
- Serine phosphatase⁸³
- Self-assembly of actin and tubulin⁸⁴
- Autodephosphorylation of CheY, a response regulator that mediates bacterial chemotaxis⁸⁵

Moreover, the EnzChek® phosphate assay is sufficiently fast and quantitative to permit stopped-flow kinetic experiments on enzymes that produce phosphate, an important development for mechanistic enzyme studies.⁶⁰ Although this kit is usually used to determine the inorganic phosphate produced by enzymes such as ATPases and GTPases, it can also be used to specifically quantitate inorganic phosphate contamination of reagents and solution, with a detection limit of ~2 μM P_i (~0.2 $\mu\text{g/mL}$) and an effective range between 2 and 150 μM inorganic phosphate (between 2 and 150 nanomoles phosphate in a 1 mL volume). For example, the assay has been used for the rapid assay of inorganic phosphate in the presence of high concentrations of acid-labile phosphates using a microplate reader.⁶¹ The reagents in this kit can also be used as a phosphate “mop” to remove almost all inorganic phosphate from a protein solution.³³

EnzChek® Pyrophosphate Assay Kit

In the EnzChek® Pyrophosphate Assay Kit (E6645), we have adapted the method provided in the EnzChek® Phosphate Assay Kit to permit the sensitive spectrophotometric detection of PP_i , which is converted by the enzyme pyrophosphatase to P_i .⁵⁶ Because two moles of P_i are released per mole of PP_i consumed, the sensitivity limit of the EnzChek® Pyrophosphate Assay Kit is 1 μM PP_i (~0.2 $\mu\text{g/mL}$). This assay has been modified to continuously detect several enzymes that liberate PP_i ^{86–89} such as aminoacyl-tRNA synthetase,⁶⁵ luciferase, cytidylyl transferase⁹⁰ and *S*-acetyl coenzyme A synthetase⁵⁶ adenylate cyclase and guanylyl cyclase.⁵⁵ Each EnzChek® Pyrophosphate Assay Kit contains:

- Inorganic pyrophosphatase
- 2-Amino-6-mercapto-7-methylpurine riboside (MESG)
- Purine nucleoside phosphorylase (PNP)
- Concentrated reaction buffer
- $\text{Na}_2\text{P}_2\text{O}_7$ standard
- Detailed protocols for detecting and quantitating PP_i

This kit contains sufficient reagents for about 100 PP_i assays using standard 1 mL assay volumes and standard cuvettes.

EnzChek® Phosphatase Assay Kit

The EnzChek® Phosphatase Assay Kit⁹¹ (E12020), which includes the DiFMUP substrate, can be used to continuously detect phosphatase activity at neutral, basic or moderately acidic pH. Using the assay outlined in the kit protocol, we have found that DiFMUP is about 100 times more sensitive than MUP for the detection of prostatic acid phosphatase at pH 5.5 (Figure 10.3.6) and can measure this activity at a pH that is optimal for the enzyme (Figure 10.3.7). The EnzChek® Phosphatase Assay Kit is perfect for the continuous assay of prostatic acid phosphatase, protein phosphatase 1 or almost any other phosphatase that can be assayed with nonprotein-based substrates such as MUP or 4-nitrophenyl phosphate (*p*NPP). Each EnzChek® Phosphatase Assay Kit contains:

- DiFMUP substrate
- Concentrated reaction buffer
- Acid phosphatase from potato for use as a positive control
- 6,8-Difluoro-7-hydroxy-4-methylcoumarin for use as a reference standard
- Detailed protocols for detecting phosphatase activity

The kit provides sufficient reagents for performing approximately 1000 assays, using a reaction volume of 100 μL per assay.

Figure 10.3.20 Enzymatic conversion of 2-amino-6-mercapto-7-methylpurine riboside (MESG) to ribose 1-phosphate and 2-amino-6-mercapto-7-methylpurine by purine nucleoside phosphorylase (PNP), reagents supplied in the EnzChek® Phosphate Assay Kit (E6646). The accompanying change in the absorption maximum (Abs) allows quantitation of inorganic phosphate (P_i) consumed in the reaction.

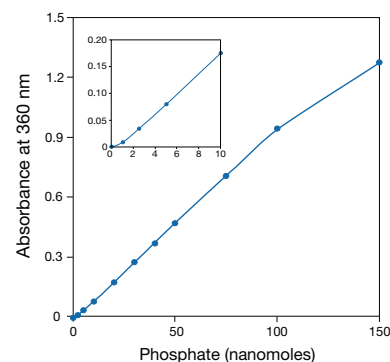

Figure 10.3.21 Quantitative analysis of inorganic phosphate using the EnzChek® Phosphate Assay Kit (E6646). KH_2PO_4 was used as the source for the inorganic phosphate, and the absorbance at 360 nm was corrected for background absorbance. The inset shows an enlargement of the standard curve, demonstrating the lower range of the assay; the units are the same.

The phosphatases listed in the table were applied at the indicated concentrations to a RediPlate™ 96 EnzChek® serine/threonine phosphatase assay microplate. Reactions were incubated at 37°C . After 1 hour, fluorescence was measured in a fluorescence microplate reader using excitation at 355 ± 20 nm and emission at 460 ± 12.5 nm.

RediPlate™ 96 EnzChek® Tyrosine Phosphatase Assay Kits

Protein tyrosine phosphatases (PTP) represent a large family of enzymes that play a very important role in intra- and intercellular signaling. PTPs work antagonistically with protein tyrosine kinases to regulate signal transduction pathways in response to a variety of signals, including hormones and mitogens.⁹² Our RediPlate™ 96 EnzChek® Tyrosine Phosphatase Assay Kit (R22067) provides researchers with a sensitive and convenient method to monitor PTP and screen PTP inhibitors in a variety of research areas^{93–96} (Figure 10.3.22).

The EnzChek® tyrosine phosphatase assay is based on 6,8-difluoro-4-methylumbelliferyl phosphate⁹⁷ (DiFMUP; D6567, D22065). The EnzChek® tyrosine phosphatase assay is continuous, allowing researchers to easily measure fluorescence at various time points in order to follow the kinetics of the reaction. Furthermore, the assay is not affected by free phosphate and is compatible with most nonionic detergents, resulting in minimal sample processing before analysis. Most importantly, each assay well contains inhibitors to help ensure that the assay is selective for tyrosine phosphatases; other phosphatases, including serine/threonine phosphatases, will not hydrolyze DiFMUP under our assay conditions (Figure 10.3.23). Unlike phosphopeptide-based assays, this DiFMUP-based assay can be used to monitor a variety of tyrosine phosphatases, including PTP-1B and CD-45 (Figure 10.3.23). Tyrosine phosphatase inhibitors can be evaluated quantitatively in the assay for their effect on tyrosine phosphatase activity.

Each RediPlate™ 96 EnzChek® Tyrosine Phosphatase Assay Kit (R22067) includes:

- One RediPlate™ 96 EnzChek® tyrosine phosphatase assay 96-well microplate
- Reaction buffer
- Detailed assay protocols

RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit

The majority of protein phosphorylation occurs on serine and threonine residues, with <0.01 – 0.05% on tyrosine residues. Serine/threonine phosphatases represent a large family of enzymes that have been implicated in the regulation of metabolism, transcription, translation, differentiation, cell cycle, cytoskeletal dynamics, oncogenesis and signal transduction. The RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit (R33700) provides a fast, simple and direct fluorescence-based assay for detecting serine/threonine phosphatases and their corresponding modulators and inhibitors⁹⁷ (Figure 10.3.22).

As with the RediPlate™ 96 EnzChek® Tyrosine Phosphatase Kit, the substrate incorporated in the RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit is DiFMUP. Inhibitors are included in each assay well to help ensure that the assay is selective for serine/threonine phosphatases; under the prescribed assay conditions, other phosphatases, including tyrosine phosphatases, do not significantly react with the substrate (Figure 10.3.24). Furthermore, unlike phosphopeptide-based assays, this DiFMUP-based assay can be used to monitor a variety of serine/threonine phosphatases including PP-1, PP-2A and PP-2B (Figure 10.3.24). Serine/threonine phosphatase inhibitors can be evaluated quantitatively in the assay for their effect on

Figure 10.3.22 Schematic diagram of the method used in the RediPlate™ EnzChek® Phosphatase Assay Kits (R22067, R33700).

serine/threonine phosphatase activity (Figure 10.3.25). Additional advantages of this RediPlate™ assay include compatibility with nonionic detergents and insensitivity to free phosphate, resulting in minimal sample processing before analysis.

Each RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit includes:

- One RediPlate™ 96 EnzChek® serine/threonine phosphatase assay 96-well microplate
- Concentrated reaction buffer
- NiCl₂
- MnCl₂
- Dithiothreitol
- Detailed assay protocols

To help ensure the integrity of the pre-dispensed reagents, the 96-well microplate provided in both RediPlate™ Protein Phosphatase Assay Kits is packaged in a resealable foil pouch and consists of twelve removable strips, each with eight wells (Figure 10.3.26). Eleven of the strips (88 wells) are preloaded with the fluorogenic substrate DiFMUP; the remaining strip, marked with black tabs, contains a dilution series of the DiFMU reference standard for generating a standard curve.

EnzChek® Ultra Phytase Assay Kit

Phytases catalyze the sequential hydrolysis of phytate (myoinositol hexakis phosphate; phytin; phytic acid) to less phosphorylated myo-inositol compounds and inorganic phosphate. The EnzChek® Ultra Phytase Assay Kit (E33701) utilizes a series of linked enzymatic reactions for the detection of phytase activity based on the measurement of phosphate released from the substrate phytic acid (Figure 10.3.27). In the initial step, phytase catalyzes the release of inorganic phosphate from phytic acid; in the presence of P_i, maltose phosphorylase converts maltose to glucose 1-phosphate and glucose. Glucose oxidase then converts the glucose to gluconolactone and H₂O₂. Finally, with horseradish peroxidase (HRP) as a catalyst, the H₂O₂ reacts with the Amplex® UltraRed reagent to generate a brightly fluorescent and strongly absorbing reaction product (excitation/emission maxima ~568/581 nm). The resulting increase in fluorescence is proportional to the amount of P_i in the sample. This relative measure of phytase activity can be used as the basis of a standard curve of phytase enzyme standards with known activity. The assay takes 1 hour at 37°C; under these conditions, the limit of detection is 0.001 FTU/mL and the intra-assay CV is ≤10%. The signal is not linear, but can cover a two-log concentration range for phytase (Figure 10.3.28).

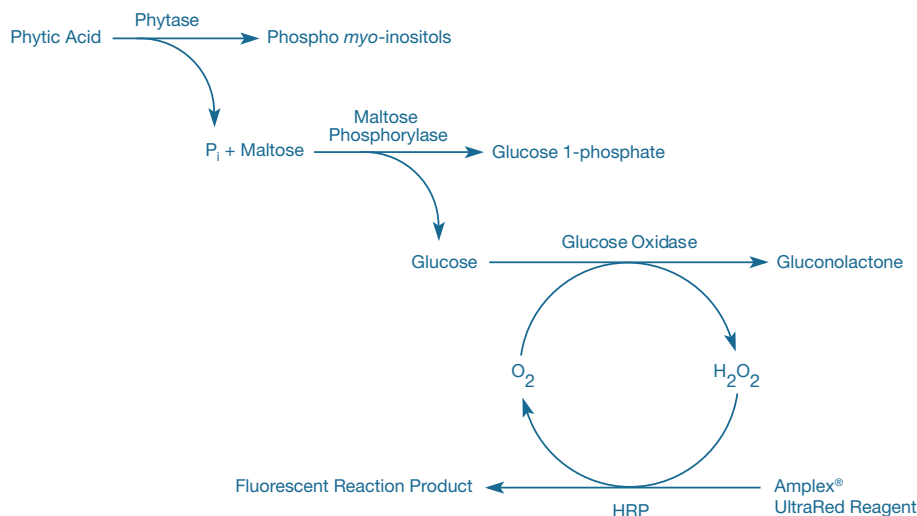

Figure 10.3.27 Principle of the EnzChek® Ultra Phytase Assay Kit (E33701).

Figure 10.3.25 Detection of PP-2A inhibition by okadaic acid using the RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit (R33700). Each reaction contained 50 μM DiFMUP, 10 mU/mL PP-2A and the indicated concentration (log scale) of okadaic acid in reaction buffer containing 50 mM Tris-HCl, 0.1 mM CaCl₂, 1 mM NiCl₂, 125 μg/mL bovine serum albumin (BSA) and 0.05% Tween® 20. Reactions were incubated at 37°C. After 30 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 355 ± 20 nm and emission at 460 ± 12.5 nm.

Figure 10.3.26 A RediPlate™ 96 microplate.

Figure 10.3.28 Assay of a standard phytase preparation using the EnzChek® Ultra phytase assay. A dilution series of Natuphos 10000 L phytase (BASF) in 0.1 M acetate buffer (pH 5.5) was assayed with the EnzChek® Ultra Phytase Assay Kit (E33701). Incubation time was 60 minutes; phytase activity is shown in FTU/mL (FTU= phytase unit, as defined by the manufacturer).

Each EnzChek® *Ultra* Phytase Assay Kit provides:

- Amplex® UltraRed reagent
- Dimethylsulfoxide (DMSO)
- Concentrated reaction buffer
- Sodium acetate, pH 5.5
- Phytic acid
- Maltose phosphorylase, recombinant from *Escherichia coli* (1 unit = the amount of enzyme that will convert maltose, in the presence of inorganic phosphate, to 1.0 mole of D-glucose and D-glucose 1-phosphate per minute at 37°C, pH 7.0)
- Glucose oxidase from *Aspergillus niger* (1 unit = the amount of enzyme that will oxidize 1.0 mole of D-glucose to D-gluconolactone and H₂O₂ per minute at 35°C, pH 5.1)
- Detailed protocols

Sufficient reagents are provided for five 96-well microplate assay with 6 mL per plate and 20% excess for pipetting considerations or partial-plate assays.

EnzChek® Paraoxonase Assay Kit

Paraoxonase is a mammalian enzyme associated with high-density lipoprotein ("good cholesterol") in serum. Low serum paraoxonase levels are positively correlated with risk of cardiovascular disease,⁹⁸ and paraoxonase activity is a better marker than the PON1 genotype for predicting susceptibility to vascular disease.⁹⁹ Paraoxonase has multiple activities including organophosphatase, phosphotriesterase, arylesterase and thiolactonase. The organophosphatase activity confers protection against toxic organophosphates such as insecticides, which are a common source of chemical intolerance, as well as nerve agents such as sarin and VX. Current methods for measuring paraoxonase in serum, including the colorimetric paraoxon assay,¹⁰⁰ are relatively insensitive and often toxic themselves, and are compromised by high background and low signal as well.

The EnzChek® Paraoxonase Assay Kit (E33702) is a highly sensitive, homogeneous fluorometric assay (excitation/emission maxima ~360/450 nm) for the organophosphatase activity of paraoxonase and is based on the hydrolysis of a fluorogenic organophosphate analog. Under standard conditions, this assay requires only 5 µL of serum, yields a signal in as little as 15 minutes and is linear for up to 60 minutes. The EnzChek® paraoxonase assay is >10-fold more sensitive

than the colorimetric paraoxon assay and, unlike the colorimetric assay, can distinguish samples of very similar paraoxonase activity. Furthermore, the EnzChek® paraoxonase assay requires only a single homogeneous reaction, which may be either continuously monitored or terminated using a stop solution. Correlation between the inhibition curves of the fluorogenic paraoxonase assay versus the colorimetric assay is excellent. The Z' factor (a statistical parameter for evaluating the signal window of an assay)¹⁰¹ is 0.95 when the assay is performed as described in the 96-well format.

Each EnzChek® Paraoxonase Assay Kit provides:

- Paraoxonase substrate
- Fluorescent reference standard
- Concentrated reaction buffer
- Stop reagent
- 96-well microplates
- Adhesive microplate covers
- Organophosphatase positive control
- Dimethylsulfoxide (DMSO)
- Detailed protocols

Sufficient reagents are provided for 100 assays using a reaction volume of 110 µL per well and a fluorescence microplate reader.

Antibody Beacon™ Tyrosine Kinase Assay Kit

The Antibody Beacon™ Tyrosine Kinase Assay Kit (A35725) provides a homogeneous solution assay for measuring the activity of tyrosine kinases and the effectiveness of potential inhibitors and modulators.⁹² The key to this tyrosine kinase assay is a small-molecule tracer ligand labeled with our bright green-fluorescent Oregon Green® 488 dye. When an anti-phosphotyrosine antibody binds this tracer ligand to form the Antibody Beacon™ detection complex, the fluorescence of the Oregon Green® 488 dye is efficiently quenched. In the presence of a phosphotyrosine-containing peptide, however, this Antibody Beacon™ detection complex is rapidly disrupted, releasing the tracer ligand and relieving its antibody-induced quenching (Figure 10.3.29). Upon its displacement by a phosphotyrosine residue, the Oregon Green® 488 dye-labeled tracer ligand exhibits an approximately 4-fold fluorescence enhancement, enabling the detection of as little as 50 nM phosphotyrosine-containing peptide with excellent signal-to-background discrimination.

Key benefits of the Antibody Beacon™ Tyrosine Kinase Assay Kit include:

- **Real-time measurements.** Unlike many other commercially available tyrosine kinase assays, the Antibody Beacon™ Tyrosine Kinase Assay Kit permits real-time monitoring of kinase activity (Figure 10.3.30). Not only is the Antibody Beacon™ detection complex rapidly dissociated in the presence of phosphotyrosine residues, but the assay components have been designed to be simultaneously combined, eliminating any delay in the measurements.
- **Simple detection protocol.** Tyrosine kinase activity is measured by a simple increase in fluorescence intensity; no special equipment, additional reagents, or extra steps are required. This assay is readily compatible with any fluorescence microplate reader.
- **Use of natural substrates.** The Antibody Beacon™ tyrosine kinase assay utilizes unlabeled peptide or protein substrates, is compatible

Figure 10.3.29 Reaction scheme for the tyrosine kinase assay used in the Antibody Beacon™ Tyrosine Kinase Assay Kit (A35725). The unlabeled natural substrate (AIYAE) is phosphorylated by the tyrosine kinase to AIY(P)AE, which displaces the quenched Oregon Green® 488 dye-labeled peptide from the anti-phosphotyrosine antibody, resulting in a large increase in its fluorescence that is proportional to the amount of AIY(P)AE formed in the reaction.

with substrates that are pre-phosphorylated at serine or threonine (but *not* at tyrosine) residues and is applicable to the assay of a wide variety of kinases.

- **Compatibility.** The anti-phosphotyrosine antibody provided in the Antibody Beacon™ Tyrosine Kinase Assay Kit is specific for phosphotyrosine residues; assay components such as ATP (up to 1 mM) and reducing agents such as dithiothreitol (DTT, up to 1 mM) do not interfere with this assay. This anti-phosphotyrosine antibody was selected from among several clones to produce the greatest fluorescence enhancement by the kinase-phosphorylated product.
- **Reliability.** This tyrosine kinase assay has a broad signal window, indicated by a Z' factor of >0.85.

The Antibody Beacon™ Tyrosine Kinase Assay Kit comes with all the reagents needed to perform this assay, including:

- Oregon Green® 488 dye–labeled tracer ligand
- Anti-phosphotyrosine antibody
- Concentrated tyrosine kinase reaction buffer
- Two generic tyrosine kinase substrate solutions: a poly(Glu:Tyr) solution and a poly(Glu:Ala:Tyr) solution
- Dithiothreitol (DTT)
- Adenosine triphosphate (ATP)
- Phosphotyrosine-containing peptide, phospho-pp60 c-src (521–533), for use as a reference
- Detailed protocols

Each kit provides sufficient reagents to perform ~400 assays using a 50 µL assay volume in a fluorescence microplate reader. We provide an extensive range of assays for protein kinases that utilize a variety of strategies to detect phosphorylation of peptide and protein substrates (Table 17.1).

ATP Determination Kit

The ATP Determination Kit (A22066) is designed to provide a convenient method for the sensitive bioluminescence-based detection of ATP with recombinant firefly luciferase and its substrate luciferin. This assay is based on luciferase's absolute requirement for ATP to produce light. In the presence of Mg²⁺, luciferase catalyzes the reaction of luciferin, ATP and O₂ to form oxyluciferin, AMP, CO₂, pyrophosphate and ~560 nm light (Section 10.6).

The luciferin–luciferase bioluminescence assay is extremely sensitive; most luminometers can detect as little as 1 picomole of pre-existing ATP or ATP as it is generated in kinetic systems (Figure 10.3.31). This sensitivity has led to its widespread use for detecting ATP in various enzymatic reactions, as well as for measuring viable cell number¹⁰² (Section 15.2, Section 15.3) and for detecting low-level bacterial contamination in samples such as blood, milk, urine, soil and sludge.^{103–107} The luciferin–luciferase bioluminescence assay has also been used to determine cell proliferation and cytotoxicity in both bacterial^{108,109} and mammalian cells,^{110,111} and to distinguish cytostatic versus cytotoxic potential of anticancer drugs on malignant cell growth.¹¹²

Each ATP Determination Kit (A22066) contains:

- Luciferin (5 vials, each containing 3.0 mg)
- Luciferase
- Dithiothreitol (DTT)
- ATP
- Concentrated reaction buffer
- Detailed protocols for ATP quantitation

Unlike most other commercially available ATP detection kits, our ATP Determination Kit provides the luciferase and luciferin packaged separately, which enables researchers to optimize the reaction conditions for their particular instruments and samples. The ATP Determination Kit provides sufficient reagents for performing 200 ATP assays using 0.5 mL sample volumes or 500 ATP assays using 0.2 mL sample volumes.

Figure 10.3.30 Real-time detection capability of the Antibody Beacon™ Tyrosine Kinase Assay Kit (A35725). Fluorescence of the Antibody Beacon™ detection complex in tyrosine kinase assay buffer was monitored over time. After ~15 seconds, an excess of phosphotyrosine-containing peptide was added to the Antibody Beacon™ detection complex and the off-rate was calculated.

Figure 10.3.31 Detection of ATP using the ATP Determination Kit (A22066). Each reaction contained 1.25 µg/mL of firefly luciferase, 50 µM D-luciferin and 1 mM DTT in 1X reaction buffer. Luminescence was measured after a 15-minute incubation.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- The molecular weight (MW) of this product is approximate because the degree of hydration and/or salt form has not been conclusively established.
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- This compound is a nonhydrolyzable substrate analog.
- Fluorescence of the unhydrolyzed substrate is very weak.
- Data represent the substrate component of this kit.
- Enzymatic phosphorylation of this substrate yields 2-amino-6-mercapto-7-methylpurine (Abs = 355 nm). (*Proc Natl Acad Sci U S A* (1992) 89:4884)
- Unstable in water. Use immediately.
- Fluorescence of BODIPY® dye-labeled guanosine derivatives is generally weak due to base-specific intramolecular quenching. (*Anal Biochem* (2001) 291:109)
- Phosphatase hydrolysis of BCIP (B6492) is coupled to reduction of NBT (N6495), yielding a water-insoluble indigo dye (Abs ~615 nm) and a water-insoluble formazan (Abs ~605 nm), respectively.

PRODUCT LIST 10.3 DETECTING ENZYMES THAT METABOLIZE PHOSPHATES AND POLYPHOSPHATES

Cat. No.	Product	Quantity
A22184	adenosine 5'-O-(3-thiotriphosphate), BODIPY® FL thioester, sodium salt (BODIPY® FL ATP-γ-S, thioester) *5 mM in buffer*	50 µL
A35725	Antibody Beacon™ Tyrosine Kinase Assay Kit *400 assays*	1 kit
A22066	ATP Determination Kit *special packaging* *200–1000 assays*	1 kit
C10552	Chemiluminescent Alkaline Phosphatase ELISA Kit #1 *with CSPD® Substrate/ Sapphire-II™ enhancer* *1000 assays*	1 kit
C10553	Chemiluminescent Alkaline Phosphatase ELISA Kit #2 *with CSPD® Substrate/ Emerald-II™ enhancer* *1000 assays*	1 kit
C10554	Chemiluminescent Alkaline Phosphatase ELISA Kit #3 *with CDP-Star® Substrate/ Sapphire-II™ enhancer* *1000 assays*	1 kit
C10555	Chemiluminescent Alkaline Phosphatase ELISA Kit #4 *with CDP-Star® Substrate/ Emerald-II™ enhancer* *1000 assays*	1 kit
C10556	Chemiluminescent Alkaline Phosphatase ELISA Sampler Kit *1000 assays*	1 kit
D6487	9H-(1,3-dichloro-9,9-dimethylacridin-2-one-7-yl) phosphate, diammonium salt (DDAO phosphate)	5 mg
D6567	6,8-difluoro-4-methylumbelliferyl phosphate (DiFMUP)	5 mg
D22065	6,8-difluoro-4-methylumbelliferyl phosphate (DiFMUP) *packaged for high-throughput screening*	10 x 10 mg
E6603	ELF® 97 Cytological Labeling Kit *with streptavidin, alkaline phosphatase conjugate* *50 assays*	1 kit
E6601	ELF® 97 Endogenous Phosphatase Detection Kit	1 kit
E6600	ELF® 97 Immunohistochemistry Kit	1 kit
E6604	ELF® 97 mRNA <i>In Situ</i> Hybridization Kit #1 *50 assays*	1 kit
E6605	ELF® 97 mRNA <i>In Situ</i> Hybridization Kit #2 *with streptavidin, alkaline phosphatase conjugate* *50 assays*	1 kit
E6588	ELF® 97 phosphatase substrate (ELF® 97 phosphate) *5 mM in water* *0.2 µm filtered*	1 mL
E6589	ELF® 97 phosphatase substrate (ELF® 97 phosphate) *5 mM in water* *contains 2 mM azide*	1 mL
E6606	ELF® spin filters *20 filters*	1 box
E33702	EnzChek® Paraoxonase Assay Kit *100 assays*	1 kit
E12020	EnzChek® Phosphatase Assay Kit *1000 assays*	1 kit
E6646	EnzChek® Phosphate Assay Kit *100 assays*	1 kit
E6645	EnzChek® Pyrophosphate Assay Kit *100 assays*	1 kit
E33701	EnzChek® Ultra Phytase Assay Kit *500 assays*	1 kit
F2999	fluorescein diphosphate, tetraammonium salt (FDP)	5 mg
G22183	guanosine 5'-O-(3-thiotriphosphate), BODIPY® FL thioester, sodium salt (BODIPY® FL GTP-γ-S, thioester) *5 mM in buffer*	50 µL
M6491	4-methylumbelliferyl phosphate, free acid (MUP)	1 g
N6547	NBT/BCIP Reagent Kit	1 kit
N6495	nitro blue tetrazolium chloride (NBT)	1 g
N10559	NovaBright™ Secreted Placental Alkaline Phosphatase (SEAP) Enzyme Reporter Gene Chemiluminescent Detection Kit *400 assays*	1 kit
N10560	NovaBright™ Secreted Placental Alkaline Phosphatase (SEAP) Enzyme Reporter Gene Chemiluminescent Detection Kit *1200 assays*	1 kit
N10577	NovaBright™ Secreted Placental Alkaline Phosphatase (SEAP) Enzyme Reporter Gene Chemiluminescent Detection Kit 2.0 *192 assays*	1 kit
N10578	NovaBright™ Secreted Placental Alkaline Phosphatase (SEAP) Enzyme Reporter Gene Chemiluminescent Detection Kit 2.0 *960 assays*	1 kit
P22061	P _i Per™ Phosphate Assay Kit *1000 assays*	1 kit
P22062	P _i Per™ Pyrophosphate Assay Kit *1000 assays*	1 kit
R33700	RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit *one 96-well microplate*	1 kit
R22067	RediPlate™ 96 EnzChek® Tyrosine Phosphatase Assay Kit *one 96-well microplate*	1 kit

Figure 10.4.1 Absorption and fluorescence emission spectra of 7-amino-4-methylcoumarin in pH 7.0 buffer.

10.4 Detecting Peptidases and Proteases

Peptidases and proteases play essential roles in protein activation, cell regulation and signaling, as well as in the generation of amino acids for protein synthesis or utilization in other metabolic pathways. In general, peptidases cleave shorter peptides, and proteases cleave longer peptides and proteins. Depending on their site of cleavage, peptidases can be classified as exopeptidases if they preferentially hydrolyze amino acid residues from the terminus of a peptide, or endopeptidases if they cleave internal peptide bonds.¹ Exopeptidases are further divided into aminopeptidases and carboxypeptidases depending on whether they hydrolyze residues from the amine or the carboxy terminus.

Although the spectral properties of fluorogenic peptidase and protease substrates and their hydrolysis products are easily predictable, the utility of a given substrate for an enzyme depends on the kinetics of hydrolysis by the enzyme, which, in turn, depends on the substrate's concentration and amino acid sequence, as well as on the pH, temperature and presence of cofactors in the medium. For measurements in live cells, the suitability of a particular substrate also hinges on its accessibility to the enzyme and the cellular retention of the hydrolysis product.² In addition to these factors, the chromophore or fluorophore conjugated to the substrate can influence its hydrolysis rate and specificity, as well as the permeability of the substrate and its hydrolysis product.

We prepare a variety of protease substrates, including selective protease substrates for caspase-3 and caspase-8—enzymes that are activated during apoptosis (Section 15.5)—and for HIV protease and renin. Our EnzChek® and DQ™ protease substrates include:

Figure 10.4.2 Sequential peptidase cleavage of a rhodamine 110-based substrate. The nonfluorescent bisamide substrate is first converted to the fluorescent monoamide and then to the highly fluorescent rhodamine 110.

- EnzChek® Protease Assay Kits (E6638, E6639, R22132), which use a heavily BODIPY® dye-labeled DQ™ casein derivative for the assay of a wide variety of proteases (Table 10.4).
- EnzChek® Peptidase/Protease Assay Kit (E33758), which uses a fluorescence resonance energy transfer (FRET)-based substrate to detect protease activity.
- The EnzChek® Polarization Assay Kit for Proteases (E6658), which uses a green-fluorescent BODIPY® FL casein conjugate with an optimal degree of labeling for fluorescence polarization-based general protease assays (Fluorescence Polarization (FP)—Note 1.4).
- EnzChek® Gelatinase/Collagenase Assay Kit (E12055) and EnzChek® Elastase Assay Kit (E12056), which use DQ™ gelatin or DQ™ elastin as substrates, provide the speed, high sensitivity and convenience required for measuring gelatinase (collagenase) or elastase activity³ and for screening protease inhibitors in a high-throughput format.
- DQ™ collagen (D12052, D12060), DQ™ BSA (D12050, D12051) and DQ™ ovalbumin (D12053), which are useful for screening protease activity and inhibitors (including *in situ* zymography⁴) and for studying antigen processing.

Peptidase Substrates

The carboxy terminus of single amino acids and short peptides can be conjugated to certain amine-containing fluorophores to create fluorogenic peptidase substrates. The dyes used to make these substrates are fluorescent at physiological pH; however, when the dyes are coupled in an amide linkage to peptides, their absorption maxima are usually shortened significantly. The resulting substrates are sometimes fluorescent but with relatively short-wavelength emission spectra. In an extreme case such as that of rhodamine 110-based substrates, detectable long-wavelength absorbance and fluorescence are completely eliminated by amide formation. Peptidase activity releases the fluorophore, restoring its free-dye fluorescence.

UV Light-Excitable Substrates Based on 7-Aminocoumarins

7-Amino-4-methylcoumarin (AMC, A191; Section 10.1) is a blue-fluorescent dye (Figure 10.4.1) whose peptide amides are used extensively as substrates for detecting enzymatic activity in cells, homogenates and solutions. The CBZ-L-phenylalanyl-L-arginine amide of AMC (A6521) is a substrate for a variety of serine proteases, including cathepsins, kallikrein and plasmin.⁵⁻¹⁴ AMC and 7-amino-4-trifluoromethylcoumarin (AFC)—a dye with somewhat longer-wavelength

spectra than AMC (excitation/emission maxima of ~380/500 nm) at pH 7—are released from the caspase-3, caspase-7 and caspase-8 substrates listed in Table 15.5; these caspases are activated during early stages of apoptosis (Section 15.5). The Z-DEVD-AMC substrate is also a component of the EnzChek® Caspase-3 Assay Kit #1 (E13183).

7-Amino-4-chloromethylcoumarin (CMAC, C2110; Section 10.1) is a mildly thiol-reactive analog of AMC; CMAC-based substrates yield fluorescent peptidase products with improved retention in live cells. The fluorogenic *t*-BOC-Leu-Met-CMAC substrate^{15,16} (A6520) has been used to measure calpain activity in hepatocytes following the addition of extracellular ATP.^{17,18}

Visible Light-Excitable Substrates Based on Rhodamine 110

Rhodamine 110 (R110, R6479; Section 10.1) is a visible light-excitable dye with much stronger absorption than AMC; R110-based substrates usually comprise two identical amino acids or peptides attached to a single fluorophore. Molecular Probes® bisamide derivatives of rhodamine 110 are sensitive and selective substrates for assaying protease activity in solution or inside live cells. Originally developed by Walter Mangel and colleagues, these substrates comprise an amino acid or peptide covalently linked to each of R110's amino groups, thereby suppressing both its visible absorption and fluorescence.^{19,20} Upon enzymatic cleavage, the nonfluorescent bisamide substrate is converted in a two-step process first to the fluorescent monoamide and then to the even more fluorescent R110 (Figure 10.4.2). The fluorescence intensities of the monoamide and of R110 are constant from pH 3–9. Both of these hydrolysis products exhibit spectral properties similar to those of fluorescein, with peak excitation and emission wavelengths of 496 nm and 520 nm (Figure 10.4.3), respectively, making them compatible with flow cytometers²¹ and other instrumentation based on the argon-ion laser. Substrates based on R110 may also be useful for sensitive spectrophotometric assays because the R110 dye has intense visible absorption (extinction coefficient at 496 nm = ~80,000 cm⁻¹M⁻¹ in pH 6 solution).

We prepare a variety of substrates based on the rhodamine 110 fluorophore (Table 10.2). Bis-(CBZ-Arg)-R110 (BZAR, R6501) is a general substrate for serine proteases that has proven to be 50- to 300-fold more sensitive than the analogous AMC-based substrate.^{19,22} This enhanced sensitivity can be attributed both to the greater fluorescence of the enzymatic product and to the enhanced reactivity of the cleavage site. In addition, BZAR inhibits guanidinobenzoate activity in tumor cells.^{22,23} The tripeptide derivative bis-(CBZ-Ile-Pro-Arg)-R110 (BZiPAR, R6505) allows direct and continuous monitoring of enzyme turnover, making it useful for determining individual kinetic constants of fast-acting, irreversible trypsin inhibitors.²⁴ BZiPAR has been shown to enter intact cells where it is cleaved by lysosomal proteases.²⁵ Simultaneous

Figure 10.4.3 Absorption and fluorescence emission spectra of rhodamine 110 in pH 7.0 buffer.

Figure 10.4.4 Detection of apoptosis in SK-N-MC neuroblastoma cells. Following a 6-hour exposure to hydrogen peroxide, cells were labeled with Hoechst 33342 (H1399, H3570, H21492), tetramethylrhodamine ethyl ester (TMRE, T669) and rhodamine 110, bis-L-aspartic acid amide (R22122) for 15 minutes. Apoptotic cells show green cytosolic fluorescence resulting from cleavage of the rhodamine 110, bis-L-aspartic acid amide substrate by active caspase-3. The staining pattern of the Hoechst 33342 dye reveals that the majority of the rhodamine 110-positive cells also contain condensed or fragmented nuclei characteristic of apoptosis. Furthermore, the rhodamine 110-positive cells are also characterized by an absence of polarized mitochondria, as indicated by their failure to load the positively charged mitochondrial indicator TMRE. The image was contributed by A.K. Stout and J.T. Greenamyre, Emory University.

measurement of enzymatic activity with BZiPAR and Ca^{2+} transients with fura-2 (F1201, F1221, F1225, F14185; Section 19.2) has been reported.²⁶ Bis-(CBZ-Phe-Arg)-R110 (R6502) has been employed for flow cytometric analysis of the cysteine proteases cathepsin B and L in human monocytes and rat macrophages.^{27–29} Bis-(CBZ-Ala-Ala-Ala-Ala)-R110 (R6506), an elastase substrate, has been used in a novel DNA detection assay.³⁰ Bis-(CBZ-Ala-Arg)-R110 (R6508) is a fluorogenic substrate for both elastase and trypsin.^{19,28} The bis-(tosyl-Gly-Pro-Arg) amide of rhodamine 110 (R22124) is a selective substrate for thrombin.³¹ Turnover of this substrate by thrombin on a membrane in the presence of thromboplastin produces both color and fluorescence that has been reported to model coagulation and blood clot formation. We also offer the human renin substrate 1 (R2931) for measuring the activity of this important blood-pressure-regulating enzyme.

Caspase Substrates and Assay Kits

Members of the caspase (CED-3/ICE) family of cysteine–aspartic acid specific proteases have been identified as crucial mediators of the complex biochemical events associated with apoptosis.^{32–35} The recognition site for caspases is marked by three to four amino acids followed by an aspartic acid residue, with the cleavage occurring after the aspartate.³⁶ The caspase proteases are typically synthesized as inactive precursors. Inhibitor release or cofactor binding activates the caspase through cleavage at internal aspartates, either by autocatalysis or by the action of another protease.³³

Caspase-3 Substrates

Caspase-3 (CPP32/apopain) is a key effector in the apoptosis pathway, amplifying the signal from initiator caspases (such as caspase-8) and signifying full commitment to cellular disassembly. In addition to cleaving other caspases in the enzyme cascade, caspase-3 has been shown to cleave poly(ADP-ribose) polymerase (PARP), DNA-dependent protein kinase, protein kinase C and actin.^{34,37} We offer a selection of fluorogenic caspase substrates (Table 15.5). The Z-DEVD-R110 substrate,^{38,39} which contains the caspase-3 recognition site Asp-Glu-Val-Asp (DEVD), is a component of our EnzChek® Caspase-3 Assay Kit #2 (E13184) and RediPlate™ 96 EnzChek® Caspase-3 Assay Kit (R35100; Table 10.3) described below and is available separately in a 20 mg unit size for high-throughput screening applications (R22120, Table 10.2). This non-fluorescent bisamide is first converted by caspase-3 (or a closely related protease) to the fluorescent monoamide and then to the even more fluorescent rhodamine 110 (excitation/emission maxima ~496/520 nm). In addition, the bis-L-aspartic acid amide of R110 (D₂-R110, R22122), which contains rhodamine 110 (R110) flanked by aspartic acid residues, may serve as a substrate for a variety of apoptosis-related proteases, including caspase-3 and caspase-7,³⁸ and does not appear to require any invasive techniques such as osmotic shock to gain entrance into the cytoplasm (Figure 10.4.4).

Table 10.3 RediPlate™ Assay Kits.

RediPlate™ Assay Kit	Cat. No.	Assay Details
EnzChek® Caspase-3 Assay Kit (Section 10.4)	R35100	A direct fluorescence-based assay for detecting caspase-3 and other DEVD-selective protease activities (e.g., caspase-7) in cell extracts and purified enzyme preparations. Caspase activity is indicated by increasing green fluorescence (excitation/emission maxima ~496/520 nm).
EnzChek® Protease Assay Kit *red fluorescence* (Section 10.4)	R22132	A direct fluorescence-based assay for detecting metallo-, serine, acid and sulfhydryl proteases and their inhibitors. Protease activity is indicated by increasing red fluorescence (excitation/emission maxima ~589/617 nm).
EnzChek® Tyrosine Phosphatase Assay Kit (Section 10.3)	R22067	An assay for monitoring protein tyrosine phosphatases (PTP) and for screening PTP inhibitors and modulators. PTP activity is indicated by increasing blue fluorescence (excitation/emission maxima ~358/452 nm).
EnzChek® Serine/Threonine Phosphatase Assay Kit (Section 10.3)	R33700	An assay for monitoring serine/threonine (Ser/Thr) phosphatases and for screening Ser/Thr inhibitors and modulators. Ser/Thr phosphatase activity is indicated by increasing blue fluorescence (excitation/emission maxima ~358/452 nm).
RiboGreen® RNA Quantitation Kit (Section 8.3)	R32700	An assay for accurately quantitating low levels of RNA (1 ng/mL) with a broad dynamic range—over three orders of magnitude using two different dye concentrations. When bound to RNA, the RiboGreen® reagent exhibits excitation/emission maxima of ~500/520 nm.

Caspase-8 Substrates

Caspase-8 plays a critical role in the early cascade of apoptosis, acting as an initiator of the caspase activation cascade. Activation of the enzyme itself is accomplished through direct interaction with the death domains of cell-surface receptors for apoptosis-inducing ligands.^{40,41} The activated protease has been shown to be involved in a pathway that mediates the release of cytochrome *c* from the mitochondria⁴² and is also known to activate downstream caspases, such as caspase-3.⁴³ The fluorogenic substrate Z-IETD-R110 (R22125, R22126; green fluorescent after cleavage) contains the caspase-8 recognition sequence Ile-Glu-Thr-Asp (IETD) (Table 15.5).

Other Caspase and Granzyme B Substrates

In addition to our R110-derived caspase-3 and -8 substrates, we offer R110-based substrates for caspase-1, -2, -6, -9 and -13, as well as substrates for granzyme B (Table 15.5). Granzyme B, a serine protease contained within cytotoxic T lymphocytes and natural killer cells, is thought to induce apoptosis in target cells by activating caspases and causing mitochondrial cytochrome *c* release.⁴⁴

EnzChek® Caspase-3 Assay Kits

The EnzChek® Caspase-3 Assay Kits permit the detection of apoptosis by assaying for increases in caspase-3 and caspase-3-like protease activities (Figure 10.4.5, Figure 10.4.6). Our EnzChek® Caspase-3 Assay Kit #1 (E13183) contains the 7-amino-4-methylcoumarin (AMC)-derived substrate Z-DEVD-AMC (Figure 10.4.7) (where Z represents a benzylloxycarbonyl group). This substrate, which is weakly fluorescent in the UV spectral range (excitation/emission maxima ~330/390 nm), yields the blue-fluorescent product AMC (A191, Section 10.1, Figure 10.4.1), which has excitation/emission maxima of 342/441 nm upon proteolytic cleavage.

The EnzChek® Caspase-3 Assay Kit #2 (E13184) contains the R110-derived substrate, Z-DEVD-R110^{38,39} (Figure 10.4.8). This substrate is a bisamide derivative of R110, containing DEVD peptides covalently linked to each of R110's amino groups, thereby suppressing both the dye's visible absorption and fluorescence. Upon enzymatic cleavage by caspase-3 (or a closely related protease), the nonfluorescent bisamide substrate is converted in a two-step process first to the fluorescent monoamide and then to the even more fluorescent R110 (R6479, Section 10.1, Figure 10.4.2, Figure 10.4.3). Both of these hydrolysis products exhibit spectral properties similar to those of fluorescein, with excitation/emission maxima of 496/520 nm. The Z-DEVD-R110 substrate (R22120) is also available separately in a 20 mg unit size for high-throughput screening applications.

Either kit can be used to continuously measure the activity of caspase-3 and closely related proteases in cell extracts and purified enzyme preparations using a fluorescence microplate reader or fluorometer. AMC-based DEVD substrates, which yield blue fluorescence upon proteolytic cleavage, are widely used to monitor caspase-3 activity.^{37,45} The longer-wavelength spectra and higher extinction coefficient of the green-fluorescent products of the R110-based substrate in Kit #2 (E13184) should provide even greater sensitivity.^{38,39} The reversible aldehyde-based inhibitor Ac-DEVD-CHO can be used to confirm that the observed fluorescence signal in both induced and control cell populations is due to the activity of caspase-3-like proteases.³⁷

Figure 10.4.8 Rhodamine 110, bis-(*N*-CBZ-L-aspartyl-L-glutamyl-L-valyl-L-aspartic acid amide, Z-DEVD-R110, E13184).

Figure 10.4.5 Detection of caspase-3 activity using the EnzChek® Caspase-3 Assay Kit #1 (E13183). Increasing amounts of purified active human (recombinant) caspase-3 (PharMingen) were allowed to react with 100 μ M Z-DEVD-AMC in 1X reaction buffer for ~45 minutes at room temperature. Fluorescence was measured in a fluorescence microplate reader using excitation at 360 ± 17.5 nm and emission detection at 465 ± 17.5 nm. Background fluorescence (386 arbitrary units), determined for a no-enzyme control, was subtracted from each value.

Figure 10.4.6 Detection of protease activity in Jurkat cells using the EnzChek® Caspase-3 Assay Kit #1 with Z-DEVD-AMC substrate (E13183). Cells were either treated with 10 μ M camptothecin for 4 hours at 37°C to induce apoptosis (induced) or left untreated (control). Both induced and control cells were then harvested, lysed and assayed. Reactions were carried out at room temperature, and fluorescence was measured in a fluorescence microplate reader using excitation at 360 ± 20 nm with emission detection at 460 ± 20 nm after the indicated amount of time.

Figure 10.4.7 7-amino-4-methylcoumarin, *N*-CBZ-L-aspartyl-L-glutamyl-L-valyl-L-aspartic acid amide (Z-DEVD-AMC, E13183).

Figure 10.4.9 Detection of protease activity in Jurkat cells using the RediPlate™ 96 EnzChek® Caspase-3 Assay Kit (R35100). Jurkat human T-cell leukemia cells were first exposed to 10 μ M camptothecin at 37°C to induce apoptosis, and then harvested and lysed according to the kit protocol. The cell lysate was separated into two samples, one of which was treated with the Ac-DEVD-CHO inhibitor (provided in the RediPlate™ 96 EnzChek® Caspase-3 Assay Kit). Assay reactions on both the inhibited and the uninhibited samples were carried out at 37°C, and fluorescence was measured in a fluorescence microplate reader (excitation/emission = 485/535 nm).

Figure 10.4.10 A RediPlate™ 96 microplate.

The EnzChek® Caspase-3 Assay Kits contain:

- Z-DEVD-AMC^{46,47} (in Kit #1, E13183) or Z-DEVD-R110^{38,48} (in Kit #2, E13184)
- Dimethylsulfoxide (DMSO)
- Concentrated cell-lysis buffer
- Concentrated reaction buffer
- Dithiothreitol (DTT)
- Ac-DEVD-CHO, a reversible aldehyde-based inhibitor
- 7-Amino-4-methylcoumarin (AMC) (in Kit E13183) or rhodamine 110 (in Kit E13184) reference standard to quantitate the amount of fluorophore released in the reaction
- Detailed protocols

Each kit provides sufficient reagents for performing ~500 assays using a volume of 100 μ L per assay. For information about additional kits and reagents for studying apoptosis, see Section 15.5.

RediPlate™ 96 EnzChek® Caspase-3 Assay Kit

Our EnzChek® Caspase-3 Assay Kit #2 is also available as a convenient RediPlate™ 96 EnzChek® Caspase-3 Assay Kit (R35100), which includes one 96-well microplate, contained in a resealable foil packet to ensure the integrity of the fluorogenic components, plus all necessary buffers and reagents for performing the assay (Figure 10.4.9). The enzyme sample to be assayed is added to the microplate in a suitable buffer, along with any compounds to be tested. Then, after incubation, the resultant fluorescence is quantitated on a fluorescence microplate reader equipped with filters appropriate for the green-fluorescent R110, with excitation/emission maxima of 496/520 nm. The microplate consists of twelve removable strips, each with eight wells, allowing researchers to perform only as many assay as required for the experiment (Figure 10.4.10). Eleven of the strips (88 wells) are preloaded with the Z-DEVD-R110 substrate. The remaining strip, marked with blackened tabs, contains a dilution series of free R110 that may be used as a fluorescence reference standard. The reversible aldehyde-based inhibitor Ac-DEVD-CHO, which is supplied in a separate vial, can be used to confirm that the observed fluorescence signal in both induced and control cell populations is due to the activity of caspase-3-like proteases.³⁷ Table 10.3 summarizes our other RediPlate™ 96 Assay Kits for protease activity, phosphatase activity (Section 10.3) and RNA quantitation (Section 8.3).

Image-iT® LIVE Green Caspase Detection Kits for Fluorescence Microscopy

The Image-iT® LIVE Green Caspase-3 and -7 Detection Kit, Image-iT® LIVE Green Caspase-8 Detection Kit and Image-iT® LIVE Green Poly Caspases Detection Kit (I35106, I35105, I35104) employ a novel approach to detect active caspases that is based on a fluorescent inhibitor of caspases (FLICA® methodology). The FLICA® inhibitor comprises a fluoromethyl ketone (FMK) moiety, which can react covalently with a cysteine, a caspase-selective amino acid sequence and a fluorescent carboxyfluorescein reporter group. Essentially an affinity label, the FLICA® inhibitor is thought to interact with the enzymatic reactive center of an activated caspase via the recognition sequence, and then to attach covalently to a cysteine through the reactive FMK moiety.⁴⁹ The FLICA® inhibitor's recognition sequence is aspartic acid–glutamic acid–valine–aspartic acid (DEVD) for caspase-3 and -7 detection, leucine–glutamic acid–threonine–aspartic acid (LETD) for caspase-8 detection and valine–alanine–aspartic acid (VAD) for detection of most caspases (including caspase-1, -3, -4, -5, -6, -7, -8 and -9). Importantly, the FLICA® inhibitor is cell permeant and not cytotoxic; unbound FLICA® molecules diffuse out of the cell and are washed away. The remaining green-fluorescent signal (excitation/emission maxima ~488/530 nm) can be used as a direct measure of the amount of active caspase that was present at the time the inhibitor was added. FLICA® reagents have been used widely to study apoptosis with flow cytometry and microscopy.^{50–54} Recent work indicates that cellular fluorescence from the bound FLICA® reagent is strongly linked to caspase activity in apoptotic cells; however, the interaction of the FLICA® reagent with other cellular sites may contribute to signal intensity in nonapoptotic cells.⁵⁵ Appropriate controls should be included in any experimental design.

The Image-iT® LIVE Green Caspase Detection Kit includes:

- FAM-DEVD-FMK caspase-3 and -7 reagent (in Kit I35106), FAM-LETD-FMK caspase-8 reagent (in Kit I35105) or FAM-VAD-FMK poly caspases reagent (in Kit I35104)
- Hoechst 33342
- Propidium iodide
- Dimethylsulfoxide (DMSO)
- Apoptosis fixative solution
- Concentrated apoptosis wash buffer
- Detailed protocols for fluorescence microscopy assays

In addition to a specific FLICA® reagent, each kit provides Hoechst 33342 and propidium iodide stains, which allow the simultaneous evaluation of caspase activation, nuclear morphology and plasma membrane integrity. Sufficient reagents are provided for 25 assays, based on labeling volumes of 300 µL. These Image-iT® LIVE Green Caspase Detection Kits can also be used in combination with other reagents for multiparametric study of apoptosis.

Image-iT® LIVE Red Caspase Detection Kits for Fluorescence Microscopy

The Image-iT® LIVE Red Caspase-3 and -7 Detection Kit and Image-iT® LIVE Red Poly Caspases Detection Kit (I35102, I35101) are analogous to the Image-iT® LIVE Green Caspase Detection Kits except that the FLICA® reagent contains a red-fluorescent sulforhodamine (SR) reporter group instead of a green-fluorescent carboxyfluorescein (FAM) reporter group. This assay's red-fluorescent signal (excitation/emission maxima ~550/595 nm) can be used as a direct measure of the amount of active caspase that was present at the time the inhibitor was added.

The Image-iT® LIVE Red Caspase Detection Kit includes:

- SR-DEVD-FMK caspase-3 and -7 reagent (in Kit I35102) or SR-VAD-FMK poly caspases reagent (in Kit I35101)
- Hoechst 33342
- SYTOX® Green nucleic acid stain
- Dimethylsulfoxide (DMSO)
- Apoptosis fixative solution
- Concentrated apoptosis wash buffer
- Detailed protocols for fluorescence microscopy assays

In addition to a specific FLICA® reagent, each kit provides Hoechst 33342 and SYTOX® Green nucleic acid stains, which allow the simultaneous evaluation of caspase activation, nuclear morphology and plasma membrane integrity. Sufficient reagents are provided for 25 assays, based on labeling volumes of 300 µL.

Vybrant® FAM Caspase Assay Kits for Flow Cytometry

Like the Image-iT® Kits described above, the Vybrant® FAM Caspase Assay Kits for flow cytometry are based on a fluorescent caspase inhibitor (FLICA® methodology). We offer three different Vybrant® FAM Caspase Assay Kits designed to target different caspases. The Vybrant® FAM Caspase-3 and -7 Assay Kit (V35118) provides a FLICA® inhibitor containing the caspase-3 and -7 recognition sequence DEVD; the Vybrant® FAM Caspase-8 Assay Kit (V35119) provides a FLICA® inhibitor containing the caspase-8 recognition sequence Leu-Glu-Thr-Asp

(LETD); and the Vybrant® FAM Poly Caspases Assay Kit (V35117) provides a FLICA® inhibitor containing the caspase recognition sequence Val-Ala-Asp (VAD), which is recognized by caspase-1, -3, -4, -5, -6, -7, -8 and -9. In addition to the selective FLICA® reagent, these kits contain the Hoechst 33342 and propidium iodide nucleic acid stains to permit simultaneous evaluation of caspase activation, membrane permeability and cell cycle.

Each Vybrant® FAM Caspase Assay Kit includes:

- FAM-DEVD-FMK caspase-3 and -7 reagent (in Kit V35118), FAM-LETD-FMK caspase-8 reagent (in Kit V35119) or FAM-VAD-FMK poly caspases reagent (in Kit V35117)
- Hoechst 33342
- Propidium iodide
- Dimethylsulfoxide (DMSO)
- Apoptosis fixative solution
- Concentrated apoptosis wash buffer
- Detailed protocols for flow cytometry assays

Sufficient reagents are provided for 25 assays, based on labeling volumes of 300 µL. These Vybrant® FAM Caspase Assay Kits can be used in combination with other fluorescent probes, such as the far-red-fluorescent allophycocyanin annexin V (A35110), for a multiparameter study of apoptosis.

Substrates for HIV Protease and Renin

Alternative strategies have been employed to create substrates specifically for some endopeptidases. Our HIV protease and renin substrates (H2930, R2931) utilize fluorescence resonance energy transfer (FRET) to generate a spectroscopic response to protease cleavage (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). In this type of substrate, both an acceptor molecule and a fluorescent molecule are attached to the peptide or protein. The acceptor molecule is carefully chosen so that its absorbance overlaps with the fluorophore's excited-state fluorescence (Figure 10.4.11), thus ensuring that the fluorescence is quenched through resonance energy transfer.⁵⁶ Enzyme hydrolysis of the substrate results in spatial separation of the fluorophore and the acceptor molecule, thereby restoring the fluorophore's fluorescence (Figure 10.4.12). See Section 9.5 for a discussion of our reagents

Figure 10.4.11 Spectral overlap between EDANS fluorescence and dabcyI absorption, which is required for efficient quenching of EDANS fluorescence by resonance energy transfer to the nonfluorescent dabcyI chromophore. Spectra are normalized to the same intensities.

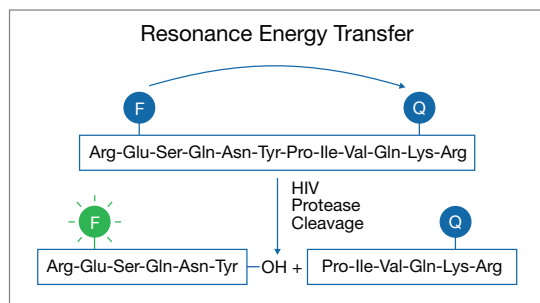

Figure 10.4.12 Principle of the fluorogenic response to protease cleavage exhibited by HIV protease substrate 1 (H2930). Quenching of the EDANS fluorophore (F) by distance-dependent resonance energy transfer to the dabcyI quencher (Q) is eliminated upon cleavage of the intervening peptide linker.

Figure 10.4.13 Principle of enzyme detection via the disruption of intramolecular self-quenching. Enzyme-catalyzed hydrolysis of the heavily labeled and almost totally quenched substrates provided in the EnzChek® Protease Assay Kits (E6638, E6639), EnzChek® Ultra Amylase Assay Kit (E33651), EnzChek® Gelatinase/Collagenase Assay Kit (E12055), EnzChek® Elastase Kit (E12056), EnzChek® Lysozyme Assay Kit (E22013)—as well as the stand-alone quenched substrates DQ™ BSA (D12050, D12051), DQ™ collagen (D12052, D12060), DQ™ ovalbumin (D12053) and DQ™ gelatin (D12054)—relieves the intramolecular self-quenching, yielding brightly fluorescent reaction products.

Figure 10.4.14 Unlabeled neutrophils that have been allowed to migrate spontaneously in gelatin matrices containing a prototype of DQ™ Green BSA (D12050) and dihydrotetramethylrosamine. Extracellular release of reactive oxygen metabolites oxidizes dihydrotetramethylrosamine to tetramethylrosamine, yielding orange fluorescence. Extracellular protease activity cleaves highly quenched DQ™ Green BSA, yielding green-fluorescent peptides. The micrograph illustrates an alternating pattern of orange and green fluorescence and shows that extracellular release of oxidants and proteolytic activity oscillate 180° out of phase during cell locomotion. Image contributed by Howard R. Petty, Wayne State University.

for synthesizing labeled peptides and peptidase substrates, including our QSY® series of nonfluorescent dyes, which have broad visible or near-infrared absorption spectra and serve as almost universal quenchers of most fluorescent donors that emit in the visible, with unusually high efficiency (Table 1.1).

Substrate for Detecting HIV Protease Activity

HIV protease substrate 1 (H2930) is a peptide that includes the HIV protease cleavage site, along with two covalently modified amino acid residues—one that has been linked to EDANS and the other to dabcyI.^{57–59} Proteolytic cleavage releases a fragment containing only the EDANS fluorophore, thus liberating it from the quenching effect of the nearby dabcyI chromophore (Figure 10.4.12). HIV protease activity can be measured by exciting the sample at ~340 nm and measuring the resulting fluorescence at 490 nm. HIV protease substrate 1 has been used to analyze the effects of solvent composition, incubation time and enzyme concentration on HIV-1 protease activity⁶⁰ and to investigate a newly designed inhibitor of the enzyme.⁶¹ HIV protease substrate 1 has also been employed to follow the inhibition of HIV-1 protease activity after the enzyme's two cysteine residues are reversibly modified by nitric oxide.⁶² One milligram of HIV protease substrate 1 is sufficient for approximately 120 enzyme assays using 2 mL assay volumes and standard fluorescence cuvettes or ~1600 assays using 150 µL assay volumes and microcuvettes.

Human Renin Substrate 1

Assaying renin activity with human renin substrate 1 (R2931) is analogous to assaying HIV protease activity with the HIV protease substrate described above. Renin, an aspartic protease, plays an important role in blood-pressure regulation and is therefore a target for anti-hypertension therapeutics. Using renin substrate 1, researchers have discovered a stable, partially active conformational variant of recombinant human prorenin.⁶³ This substrate has also been used to investigate the kinetics and pH stability of recombinant human renin.⁶⁴ A fluorogenic substrate similar to our renin substrate 1 was used to develop a microplate assay for screening renin inhibitors.⁶⁵ One milligram of the renin substrate 1 is sufficient for approximately 100 enzyme assays using 2 mL volumes and standard fluorescence cuvettes or ~1400 assays using 150 µL assay volumes and microcuvettes. The short-wavelength excitation maximum (335 nm) of the EDANS fluorophore precludes use of this substrate in most fluorescence microplate readers. We also have a fluorogenic substrate for thrombin (rhodamine 110, bis-(tosyl-Gly-Pro-Arg) amide, R22124) that is useful for measuring the activity of this enzyme, which is important for coagulation and blood clot formation.³¹

EnzChek® Protease Assay Kits and Fluorescein Casein

Often it is necessary to have fluorogenic substrates for the assay of purified enzymes with unknown specificity or for which there are no known useful substrates. Assay for contamination of biological preparations by unknown proteases requires substrates that can detect a variety of enzymes. We have developed a method of relieving the fluorescence quenching of BODIPY® dye-labeled biopolymers by enzymatic hydrolysis (Figure 10.4.13), which we have applied to several of the general or selective protease assay kits and DQ™ reagents described in this section. We have also described the method's use in

an assay for dextranase,⁶⁶ and others have applied it to the assay of *O*-sialoglycoprotein endopeptidase⁶⁷ and enzymes that process vesicular stomatitis virus⁶⁸ (VSV). The DQ™ and EnzChek® protease assay reagents may have significant potential for detecting matrix metalloproteinase (MMP) activity in living tissues by simple incubation of the tissue with the protein-based fluorogenic substrates.² Fluorescent products have been shown to accumulate on the cell's surface where proteases are active, including in living human breast cancer cells.⁶⁹ These quenched protease substrates are particularly useful for following cell migration through matrices^{70–72} (Figure 10.4.14).

The EnzChek® Protease Assay Kits provide exceptionally fast, simple and direct fluorescence assays for detecting metallo-, serine, acid and thiol proteases. The EnzChek® Protease and EnzChek® Peptidase/Protease Assay Kits (E6638, E6639, E33758) measure the increase in fluorescence intensity that results from protease hydrolysis of a quenched substrate, whereas our EnzChek® Polarization Assay Kit for Proteases (E6658) monitors fluorescence polarization changes that occur during protease hydrolysis of a lightly labeled fluorescent casein derivative. Although the detection principles of these protease assays are quite different, no separation steps are required for either, and both types of assays are rapid, sensitive and versatile.

EnzChek® Protease Assay Kits for Fluorescence Intensity Measurements

The EnzChek® Protease Assay Kits contain a casein derivative that is heavily labeled with either the green-fluorescent BODIPY® FL or red-fluorescent BODIPY® TR-X dye, resulting in almost total quenching of the conjugate's fluorescence; they typically exhibit <3% of the fluorescence of the corresponding free dyes.^{73–75} Protease-catalyzed hydrolysis relieves this quenching, yielding brightly fluorescent BODIPY® FL dye- or BODIPY® TR-X dye-labeled peptides^{74,75} (Figure 10.4.13). The increase in fluorescence, which can be measured with a spectrofluorometer, minifluorometer or fluorescence microplate reader, is directly proportional to protease activity.

In contrast to the conventional fluorescein thiocarbonyl (FTC)–casein protease assay, these EnzChek® assays do not involve any separation steps and, consequently, can be used to continuously measure the kinetics of a variety of exopeptidases and endopeptidases over a wide pH range. They can also be used to measure the total substrate turnover at a fixed time following addition of the enzyme. We have found that these protease assays are over 100-times more sensitive and much easier to perform than the labor-intensive FTC–casein assay. Detection limits for fluorescence intensity measurements with these kits are given in Table 10.4.

Hydrolysis of the fluorogenic substrates by proteases provides a sensitive assay of cell proliferation and a means of detecting the sterility of a sample. In addition to their utility for detecting protease contamination in culture medium and other experimental samples, BODIPY® FL casein and BODIPY® TR-X casein have significant potential as general, nontoxic, pH-insensitive markers for phagocytic cells in culture (Section 16.1). We have shown that uptake of these quenched conjugates by neutrophils is accompanied by hydrolysis of the labeled proteins by intracellular proteases and generation of fluorescent products that are well retained in cells. This phagocytosis assay is readily performed in a fluorescence microplate reader or a flow cytometer; localization of the fluorescent products can be determined by fluorescence microscopy. The same substrates can readily detect secretion of proteases from live cells.

BODIPY® FL casein and BODIPY® TR-X casein can be used interchangeably, depending on whether green or red fluorescence is desired. The peptide hydrolysis products of BODIPY® FL casein exhibit green fluorescence that is optimally excited by the argon-ion laser, permitting flow sorting of the cells. The red-fluorescent BODIPY® TR-X-labeled peptides, with excitation and emission spectra similar to those of the Texas Red® fluorophore, should be useful for multilabeling experiments or measurements in the presence of green autofluorescence.

The EnzChek® Protease Assay Kit includes:

- BODIPY® FL casein (in Kit E6638) or BODIPY® TR-X casein (in Kit E6639)
- Concentrated digestion buffer
- Detailed protocols

Each kit provides sufficient reagents for ~100 assays using 2 mL assay volumes and standard fluorescence cuvettes or ~1000 assays using 200 µL assay volumes and 96-well microplates.

The EnzChek® Protease Assay Kit containing red-fluorescent BODIPY® TR-X casein is also available as a convenient RediPlate™ 96 Protease Assay Kit (R22132). Each RediPlate™ 96 EnzChek® Protease Assay Kit includes one 96-well microplate, with all of the necessary reagents predispensed into the wells, where 88 wells (11 lanes) are intended for assays and 8 wells (1 lane) include a dilution series of an appropriate reference standard for generation of standard curves. The enzyme sample to be assayed is added to the microplate in a suitable buffer, along with any compounds to be tested. Then, after incubation, the resultant fluorescence is quantitated on a fluorescence microplate reader equipped with filters appropriate for the green- or red-fluorescent dye. Each RediPlate™ 96 microplate has removable lanes that allow researchers to perform only as many assays as required for the experiment

Table 10.4 Detection limits of the EnzChek® Protease Assay Kits.

Enzyme (Source)	Class	Detection Limit (Units) *	Buffer Conditions
Elastase, Type IV (porcine pancreas)	Serine protease	2.2×10^{-3}	10 mM Tris-HCl, pH 8.8
Chymotrypsin, Type II (bovine pancreas)	Serine protease	5.0×10^{-5}	10 mM Tris-HCl, pH 7.8
Thermolysin (<i>Bacillus thermoproteolyticus</i> Rokko)	Acid protease	4.4×10^{-5}	10 mM Tris-HCl, pH 7.8
Trypsin, Type IX (porcine pancreas)	Serine protease	1.3×10^{-2}	10 mM Tris-HCl, pH 7.8
Papain (papaya latex)	Cysteine protease	2.1×10^{-4}	10 mM MES, pH 6.2
Pepsin (porcine stomach mucosa)	Acid protease	2.1×10^{-3}	10 mM HCl, pH 2.0
Elastase (<i>Pseudomonas aeruginosa</i>)	Metalloprotease	1.0×10^{-3}	20 mM sodium phosphate, pH 8.0
Cathepsin D	Acid protease	2.0×10^{-4}	20 mM sodium citrate, pH 5.0
Elastase (human leukocyte)	Serine protease	1.0×10^{-3}	10 mM Tris-HCl, pH 7.5

* The detection limit is defined as the amount of enzyme required to cause a 10–20% change in fluorescence compared with the control sample at 22°C. Enzyme unit definitions are standard definitions for each individual enzyme. Detection limits were determined with BODIPY® FL casein and with BODIPY® TR-X casein; both substrates yielded similar results. Detection limits may vary with instrumentation.

(Figure 10.4.10). Resealable packaging ensures plate and well integrity between experiments. Table 10.3 summarizes our other RediPlate™ Assay Kits for caspase-3 activity, phosphatase activity (Section 10.3) and RNA quantitation (Section 8.3).

EnzChek® Peptidase/Protease Assay Kit

The EnzChek® Peptidase/Protease Assay Kit (E33758) provides a FRET (fluorescence resonance energy transfer)-based method for the simple and accurate quantitation of a wide range of protease activities. The EnzChek® peptidase/protease substrate comprises a fluorophore and a quencher moiety separated by an amino acid sequence. Upon protease cleavage, the fluorophore separates from the quencher and is free to emit a detectable fluorescent signal (excitation/emission maxima ~502/528 nm). The magnitude of the resultant signal is proportional to the degree of substrate cleavage and can therefore be used to quantitate the enzyme activity present (Figure 10.4.15). The assay is performed in a simple mix-incubate-read format and can be completed in 60 minutes or less.

The EnzChek® Peptidase/Protease Assay Kit contains:

- EnzChek® peptidase/protease substrate
- Concentrated digestion buffer (200 mM Tris-HCl, pH 7.8)
- Substrate solvent (50% DMSO in 10 mM Tris-HCl, pH 7.8)
- Detailed protocols

Sufficient materials are supplied for 100 assays, based on a 100 μ L assay volume in a 96-well microplate format. The EnzChek® peptidase/protease assay can be adapted for use in cuvettes or 384-well microplates.

EnzChek® Protease Assay Kit for Fluorescence Polarization Measurements

When a fluorescent molecule tethered to a protein is excited by polarized fluorescent light, the polarization of fluorescence emission is dependent on the rate of molecular tumbling. Upon proteolytic cleavage of the fluorescently labeled protein, the resultant smaller peptides tumble faster, and the emitted light is depolarized relative to the light measured from the intact conjugate. The EnzChek® Polarization Assay Kit for Proteases⁷⁶ (E6658) contains green-fluorescent BODIPY® FL casein with an optimal degree of labeling for fluorescence polarization-based

Figure 10.4.15 Sample standard curves obtained with the EnzChek® Peptidase/Protease Assay Kit. Trypsin (EC 3.4.21.4) was assayed in 10 mM Tris-HCl (pH 7.8) digestion buffer from 10 to 1200 mU/mL using the EnzChek® peptidase/protease substrate. The inset shows a separate experiment using the same enzyme, but at activities from 2 to 100 mU/mL. Samples were incubated for 60 minutes at room temperature. Fluorescence was measured at 490/520 nm; background fluorescence was subtracted from the inset data.

protease assays.^{77,78} Fluorescence polarization technology is more sensitive than many nonradioactive protease assays and allows measurements to be taken in real time, permitting the collection of kinetics data (Fluorescence Polarization (FP)—Note 1.4). Our BODIPY® FL dye has an adequate fluorescence lifetime and pH-insensitive fluorescence—two prerequisites for successful measurement of protease activity by fluorescence polarization.

The EnzChek® Polarization Assay Kit for Proteases contains:

- BODIPY® FL casein
- Concentrated digestion buffer
- Detailed protocols

Each kit provides sufficient reagents for ~100 assays using 2 mL assay volumes and standard fluorescence cuvettes or ~1000 assays using 200 μ L assay volumes and 96-well microplates. With the advent of high-capacity automated instrumentation, this kit provides an important tool for high-throughput screening of proteases and their inhibitors in research laboratories.

Fluorescein Casein

We also offer fluorescein casein (C2990) for assaying protease activity. In this assay, unhydrolyzed fluorescein casein must be precipitated with trichloroacetic acid, separated by centrifugation, transferred for measurement and then pH-adjusted for fluorescein signal enhancement.^{79–83} Fluorescein casein may be useful for a continuous assay if monitored by fluorescence polarization.⁷⁸ Fluorescein casein is rapidly degraded by *Bacteroides gingivalis* but only slowly by streptococci.⁸⁴

EnzChek® Gelatinase/Collagenase Assay Kit

Collagen is a major component of the extracellular matrix, which not only serves as scaffolding to stabilize tissue structure, but also influences the development, migration, proliferation and metabolism of cells that contact it. Gelatinases and collagenases—matrix metalloproteinases (MMPs) that digest collagen or gelatin (denatured collagen)—are increasingly important to our understanding of both normal development and carcinogenesis.⁸⁵ For example, gelatinase A (20,000-dalton MMP-2) is primarily responsible for degrading the helical domains of type IV collagen, the principal collagen of basement membranes.⁸⁶ Thus, gelatinase A likely plays a major role in the turnover of basement membrane during fetal tissue development, wound healing, angiogenesis and tumor invasion.

The EnzChek® Gelatinase/Collagenase Assay Kit (E12055) provides a fast, sensitive and convenient assay for measuring gelatinase or collagenase activity or for screening inhibitors⁸⁷ in a high-throughput format. This kit contains:

- DQ™ gelatin, a gelatin conjugate so heavily labeled with fluorescein that its fluorescence is quenched; this substrate is also available separately (D12054)
- 1,10-Phenanthroline, a general metalloproteinase inhibitor
- Type IV collagenase from *Clostridium histolyticum* for use as a positive control
- Concentrated reaction buffer
- Detailed protocols

DQ™ gelatin, the highly quenched gelatinase/collagenase substrate provided, is efficiently digested by most, if not all, gelatinases and collagenases, releasing brightly fluorescent peptides (Figure 10.4.13). The increase in fluorescence upon digestion is proportional to proteolytic activity and can be monitored with a fluorescence microplate reader, minifluorometer or spectrofluorometer. Depending on the substrate concentration used in each reaction, sufficient reagents are supplied for 250–1000 assays using 200 µL assay volumes and 96-well microplates. Using 100 µg/mL DQ™ gelatin and a 2-hour incubation period, we have detected as little as 2×10^{-3} U/mL (7 ng protein/mL) of *C. histolyticum* collagenase, where one unit is defined as the amount of enzyme required to liberate 1 µmole L-leucine equivalents from collagen in 5 hours at 37°C, pH 7.5. Longer incubation times increase the sensitivity, whereas higher enzyme concentrations decrease the incubation times. Using human gelatinase A (not provided), 100 µg/mL DQ™ gelatin and a 24-hour incubation period, we have detected concentrations of gelatinase as low as 3×10^{-4} U/mL, where one unit is defined as the amount of enzyme that can hydrolyze 1 mg of type IV collagen in 1 hour at 37°C, pH 7.5. DQ™ gelatin and some of our other highly quenched protease substrates have been utilized for *in situ* detection of matrix metalloproteinase and other protease activity in cell preparations, tissue sections and SDS gels.^{3,88–91}

EnzChek® Elastase Assay Kit

The EnzChek® Elastase Assay Kit (E12056) provides a fast, sensitive and convenient assay for measuring elastase activity or for screening inhibitors in a high-throughput format. This kit contains DQ™ elastin—soluble bovine neck ligament elastin that has been labeled with our BODIPY® FL dye such that the conjugate's fluorescence is quenched. Upon digestion by elastase or other proteases, the fluorescence is revealed (Figure 10.4.13). The resulting increase in fluorescence can be monitored with a fluorescence microplate reader, minifluorometer or spectrofluorometer. Digestion products from the DQ™ elastin substrate have absorption maxima at ~505 nm and fluorescence emission maxima at ~515 nm. Because the assay is continuous, kinetics data can be obtained easily. Furthermore, because fluorescence of the BODIPY® FL dye is pH insensitive between pH 3 and 9, the assay can be performed under a variety of buffer conditions. Please note that DQ™ elastin is also digested by proteases other than elastase.

The EnzChek® Elastase Assay Kit (A10256) contains:

- DQ™ elastin substrate
- Concentrated reaction buffer
- Elastase from pig pancreas for use as a positive control
- *N*-Methoxysuccinyl-Ala-Ala-Pro-Val-chloromethyl ketone, a selective elastase inhibitor
- Detailed protocols

Each kit provides sufficient reagents for approximately 600 assays using a fluorescence microplate reader and reaction volumes of 200 µL. The *N*-methoxysuccinyl-Ala-Ala-Pro-Val-chloromethyl ketone inhibitor can be used to confirm the identity of the protease responsible for substrate digestion or, alternatively, as a control inhibitor for use when screening for elastase inhibitors.

DQ™ Substrates

DQ™ Collagens

Our DQ™ collagens, type I (D12060) and type IV (D12052), are complementary reagents to the DQ™ gelatin provided in the EnzChek® Gelatinase/Collagenase Assay Kit. Like DQ™ gelatin, these highly quenched substrates are heavily labeled with fluorescein and release fluorescent peptides when enzymatically cleaved. DQ™ collagen, type I should be useful in assays detecting matrix metalloproteinase (MMP-1) activity.⁹² DQ™ collagen, type IV may prove particularly useful in the development of assays for gelatinase A (MMP-2) and gelatinase A inhibitors, as well as for other gelatinases and collagenases that specifically degrade type IV collagen. DQ™ collagens may be used with the EnzChek® Gelatinase/Collagenase Assay Kit, and a sample protocol is included. Because of its more complex structure, DQ™ collagen generally requires either greater amounts of the enzyme or longer incubation periods than does DQ™ gelatin. Please note that both the DQ™ collagens and DQ™ gelatin can be digested by proteases other than gelatinases and collagenases. The fluorescence generated by hydrolysis of DQ™ collagen (D12052) by cellular collagenase has been used to visualize the migratory pathway followed by tumor cells during invasion of a gelatin matrix and to image proteolysis by living breast cancer cells.^{69,70}

In addition to the DQ™ substrates, we have prepared gelatin and collagen conjugates that have been labeled to maximize probe fluorescence and minimize dye quenching. We offer two green-fluorescent conjugates of gelatin, one in which gelatin is coupled to our photostable Oregon Green® 488 dye (G13186, Section 15.6) and the other to fluorescein (G13187, Section 15.6).

DQ™ BSA

DQ™ Green BSA (D12050, excitation/emission maxima ~500/506 nm) and DQ™ Red BSA (D12051, excitation/emission maxima ~589/617 nm) are bovine serum albumin (BSA) conjugates that have been labeled to such a high degree that the BODIPY® dyes used to label them are strongly self-quenched. Proteolysis of the DQ™ BSA can easily be monitored as proteolytic fragments containing the fluorophores are released from the larger conjugate and become brightly fluorescent⁹³ (Figure 10.4.13). An unlabeled neutrophil making its way through a gelatin matrix containing a DQ™ Green BSA prototype, as well as dihydrotetramethylrosamine, a nonfluorescent probe that fluoresces bright orange upon oxidation, leaves behind a fluorescent trail⁷² (Figure 10.4.14). The alternating green- and orange-fluorescent bands dramatically demonstrate that the proteolytic and oxidative activities of the migrating neutrophil are oscillatory and are 180° out of phase with each other. Intracellular processing of a similar BODIPY® BSA conjugate by J774 macrophages can be completely inhibited by protease inhibitors.⁹³ DQ™ Green BSA has been embedded in a gelatin matrix and used to image both extracellular and intracellular proteolysis in living cells. DQ™ BSA can be complexed with our rabbit IgG fraction anti-BSA (A11133, Section 7.5) to form an immune complex that is internalized through the Fc receptor and processed in the phagosome to highly fluorescent peptides (Section 16.1). DQ™ Green BSA has been used for imaging proteolysis in living breast cancer cells.⁶⁹

DQ™ Ovalbumin

DQ™ ovalbumin^{94,95} (D12053) is a self-quenched ovalbumin conjugate designed specifically for the study of antigen processing. Ovalbumin is efficiently processed through mannose receptor-mediated endocytosis by antigen-presenting cells and is widely used for studying antigen processing.^{96–98} DQ™ ovalbumin is labeled with our pH-insensitive, green-fluorescent BODIPY® FL dye such that the fluorescence is almost completely quenched. Upon endocytosis and proteolysis, highly fluorescent peptides are released. DQ™ ovalbumin appears to be an excellent indicator of macrophage-mediated antigen processing in flow cytometry and microscopy assays.

Alternative Methods for Detecting Protease Activity

Peptidases typically liberate a free amine for each hydrolysis step. Thus, fluorogenic amine detection reagents such as fluorescamine (F2332, F20261; Section 1.8) and *o*-phthaldialdehyde (P2331MP, Section 1.8) have been used to detect the rate of amine production by peptidases.^{99–102}

Peptidases that liberate single free amino acids for which specific oxidases exist can be analyzed by coupling the hydrolytic reaction to oxidation of our Amplex® Red reagent (Section 10.5) to the red-fluorescent dye resorufin. For example, glutamic acid production can be monitored using glutamate oxidase¹⁰³ and D-amino acid liberation monitored using a D-amino acid oxidase.

Protease assays conducted in highly autofluorescent or strongly light-scattering solutions (such as crude cell and tissue extracts) often can be improved by extracting the fluorescent hydrolysis product from the assay mixture with an organic solvent such as toluene, chloroform or ethyl acetate.¹⁰⁴ Most unhydrolyzed peptidase substrates will remain in the aqueous layer.

Endopeptidase substrates that are singly labeled at the amine terminus with a fluorophore usually do not undergo a fluorescence change

upon hydrolysis of internal peptide bonds; however, fluorescence (or absorbance) of the fluorophore that remains attached to the cleaved peptide can be used to detect the hydrolysis product following separation by TLC, HPLC or capillary electrophoresis.

Protease Inhibitors

Alexa Fluor® 488 Soybean Trypsin Inhibitor

Trypsin inhibitor from soybean (SBTI) is a 21,000-dalton protein that inhibits the catalytic activity of serine proteases.^{105–107} SBTI binds to acrosin, an acrosomal serine protease that is associated with binding of spermatozoa and penetration of the zona pellucida,^{108,109} and SBTI binding patterns in non-fixed human sperm have demonstrated its usefulness for detecting acrosome-reacted sperm.¹¹⁰ In particular, an Alexa Fluor® 488 conjugate of the protein has been used to measure the acrosomal status of macaque sperm and to determine the localization of acrosin during the reaction.¹¹¹ We provide a fluorescent SBTI conjugate with one of our best fluorophores, the Alexa Fluor® 488 dye (T23011). Alexa Fluor® 488 dye (Section 1.3) has spectral characteristics similar to fluorescein (excitation at 495 nm and emission at 519 nm) but produces conjugates that are brighter and more photostable. Furthermore, the fluorescence of Alexa Fluor® 488 conjugates is insensitive to pH from 4 to 10.

BODIPY® FL Pepstatin

Pepstatin A is an inhibitor of carboxyl (acid) proteases that contain aspartate residues at their active sites, including cathepsin D, pepsin and renin.^{112,113} We have prepared the green-fluorescent BODIPY® FL pepstatin A analog (P12271), which we have shown binds to cathepsin D in live cells^{114,115} (Section 15.5).

Leupeptin Hemisulfate

Leupeptin hemisulfate (L6543) can be used to inhibit serine and cysteine proteases. It does not inhibit chymotrypsin and thrombin.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. Fluorescence of the unhydrolyzed substrate is very weak.
2. Data represent the substrate component of this kit.
3. Fluorescence of this substrate is >99% quenched. The proteolytic cleavage products fluoresce at 500 nm (excitation at 335 nm).

PRODUCT LIST 10.4 DETECTING PEPTIDASES AND PROTEASES

Cat. No.	Product	Quantity
A6520	7-amino-4-chloromethylcoumarin, t-BOC-L-leucyl-L-methionine amide (CMAC, t-BOC-Leu-Met)	5 mg
A6521	7-amino-4-methylcoumarin, CBZ-L-phenylalanyl-L-arginine amide, hydrochloride	25 mg
C2990	casein, fluorescein conjugate	25 mg
D12060	DQ™ collagen, type I from bovine skin, fluorescein conjugate	1 mg
D12052	DQ™ collagen, type IV from human placenta, fluorescein conjugate	1 mg
D12054	DQ™ gelatin from pig skin, fluorescein conjugate *special packaging*	5 x 1 mg
D12050	DQ™ Green BSA *special packaging*	5 x 1 mg
D12053	DQ™ ovalbumin *special packaging*	5 x 1 mg
D12051	DQ™ Red BSA *special packaging*	5 x 1 mg
E13183	EnzChek® Caspase-3 Assay Kit #1 *Z-DEVD-AMC substrate* *500 assays*	1 kit
E13184	EnzChek® Caspase-3 Assay Kit #2 *Z-DEVD-R110 substrate* *500 assays*	1 kit
E12056	EnzChek® Elastase Assay Kit *600 assays*	1 kit
E12055	EnzChek® Gelatinase/Collagenase Assay Kit *250–2000 assays*	1 kit
E33758	EnzChek® Peptidase/Protease Assay Kit *100 assays*	1 kit
E6658	EnzChek® Polarization Assay Kit for Proteases *green fluorescence* *100–1000 assays*	1 kit
E6638	EnzChek® Protease Assay Kit *green fluorescence* *100–1000 assays*	1 kit

V35118	Vybrant® FAM Caspase-3 and -7 Assay Kit *for flow cytometry* *25 assays*	1 kit
V35119	Vybrant® FAM Caspase-8 Assay Kit *for flow cytometry* *25 assays*	1 kit
V35117	Vybrant® FAM Poly Caspases Assay Kit *for flow cytometry* *25 assays*	1 kit

10.5 Substrates for Oxidases, Including Amplex® Red Kits

Oxidases, the most useful of which is undoubtedly horseradish peroxidase (HRP), are important enzymes that are used in a wide variety of bioassays. Peroxidase activity is also present in many cells. Reagents for quantitating peroxidase and the activity of a variety of other oxidases are described in this section; reagents for detecting the activity of cellular peroxidases and the oxygen radicals produced by these peroxidases are described in Section 16.1 and Section 18.2. Antibody and streptavidin conjugates of horseradish peroxidase are listed in the product list for this section and described in Section 7.2 and Section 7.6. Tyramide signal amplification (TSA) technology, described in Section 6.2, makes extensive use of peroxidase-conjugated reagents and fluorescent dye- or hapten-labeled tyramides to deposit a detectable product at the site of enzymatic activity.

We have used our extremely versatile Amplex® Red reagent—one of the most stable and sensitive fluorogenic substrate known for horseradish peroxidase—to develop a variety of novel fluorogenic and chromogenic assays for enzymes that produce hydrogen peroxide. Furthermore, these coupled assays permit the ultrasensitive quantitation of a diverse assortment of analytes, including glucose, galactose, cholesterol, glutamic acid, xanthine (or hypoxanthine), uric acid, choline and acetylcholine, as well as hydrogen peroxide. The P_iPer™ Phosphate and P_iPer™ Pyrophosphate Assay Kits (P22061, P22062), described in Section 10.3, also utilize the Amplex® Red reagent for the continuous assays of enzymes that produce either inorganic phosphate or pyrophosphate.

Peroxidases

Amplex® Red Reagent: Stable Substrate for Peroxidase Detection

In the presence of horseradish peroxidase (HRP), Amplex® Red reagent (10-acetyl-3,7-dihydroxyphenoxazine, A12222, A22177; Figure 10.5.1) reacts with H₂O₂ in a 1:1 stoichiometry to produce highly fluorescent resorufin¹ (R363, Section 10.1, Figure 10.5.2). Amplex® Red reagent has greater stability, yields less background and produces a red-fluorescent product (excitation/emission maxima ~571/585 nm, Figure 10.5.3) that is more readily detected than the similar reduced methylene blue derivatives commonly used for colorimetric determination of lipid peroxides in plasma, sera, cell extracts and a variety of membrane systems.^{2–4}

Amplex® Red reagent has been used to detect the release of H₂O₂ from activated human leukocytes,^{1,5} to measure the activity of monoamine oxidase in bovine brain tissue,⁶ to demonstrate the extracellular production of H₂O₂ produced by UV light stimulation of human keratinocytes^{7–9} and for microplate assays of H₂O₂ and lipid hydroperoxide generation by isolated mitochondria.^{10–12} Amplex® Red reagent is available in a single 5 mg vial (A12222) or packaged as a set of 10 vials, each containing 10 mg of the substrate, for high-throughput screening applications (A22177).

Figure 10.5.1 Amplex® Red reagent (A12222).

Figure 10.5.3 Absorption and fluorescence emission spectra of resorufin in pH 9.0 buffer.

Figure 10.5.2 Principle of coupled enzymatic assays using Amplex® Red reagent. Oxidation of glucose by glucose oxidase results in generation of H₂O₂, which is coupled to conversion of the Amplex® Red reagent to fluorescent resorufin by HRP. The detection scheme shown here is used in the Amplex® Red Glucose/Glucose Oxidase Assay Kit (A22189).

Figure 10.5.4 Detection of H₂O₂ using Amplex® UltraRed reagent (■) or Amplex® Red reagent (▲). Reactions containing 50 μM Amplex® UltraRed or Amplex® Red reagent, 1 U/mL HRP and the indicated amount of H₂O₂ in 50 mM sodium phosphate buffer, pH 7.4, were incubated for 30 minutes at room temperature. The inset shows the sensitivity and linearity of the Amplex® UltraRed assay at low levels of H₂O₂.

Figure 10.5.5 Comparison of pH-dependent fluorescence of Amplex® UltraRed reagent (●) and Amplex® Red reagent (□). Fluorescence intensities were measured using excitation/emission of ~570/585 nm.

Figure 10.5.6 Absorption and fluorescence emission spectra of the product generated by horseradish peroxidase-mediated oxidation of the Amplex® UltraRed reagent in pH 7.5 buffer.

Amplex® UltraRed Reagent: Brighter and More Sensitive than the Amplex® Red Reagent

Amplex® UltraRed reagent (A36006) improves upon the performance of Amplex® Red reagent, offering brighter fluorescence and enhanced sensitivity on a per-mole basis in horseradish peroxidase or horseradish peroxidase-coupled enzyme assays¹³ (Table 10.5, Figure 10.5.4). Fluorescence of oxidized Amplex® UltraRed reagent is also less sensitive to pH (Figure 10.5.5), and the substrate and its oxidation product exhibit greater stability than Amplex® Red reagent in the presence of H₂O₂ or thiols such as dithiothreitol (DTT). Like Amplex® Red reagent, nonfluorescent Amplex® UltraRed reagent reacts with H₂O₂ in a 1:1 stoichiometric ratio to produce a brightly fluorescent and strongly absorbing reaction product (excitation/emission maxima ~568/581 nm) (Figure 10.5.6). Although the primary applications of the Amplex® UltraRed reagent are enzyme-linked immunosorbent assays (ELISAs) and HRP-coupled solution assays,¹³ it is also frequently used (in combination with HRP) to detect H₂O₂ production by isolated mitochondria¹⁴ and cell cultures.^{15,16}

Amplex® Red/UltraRed Stop Reagent

Amplex® Red and Amplex® UltraRed Assay Kits provide sensitive biomolecular assays based on hydrogen peroxide-generating enzyme systems linked to peroxidase-mediated oxidation of the fluorogenic Amplex® Red or Amplex® UltraRed reagent. Typically, detection reactions are performed in microplate wells and are initiated by adding the fluorogenic Amplex® or Amplex® UltraRed reagent, resulting in a continuous fluorescence increase that proceeds for 30 minutes or more. Ultimately, unknown analyte concentrations are determined by referencing fluorescence intensities measured at a certain time point during the reaction to parallel measurements at the same time point on standard samples of known concentration. Clearly, it is quite critical to ensure that the timing of the standard and unknown sample measurements is the same. The Amplex® Red/UltraRed stop reagent (A33855) provides convenience and control by allowing the fluorescence signal-generating reaction to be terminated at a user-determined time point. After addition of the stop reagent, the fluorescence signal remains stable for at least 3 hours. The Amplex® Red/UltraRed stop reagent is compatible with all Amplex® Red and Amplex® UltraRed Assay Kits and will terminate reactions containing up to 0.1 units/mL HRP and 5 μM H₂O₂.

Coupled Enzymatic Reactions with the Amplex® Red and Amplex® UltraRed Reagents

Because H₂O₂ is produced in many different enzymatic reactions, the Amplex® Red and Amplex® UltraRed reagents can be used in coupled enzymatic reactions to detect the activity of many different enzymes such as NADPH oxidase¹⁷ and lysyl oxidase,¹⁸ or, when the substrate concentration is limited, to assay solutions for metabolically active constituents such as glucose, pyruvate,¹³ acetylcholine and cholesterol.

Table 10.5 Advantages of the Amplex® UltraRed reagent over chromogenic reagents.

Peroxidase Detection Reagent	Abs *	Em *	Notes
Amplex® UltraRed reagent	568	581	<ul style="list-style-type: none"> • More resistant to oxidation • More sensitive • Fast fluorescence (and color) development
Amplex® Red reagent	570	585	<ul style="list-style-type: none"> • Resistant to oxidation • Sensitive • Fast fluorescence (and color) development
ABTS (2'-azino-bis-(3-ethyl-benzothiazoline-6-sulfonic acid))	405	NA	<ul style="list-style-type: none"> • Readily oxidized • Slow color development
OPD (<i>o</i> -phenylenediamine)	492	NA	<ul style="list-style-type: none"> • Light sensitive
TMB (3,3',5,5'-tetramethylbenzidine)	450 (stopped reaction) 653 (kinetic assay)	NA	<ul style="list-style-type: none"> • Readily oxidizes • Precipitates easily due to low water solubility

* Absorption (Abs) and fluorescence emission (Em) maxima, in nm. NA = Not applicable.

Advantages of Amplex® Red reagent- and Amplex® UltraRed reagent-based assays include the following:

- The Amplex® Red and Amplex® UltraRed reagents are fluorogenic substrates with extremely low background color or fluorescence.
- Stock solutions of the Amplex® Red and Amplex® UltraRed reagents are chemically stable.
- The fluorescent peroxidase reaction products are also stable.
- The long-wavelength spectra of the peroxidase reaction products (Figure 10.5.3, Figure 10.5.6) result in little interference from blue or green autofluorescence in biological samples.
- The peroxidase reaction products can be detected by either fluorescence- or absorption-based methods.
- In most cases, Amplex® Red and Amplex® UltraRed assays can detect either unlabeled natural biomolecules, including amino acids, sugars or lipids, or the activity of enzymes that metabolize these substrates.

The Amplex® Red reagent is also utilized as the detection reagent in our many Amplex® Red assay kits. Substituting the Amplex® UltraRed reagent in these kits should offer even greater sensitivity.

The Amplex® Red assay kits include:

- Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit (A22188)
- Amplex® Red Catalase Assay Kit (A22180)
- Amplex® Red Monoamine Oxidase Assay Kit (A12214)
- Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit¹⁹ (A12221)
- Amplex® Red Glucose/Glucose Oxidase Assay Kit (A22189)
- Amplex® Red Galactose/Galactose Oxidase Assay Kit (A22179)
- Amplex® Red Neuraminidase (Sialidase) Assay Kit (A22178)
- Amplex® Red Cholesterol Assay Kit (A12216)
- Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit (A12217)
- Amplex® Red Phosphatidylcholine-Specific Phospholipase C Assay Kit²⁰ (A12218, Section 17.4)
- Amplex® Red Phospholipase D Assay Kit^{20,21} (A12219, Section 17.4)
- Amplex® Red Sphingomyelinase Assay Kit (A12220, Section 13.3)
- Amplex® Red Uric Acid/Uricase Assay Kit (A22181)
- Amplex® Red Xanthine/Xanthine Oxidase Assay Kit (A22182)

The Amplex® UltraRed assay kits include:

- Amplex® ELISA Development Kits for Mouse IgG and for Rabbit IgG (A33851, A33852; Section 6.2)
- EnzChek® Myeloperoxidase (MPO) Activity Assay Kit (E33856)
- Zen™ Myeloperoxidase (MPO) ELISA Kit (Z33857)
- EnzChek® Ultra Phytase Assay Kit (E33701)

Most of these Amplex® Red and Amplex® UltraRed kits are further discussed in this section; however, some are only presented in the sections listed above.

Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit

The Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit (A22188) provides a simple, sensitive, one-step assay for detecting H₂O₂ (Figure 10.5.7) or the activity of horseradish peroxidase either by measuring fluorescence with a fluorescence-based microplate reader or a fluorometer (Figure 10.5.8) or by measuring absorption with an absorption-based microplate reader or a spectrophotometer. The Amplex® Red peroxidase substrate can detect the presence of active peroxidases and the release of H₂O₂ from biological samples, including cells and cell extracts.^{1,10,22,23}

The Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- H₂O₂ for use as a positive control
- Concentrated reaction buffer
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using a fluorescence- or absorption-based microplate reader and a reaction volume of 100 µL per assay.

Figure 10.5.7 Detection of H₂O₂ using the Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit (A22188). Reactions containing 50 µM Amplex® Red reagent, 1 U/mL HRP and the indicated amount of H₂O₂ in 50 mM sodium phosphate buffer, pH 7.4, were incubated for 30 minutes at room temperature. Fluorescence was measured with a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 580 ± 25 nm. Background fluorescence (24 units), determined for a no-H₂O₂ control reaction, was subtracted from each value. The inset shows the sensitivity and linearity of the assay at low levels of H₂O₂.

Figure 10.5.8 Detection of HRP using the Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit (A22188). Reactions containing 50 µM Amplex® Red reagent, 1 mM H₂O₂ and the indicated amount of HRP in 50 mM sodium phosphate buffer, pH 7.4, were incubated for 30 minutes at room temperature. Fluorescence was measured with a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. Background fluorescence (3 units), determined for a no-HRP control reaction, was subtracted from each value. The inset shows the sensitivity of the assay at very low levels of HRP.

Other Substrates for Peroxidase Assays

Although HRP is an important enzyme for both histochemistry and ELISAs, fluorogenic peroxidase substrates have not been extensively used for its detection. Fluorogenic peroxidase substrates such as the dihydrofluoresceins (also known as fluoresceins) (D399, C400, C13293), dihydrocalcein AM (D23805, Figure 10.5.9), dihydrorhodamines (D632, D633, D23806; Section 18.3) and dihydroethidium (hydroethidine; D1168, D11347, D23107; Section 18.2) are converted to highly fluorescent products in the presence of the enzyme and hydrogen peroxide. Because these substrates are insufficiently stable for routine use in ELISA assays, we have converted the dihydrofluoresceins to diacetates. When used in intracellular applications, the acetates are cleaved by endogenous esterases, releasing the intact substrate. However, when used for *in vitro* assays, an esterase or a mild base must first be added to cleave the acetates, releasing the substrate. The dihydrofluoresceins have been used to measure peroxidase activity²⁴ and to detect hydroperoxide formation.^{25–28}

In addition to being a reagent for derivatization of aldehydes and ketones (Section 3.3) and detection of nitric oxide (Section 18.3), NBD methylhydrazine (*N*-methyl-4-hydrazino-7-nitrobenzofurazan, M20490) has been reported to be useful as a fluorogenic peroxidase substrate, with a sensitivity limit for detection of H₂O₂ of about 75 nM.²⁹

Figure 10.5.9 Dihydrocalcein, AM (D23805).

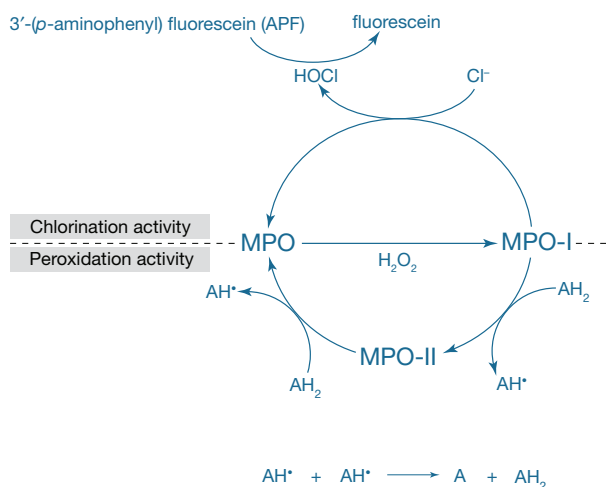

Figure 10.5.10 Schematic diagram for detection of chlorination and peroxidation activity of MPO using the EnzChek® Myeloperoxidase (MPO) Activity Assay Kit (E33856). AH₂ represents the nonfluorescent Amplex® UltraRed substrate, and A represents its fluorescent oxidation product.

Luminol and MCLA: Chemiluminescent Peroxidase Substrates

Nonisotopic immunoassays utilizing peroxidase conjugates and the chemiluminescent horseradish peroxidase substrate luminol (L8455) have provided a rapid and sensitive method for quantitating a wide variety of analytes, including cholesterol,³⁰ digoxin³¹ and acetylcholine.³² Addition of trace amounts of luciferin (L2911, L2912, L2916; Section 10.6) has been shown to considerably enhance the sensitivity in the assay of thyroxine, digoxin, α -fetoprotein and other analytes.³³ A method that employs luminol has been developed for the quantitation of very limiting samples of human DNA from single hairs, saliva, small blood stains and paraffin-embedded and fixed tissue sections. Using a biotinylated oligodeoxynucleotide probe to membrane-immobilized DNA, horseradish peroxidase streptavidin and luminol, researchers have detected 150 pg of human DNA.³⁴

MCLA (M23800) is principally utilized as a superoxide-sensitive chemiluminescent probe (Section 18.2). MCLA has also been utilized for the determination of both horseradish peroxidase³⁵ and myeloperoxidase.^{36,37,38}

DAB Histochemistry Kits

The use of horseradish peroxidase (HRP) for enzyme-amplified immunodetection—commonly referred to as immunoperoxidase labeling—is a well-established standard histochemical technique.^{39,40} The most widely used HRP substrate for these applications is diaminobenzidine (DAB), which generates a brown-colored polymeric oxidation product localized at HRP-labeled sites. The DAB reaction product can be visualized directly by bright-field light microscopy or, following osmication, by electron microscopy. We offer DAB Histochemistry Kits for detecting mouse IgG primary antibodies (D22185; Section 7.2) and biotinylated antibodies and tracers (D22187; Section 7.6). Each kit contains sufficient materials to stain approximately 200 slides, including:

- Diaminobenzidine (DAB)
- HRP-labeled goat anti-mouse IgG antibody (in Kit D22185) or streptavidin (in Kit D22187) conjugate
- Hydrogen peroxide (H₂O₂) reaction additive
- Blocking reagent
- Staining buffer
- Detailed staining protocols

Myeloperoxidase

Myeloperoxidase (MPO, EC 1.11.1.7) is a lysosomal hemoprotein located in the azurophilic granules of polymorphonuclear (PMN) leukocytes and monocytes. It is a dimeric protein composed of two 59 kD and two 13.5 kD subunits. MPO is a unique peroxidase that catalyzes the conversion of hydrogen peroxide (H₂O₂) and chloride to hypochlorous acid, a strong oxidant with powerful antimicrobial activity and broad-spectrum reactivity with biomolecules. MPO is considered an important marker for inflammatory diseases, autoimmune diseases and cancer. MPO is also experimentally and clinically important for distinguishing myeloid from lymphoid leukemia and, due to its role in the pathology of atherosclerosis, has been advocated as a prognostic marker of cardiovascular disease.

The ferric, or native, MPO reacts with hydrogen peroxide (H₂O₂) to form the active intermediate MPO-I, which oxidizes chloride (Cl⁻) to HOCl; these reactions make up the chlorination cycle (Figure 10.5.10). MPO also oxidizes a variety of substrates, including phenols and

anilines, via the classic peroxidation cycle. The relative concentrations of chloride and the reducing substrate determine whether MPO uses hydrogen peroxide for chlorination or peroxidation. Assays based on measurement of chlorination activity are more specific for MPO than those based on peroxidase substrates such as tetramethylbenzidine (TMB).

EnzChek® Myeloperoxidase (MPO) Activity Assay Kit

The EnzChek® Myeloperoxidase (MPO) Activity Assay Kit (E33856) provides assays that enable rapid and sensitive determination of both chlorination and peroxidation activities of MPO in solution and in cell lysates^{41–43} (Figure 10.5.10). For detection of chlorination, the kit provides nonfluorescent 3'-(*p*-aminophenyl) fluorescein (APF), which is selectively cleaved by hypochlorite (OCl^-) to yield fluorescein. Peroxidation is detected using nonfluorescent Amplex® UltraRed reagent, which is oxidized by the H_2O_2 -generated redox intermediates MPO-I and MPO-II to form a fluorescent product. The EnzChek® Myeloperoxidase Activity Assay Kit can be used to continuously detect these activities at room temperature over a broad dynamic range (1.5 to 200 ng/mL) (Figure 10.5.11). The speed (30 minutes), sensitivity, and mix-and-read convenience make this kit ideal for measuring MPO activities and for high-throughput screening for MPO-specific inhibitors.

The EnzChek® Myeloperoxidase (MPO) Activity Assay Kit contains:

- 3'-(*p*-aminophenyl) fluorescein (APF)
- Amplex® UltraRed reagent
- Human myeloperoxidase (MPO) standard
- Chlorination inhibitor
- Peroxidation inhibitor
- Hydrogen peroxide (H_2O_2)
- Phosphate-buffered saline (PBS)
- Dimethylsulfoxide (DMSO)
- Detailed protocols

Sufficient reagents are provided to perform 200 assays for chlorination and 200 assays for peroxidation activity in a 96-well fluorescence microplate format (100 μL per assay).

Zen™ Myeloperoxidase (MPO) ELISA Kit

The Zen™ Myeloperoxidase (MPO) ELISA Kit (Z33857) provides a comprehensive set of components designed for accurate and sensitive quantitation of human MPO in a variety of biological samples, including human serum. This sandwich immunoassay utilizes the Amplex® UltraRed reagent, a fluorogenic substrate for horseradish peroxidase (HRP) that reacts with H_2O_2 in a 1:1 stoichiometric ratio to produce the brightly fluorescent and strongly absorbing Amplex® UltraRed oxidation product (excitation/emission maxima ~568/581 nm). Because the Amplex® UltraRed product has long-wavelength emission, there is little interference from the blue or green autofluorescence found in most biological samples. With a high extinction coefficient, good quantum efficiency, and resistance to autooxidation, the fluorescence-based Amplex® UltraRed reagent delivers better sensitivity and a broader assay range than colorimetric reagents.

The Zen™ Myeloperoxidase (MPO) ELISA Kit contains:

- Amplex® UltraRed reagent
- Dimethylsulfoxide (DMSO)
- Concentrated phosphate-buffered saline (PBS)
- Horseradish peroxidase (HRP)-labeled goat anti-rabbit IgG antibody
- Amplex® stop reagent
- Hydrogen peroxide (H_2O_2)
- MPO standard
- Bovine serum albumin (BSA)
- Tween® 20
- Mouse anti-MPO antibody (capture antibody)
- Rabbit anti-MPO antibody (detection antibody)
- Zen™ microplates for oriented capture antibody coating
- Detailed protocols

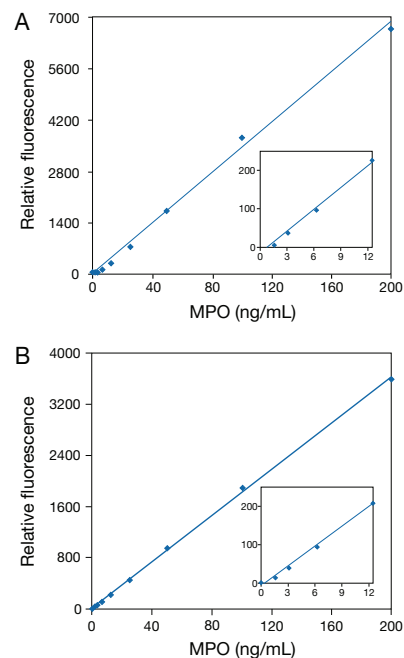

Figure 10.5.11 Typical standard curves for detection of MPO using the APF-based chlorination assay (A) and Amplex® UltraRed-based peroxidation assay (B) provided in the EnzChek® Myeloperoxidase (MPO) Activity Assay Kit (E33856). Reactions were incubated at room temperature for 30 minutes. Values on the x-axes are concentrations of MPO in the standards prior to adding the detection reagent. Fluorescence was measured with a fluorescence microplate reader using fluorescence excitation and emission at 485 and 530 nm, respectively, for the APF assay, or excitation and emission at 530 and 590 nm, respectively, for the Amplex® UltraRed assay. The background fluorescence measured for each zero-MPO control reaction was subtracted from each fluorescence measurement before plotting.

Figure 10.5.12 Typical standard curve for detection of MPO using the Zen™ Myeloperoxidase (MPO) ELISA Kit (Z33857). The sandwich ELISA was carried out as described in the protocol using a mouse anti-MPO primary capture antibody, MPO standards ranging from 0.2 ng/mL to 100 ng/mL, and a rabbit anti-MPO detection antibody.

Figure 10.5.13 Subtractive detection of catalase using the Amplex® Red Catalase Assay Kit (A22180). Reactions containing the indicated amount of catalase and 20 μM H_2O_2 in 1X reaction buffer were incubated for 30 minutes. The final reactions containing 50 μM Amplex® Red reagent and 0.2 U/mL HRP and was incubated at 37°C. After 30 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. The change in fluorescence is reported as the observed fluorescence intensity subtracted from that of a no-catalase control.

Figure 10.5.14 Detection of glucose using the Amplex® Red Glucose/Glucose Oxidase Assay Kit (A22189). Reactions containing 50 μM Amplex® Red reagent, 0.1 U/mL HRP, 1 U/mL glucose oxidase and the indicated amount of glucose in 50 mM sodium phosphate buffer, pH 7.4, were incubated for 1 hour at room temperature. Fluorescence was then measured with a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. Background fluorescence (arbitrary units), determined for a no-glucose control reaction, has been subtracted from each value. The inset shows the sensitivity and linearity of the assay at low levels of glucose (0–15 μM).

Sufficient reagents are provided for 200 assays in a microplate format, using a 100 μL per well reaction volume. The Zen™ Myeloperoxidase (MPO) ELISA Kit can be used to detect from 0.2 to 100 ng/mL MPO at room temperature (Figure 10.5.12).

Catalase

The Amplex® Red Catalase Assay Kit (A22180) provides a sensitive subtractive assay for measuring catalase activity. Catalase is a heme-containing redox protein found in nearly all animal and plant cells, as well as in aerobic microorganisms. In eukaryotic cells, it is concentrated in the peroxisomes. Catalase is an important enzyme because H_2O_2 is a powerful oxidizing agent that is potentially damaging to cells. By preventing excessive buildup of H_2O_2 , catalase allows important cellular processes that produce H_2O_2 as a by-product to take place safely.

In the assay, catalase first reacts with H_2O_2 to produce water and oxygen (O_2). Next, the Amplex® Red reagent reacts with a 1:1 stoichiometry with any unreacted H_2O_2 in the presence of horseradish peroxidase to produce the highly fluorescent oxidation product, resorufin. Therefore, as catalase activity increases, the signal from resorufin decreases (Figure 10.5.13). The results are typically plotted by subtracting the observed fluorescence from that of a no-catalase control. Using this kit, it is possible to detect catalase activity in a purified system at levels as low as 50 mU/mL.

The Amplex® Red Catalase Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- Hydrogen peroxide (H_2O_2)
- Concentrated reaction buffer
- Catalase
- Detailed protocols

Each kit provides sufficient reagents for approximately 400 assays using either a fluorescence- or absorption-based microplate reader and a reaction volume of 100 μL per assay.

Glucose and Glucose Oxidase

Glucose oxidase is widely used for glucose determination and, when conjugated to antibodies, for use in enzyme immunoassays (EIAs). Amplex® Red reagent can be utilized for the ultra-sensitive detection of both glucose and glucose oxidase. In this enzyme-coupled assay, glucose oxidase reacts with glucose to form gluconolactone and H_2O_2 . The H_2O_2 is then detected using the Amplex® Red reagent peroxidase substrate (Figure 10.5.2). The Amplex® Red Glucose/Glucose Oxidase Assay Kit (A22189) can be used to detect glucose levels as low as 3 μM or 0.5 $\mu\text{g}/\text{mL}$ (Figure 10.5.14) and is at least 10-fold more sensitive than assays using *o*-dianisidine as the peroxidase substrate. This kit can also be used to detect glucose oxidase levels as low as 0.05 mU/mL (Figure 10.5.15). We have even shown that the Amplex® Red reagent can detect glucose liberated from native dextrans by dextranase⁴⁴ and from carboxymethylcellulose by cellulase.⁴⁵

The Amplex® Red Glucose/Glucose Oxidase Assay Kit contains:

- Amplex® Red reagent
- DMSO
- Horseradish peroxidase (HRP)
- Hydrogen peroxide (H_2O_2) for use as a positive control
- Concentrated reaction buffer
- Glucose oxidase
- D-glucose
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using either a fluorescence- or absorption-based microplate reader and a reaction volume of 100 μL per assay.

Galactose and Galactose Oxidase

The Amplex® Red Galactose/Galactose Oxidase Assay Kit (A22179) provides the reagents and a general protocol for the assay of terminal galactosylated proteins, galactose-producing enzymes and for the assay of galactose oxidase. Unlike glucose oxidase, galactose oxidase can produce H_2O_2 from either free galactose or from polysaccharides—including glycoproteins in solution or on cell surfaces—in which galactose is the terminal residue, producing an aldehyde moiety on the 6-position of the galactose (Figure 10.5.16). We have used our Amplex® Red galactose oxidase assay for the quantitative assay of mucin-type glycoproteins by using a method similar to one described by Kinoshita and collaborators.⁴⁶

The Amplex® Red Galactose/Galactose Oxidase Assay Kit (A22179) contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- Hydrogen peroxide (H_2O_2)
- Concentrated reaction buffer
- Galactose oxidase from *Dactylium dendroides*
- D-Galactose
- Detailed protocols

Sufficient reagents are provided for approximately 400 assays using either a fluorescence- or absorption-based microplate reader and a reaction volume of 100 μL per assay. The Amplex® Red galactose/galactose oxidase assay is designed to accurately measure as low as 4 μM galactose and 2 mU/mL galactose oxidase activity (Figure 10.5.17, Figure 10.5.18). Because of the high absorption of resorufin, the spectrophotometric assay has only slightly lower sensitivity than the fluorometric assay. The Amplex® Red Neuraminidase (Sialidase) Assay Kit (A22178) utilizes this galactose oxidase-coupled chemistry for continuous assay of neuraminidase-catalyzed hydrolysis of fetuin, a sialoglyconjugate. This product is described in detail in Section 10.2.

Figure 10.5.16 Detection scheme utilized in the Amplex® Red Galactose/Galactose Oxidase Assay Kit (A22179). Oxidation of the terminal galactose residue of a glycoprotein, glycolipid or polysaccharide results in the generation of H_2O_2 , which, in the presence of horseradish peroxidase (HRP), reacts stoichiometrically with the Amplex® Red reagent to generate the red-fluorescent oxidation product, resorufin.

Figure 10.5.15 Detection of glucose oxidase using the Amplex® Red Glucose/Glucose Oxidase Assay Kit (A22189). Reactions containing 50 μM Amplex® Red reagent, 1 U/mL HRP, 50 mM glucose and the indicated amount of glucose oxidase in 50 mM sodium phosphate buffer, pH 7.4, were incubated for 30 minutes at room temperature. Fluorescence was measured with a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. Background fluorescence (19 units) determined for a no-glucose oxidase control reaction was subtracted from each value. The inset shows the assay's sensitivity at low levels of glucose oxidase (0–0.2 mU/mL).

Figure 10.5.17 Detection of galactose using the Amplex® Red Galactose/Galactose Oxidase Assay Kit (A22179). Each reaction contained 50 μM Amplex® Red reagent, 0.1 U/mL HRP, 2 U/mL of galactose oxidase and the indicated amount of galactose in 1X reaction buffer. Reactions were incubated at 37°C. After 30 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. A background fluorescence of 93 units was subtracted from each data point.

Figure 10.5.18 Detection of galactose oxidase activity using the Amplex® Red Galactose/Galactose Oxidase Assay Kit (A22179). Each reaction contained 50 μM Amplex® Red reagent, 0.1 U/mL HRP, 100 μM galactose and the indicated amount of galactose oxidase in 1X reaction buffer. Reactions were incubated at 37°C. After 20 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm with fluorescence detection at 590 ± 17.5 nm.

Figure 10.5.19 Detection of cholesterol using the Amplex® Red reagent-based assay. Each reaction contained 150 µM Amplex® Red reagent, 1 U/mL HRP, 1 U/mL cholesterol oxidase, 0.1 µM cholesterol esterase and the indicated amount of the cholesterol in 1X Reaction Buffer. Reactions were incubated at 37°C for 30 minutes. Fluorescence was measured with a fluorescence microplate reader using excitation at 560 ± 10 nm and fluorescence detection at 590 ± 10 nm. Background fluorescence (340 arbitrary units), determined for the no-cholesterol control reaction, has been subtracted from each value.

Figure 10.5.21 Detection of semicarbazide-sensitive amine oxidase (SSAO) activity using the Amplex® Red Monoamine Oxidase Assay Kit (A12214) and benzylamine as the substrate. Each reaction contained 1 mM benzylamine, 1 U/mL HRP, 200 µM Amplex® Red reagent and the indicated amount of SSAO in 50 mM potassium phosphate, pH 7.4. Reactions were incubated at room temperature for 15 minutes. Fluorescence was measured with a fluorescence microplate reader using excitation at 560 ± 10 nm and fluorescence detection at 590 ± 10 nm.

Figure 10.5.20 Enzyme-coupled Amplex® Red assays. Enzyme reactions that produce H_2O_2 can be made into Amplex® Red assays. The Amplex® Red Cholesterol Assay Kit (A12216) uses cholesterol oxidase to produce H_2O_2 , which is then detected by the Amplex® Red reagent in the presence of horseradish peroxidase (HRP). Similarly, the Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit (A12217) uses choline oxidase to produce H_2O_2 .

Cholesterol and Cholesterol Oxidase

The Amplex® Red Cholesterol Assay Kit (A12216) provides an exceptionally sensitive assay for both cholesterol and cholesteryl esters in complex mixtures that is suitable for use with either fluorescence microplate readers or fluorometers. The assay provided in this kit can detect as little as 5 ng/mL (5×10^{-4} mg/dL) cholesterol (Figure 10.5.19) and is designed to accurately measure the cholesterol or cholesteryl ester content in the equivalent of 0.01 µL of human serum.⁴⁷ The assay uses an enzyme-coupled reaction scheme in which cholesteryl esters are hydrolyzed by cholesterol esterase into cholesterol, which is then oxidized by cholesterol oxidase to yield H_2O_2 and the corresponding ketone steroidal product (Figure 10.5.20). The H_2O_2 is then detected using the Amplex® Red reagent in combination with HRP. The Amplex® Red cholesterol assay is continuous and requires no separation or wash steps. These characteristics make the assay particularly well suited for the rapid and direct analysis of cholesterol in blood and food samples using automated instruments. By performing two separate measurements in the presence and absence of cholesterol esterase, this assay is also useful for determining the fraction of cholesterol that is in the form of cholesteryl esters within a sample.⁴⁸ In addition, by adding an excess of cholesterol to the reaction, this assay can be used to sensitively detect the activity of cholesterol oxidase.

The Amplex® Red Cholesterol Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- Hydrogen peroxide (H_2O_2) for use as a positive control
- Concentrated reaction buffer
- Cholesterol oxidase from *Streptomyces*
- Cholesterol esterase from *Pseudomonas*
- Cholesterol for preparation of a standard curve
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using a fluorescence microplate reader and a reaction volume of 100 µL per assay.

Monoamine Oxidase

Monoamine oxidase, which inactivates several primary, secondary and tertiary amines via oxidative transamination, serves to regulate tissue levels of amine neurotransmitters and dietary amines. The Amplex® Red Monoamine Oxidase Assay Kit (A12214) provides a simple fluorometric method for the continuous measurement of amine oxidase activity in tissue homogenates or purified preparations. We have found that the assay is able to sensitively detect both monoamine oxidase (MAO) activity and semicarbazide-sensitive amine oxidase (SSAO) activity and is useful for performing both end-point and continuous measurements of amine oxidase activity. The assay is able to detect both MAO-A and MAO-B from cow brain tissue using as little as 200 µg of total protein per sample⁶ and has been used to measure plasma amine oxidase (an SSAO) activity levels as low as 1.2×10^{-5} U/mL using a commercially available enzyme (Figure 10.5.21).

To facilitate discrimination of MAO-A and MAO-B activity, two MAO substrates and two MAO inhibitors are included in the kit. *p*-Tyramine is a substrate for both MAO-A and MAO-B, whereas benzylamine is a substrate for MAO-B.⁴⁹ Both *p*-tyramine and benzylamine are also substrates for SSAO enzymes. Clorgyline is a specific inhibitor of MAO-A activity, and pargyline is a specific inhibitor of MAO-B activity.^{50,51} The potential applications of this kit include the measurement of amine oxidase activity in normal and diseased tissues, blood samples and other biological fluids, the screening of drugs as possible MAO inhibitors or substrates and the determination of kinetic constants for different amine oxidase substrates.

The Amplex® Red Monoamine Oxidase Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- Hydrogen peroxide (H₂O₂) for use as a positive control
- Concentrated reaction buffer
- Benzylamine, a substrate for MAO-B and SSAO enzymes
- *p*-Tyramine, a substrate for MAO-A, MAO-B and SSAO enzymes
- Clorgyline, a specific inhibitor of MAO-A activity
- Pargyline, a specific inhibitor of MAO-B activity
- Resorufin, for use as a reference standard
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using a reaction volume of 200 µL per assay.

Glutamic Acid and Glutamate Oxidase

The Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit (A12221) provides an ultrasensitive method for continuously detecting glutamic acid⁵² or for monitoring glutamate oxidase activity in a fluorescence microplate reader or a fluorometer.¹⁹ In this assay, L-glutamic acid is oxidized by glutamate oxidase to produce α-ketoglutarate, NH₃ and H₂O₂. L-Alanine and L-glutamate-pyruvate transaminase are also included in the reaction. Thus, the L-glutamic acid is regenerated by transamination of α-ketoglutarate, resulting in multiple cycles of the initial reaction and a significant amplification of the H₂O₂ produced. Hydrogen peroxide reacts with the Amplex® Red reagent in a 1:1 stoichiometry in a reaction catalyzed by horseradish peroxidase (HRP) to generate the highly fluorescent product resorufin^{1,5} (R363, Section 10.1). Because resorufin has absorption/emission maxima of ~571/ 585 nm, there is little interference from autofluorescence in most biological samples.

If the concentration of L-glutamic acid is limiting in this assay, then the fluorescence increase is proportional to the initial L-glutamic acid concentration. The Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit allows detection of as little as 10 nM L-glutamic acid in purified systems using a 30-minute reaction time (Figure 10.5.22). If the reaction is modified to include an excess of L-glutamic acid, then this kit can be used to continuously monitor glutamate oxidase activity. For example, purified L-glutamate oxidase from *Streptomyces* can be detected at levels as low as 0.04 mU/mL (Figure 10.5.23). The Amplex® Red reagent has been used to quantitate the activity of glutamate-producing enzymes in a high-throughput assay for drug discovery.⁵²

Figure 10.5.22 Detection of L-glutamic acid using the Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit (A12221). Each reaction contained 50 µM Amplex® Red reagent, 0.125 U/mL HRP, 0.04 U/mL L-glutamate oxidase, 0.25 U/mL L-glutamate-pyruvate transaminase, 100 µM L-alanine and the indicated amount of L-glutamic acid in 1X reaction buffer. Reactions were incubated at 37°C. After 30 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. The inset shows the assay sensitivity at low levels of glutamic acid (0–0.1 µM).

Figure 10.5.23 Detection of L-glutamate oxidase using the Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit (A12221). Each reaction contained 50 µM Amplex® Red reagent, 0.125 U/mL HRP, 0.25 U/mL L-glutamate-pyruvate transaminase, 20 µM L-glutamic acid, 100 µM L-alanine and the indicated amount of *Streptomyces* L-glutamate oxidase in 1X reaction buffer. Reactions were incubated at 37°C. After 60 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. The inset represents data from a separate experiment for lower L-glutamate oxidase concentrations and incubation time of 60 minutes (0–1.25 mU/mL).

Figure 10.5.24 Detection of electric eel acetylcholinesterase activity using the Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit (A12217). Each reaction contained 50 μ M acetylcholine, 200 μ M Amplex® Red reagent, 1 U/mL HRP, 0.1 U/mL choline oxidase and the indicated amount of acetylcholinesterase in 1X reaction buffer. Reactions were incubated at room temperature. After 15 and 60 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 560 ± 10 nm and fluorescence detection at 590 ± 10 nm. The inset shows the sensitivity of the 15 min (□) and 60 min (●) assays at low levels of acetylcholinesterase activity (0–13 mU/mL).

Figure 10.5.25 Detection of acetylcholine using the Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit (A12217). Each reaction contained 200 μ M Amplex® Red reagent, 1 U/mL HRP, 0.1 U/mL choline oxidase, 0.5 U/mL acetylcholinesterase and the indicated amount of acetylcholine in 1X reaction buffer. Reactions were incubated at room temperature. After 15 and 60 minutes, fluorescence was measured with a fluorescence microplate reader using excitation at 560 ± 10 nm and fluorescence detection at 590 ± 10 nm. The inset shows the sensitivity of the 15 min (□) and 60 min (●) assays at low levels of acetylcholine (0–3 μ M).

The Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- Hydrogen peroxide (H_2O_2)
- Concentrated reaction buffer
- L-Glutamate oxidase from *Streptomyces* sp.
- L-Glutamate-pyruvate transaminase from pig heart
- L-Glutamic acid
- L-Alanine
- Detailed protocols

Each kit provides sufficient reagents for approximately 200 assays using a fluorescence microplate reader and a reaction volume of 100 μ L per assay.

Acetylcholine, Acetylcholinesterase and Choline Oxidase

Acetylcholine, the neurotransmitter released from the nerve terminal at neuromuscular junctions, binds to the acetylcholine receptor and opens its transmitter-gated ion channel (Section 16.3). The action of acetylcholine (ACh) is regulated by acetylcholinesterase (AChE), which hydrolyzes ACh to choline and acetate. The Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit (A12217) provides an ultrasensitive method for continuously monitoring AChE activity or for detecting ACh in a fluorescence microplate reader or a fluorometer. Other uses for this kit include screening for AChE inhibitors and measuring the release of ACh from synaptosomes.^{53,54}

In the assay, AChE activity is monitored indirectly using the Amplex® Red reagent (Figure 10.5.20). First, AChE converts the acetylcholine substrate to choline. Choline is in turn oxidized by choline oxidase to betaine and H_2O_2 , the latter of which, in the presence of HRP, reacts with the Amplex® Red reagent to generate the red-fluorescent product resorufin. Experiments with purified AChE from electric eel indicate that the Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit can detect AChE levels as low as 0.002 U/mL using a reaction time of 1 hour (Figure 10.5.24). We have been able to detect acetylcholinesterase activity from a tissue sample with total protein content as low as 200 ng/mL or 20 ng/well in a microplate assay. By providing an excess of AChE in the assay, the kit can also be used to detect acetylcholine levels as low as 0.3 μ M, with a range of detection from 0.3 μ M to ~100 μ M acetylcholine (Figure 10.5.25).

The Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- Hydrogen peroxide (H_2O_2) for use as a positive control
- Concentrated reaction buffer
- Choline oxidase from *Alcaligenes* sp.
- Acetylcholine (ACh)
- Acetylcholinesterase (AChE) from electric eel
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using a fluorescence microplate reader and a reaction volume of 200 μ L per assay.

Xanthine and Xanthine Oxidase

Xanthine oxidase (E.C. 1.2.3.2) plays a key role in the production of free radicals, including superoxide, in the body. The Amplex® Red Xanthine/Xanthine Oxidase Assay Kit (A22182) provides an ultrasensitive method for detecting xanthine or hypoxanthine or for monitoring xanthine oxidase activity. In the assay, xanthine oxidase catalyzes the oxidation of purine nucleotides,

hypoxanthine or xanthine, to uric acid and superoxide. In the reaction mixture, the superoxide spontaneously degrades to H_2O_2 , which in the presence of HRP reacts stoichiometrically with Amplex® Red reagent to generate the red-fluorescent oxidation product, resorufin. Resorufin has absorption and fluorescence emission maxima of approximately 571 nm and 585 nm, respectively, and because the extinction coefficient is high ($54,000 \text{ cm}^{-1}\text{M}^{-1}$), the assay can be performed either fluorometrically or spectrophotometrically.

The Amplex® Red Xanthine/Xanthine Oxidase Assay Kit (A22182) contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- H_2O_2
- Concentrated reaction buffer
- Xanthine oxidase from buttermilk
- Hypoxanthine
- Xanthine
- Detailed protocols

Each kit provides sufficient reagents for approximately 400 assays using either a fluorescence- or absorption-based microplate reader and a reaction volume of 100 μL per assay.

In healthy individuals, xanthine oxidase is present in appreciable amounts only in the liver and jejunum. In various liver disorders, however, the enzyme is released into circulation. Therefore, determination of serum xanthine oxidase levels serves as a sensitive indicator of acute liver damage such as jaundice. The Amplex® Red xanthine/xanthine oxidase assay has been used as a marker of recovery from exercise stress.⁵⁵ Previously, researchers have utilized chemiluminescence or absorbance to monitor xanthine oxidase activity. The Amplex® Red Xanthine/Xanthine Oxidase Assay Kit permits the detection of xanthine oxidase in a purified system at levels as low as 0.1 mU/mL by fluorescence (Figure 10.5.26). This kit can also be used to detect as little as 200 nM hypoxanthine or xanthine (Figure 10.5.27), and, when coupled to the purine nucleotide phosphorylase enzyme, to detect inorganic phosphate.⁵⁶

Uric Acid and Uricase

Serum uric acid is the end product of purine metabolism in the body tissues and is cleared through the kidneys by glomerular filtration. Most animals can metabolize uric acid to more readily excreted products, but humans lack the necessary enzyme, urate oxidase (uricase), as a result of the presence of two "nonsense mutations" in the human gene for uricase. Increased uric acid levels may result from leukemia, polycythemia, ingestion of foods high in nucleoproteins (e.g., liver and kidney) or impaired renal function. Gout results from the deposit of uric acid in body joints.

The Amplex® Red Uric Acid/Uricase Assay Kit (A22181) provides an ultrasensitive method for detecting uric acid or for monitoring uricase activity.⁵⁷ In the assay, uricase catalyzes the conversion of uric acid to allantoin, H_2O_2 and carbon dioxide. In the presence of HRP, the H_2O_2 reacts stoichiometrically with Amplex® Red reagent to generate the red-fluorescent oxidation product, resorufin. Resorufin has absorption and fluorescence emission maxima of approximately 571 nm and 585 nm, respectively, and because the extinction coefficient is high ($54,000 \text{ cm}^{-1}\text{M}^{-1}$), the assay can be performed either fluorometrically or spectrophotometrically. Previous literature reports colorimetric detection limits at 3.6 μM , whereas the Amplex® Red Uric Acid/Uricase Assay Kit can be used to detect as little as 100 nM uric acid in a purified system. A biosensor containing an encapsulated uricase-peroxidase system and the Amplex® Red reagent exhibits a high specificity for uric acid in the presence of interfering species and a linear response from 20 nM to 1 μM uric acid.⁵⁷ The Amplex® Red Uric Acid/Uricase Assay Kit can also be used to detect as little as 0.2 mU/mL uricase in a purified system.

The Amplex® Red Uric Acid/Uricase Assay Kit (A22181) contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- Hydrogen peroxide (H_2O_2)
- Concentrated reaction buffer
- Uricase
- Uric acid
- Detailed protocols

Each kit provides sufficient reagents for approximately 400 assays using either a fluorescence- or absorption-based microplate reader and a reaction volume of 100 μL per assay.

Figure 10.5.26 Detection of xanthine oxidase using the Amplex® Red Xanthine/Xanthine Oxidase Assay Kit (A22182). Each reaction contained 50 μM Amplex® Red reagent, 0.2 U/mL horseradish peroxidase, 0.1 mM hypoxanthine and the indicated amount of xanthine oxidase in 1X reaction buffer. After 30 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at $530 \pm 12.5 \text{ nm}$ and detection at $590 \pm 17.5 \text{ nm}$. A background of 65 fluorescence units was subtracted from each data point. The inset shows the assay's sensitivity and linearity at low hypoxanthine concentrations.

Figure 10.5.27 Detection of hypoxanthine using the Amplex® Red Xanthine/Xanthine Oxidase Assay Kit (A22182). Each reaction contained 50 μM Amplex® Red reagent, 0.2 U/mL horseradish peroxidase, 20 mU/mL xanthine oxidase and the indicated amount of hypoxanthine in 1X reaction buffer. Reactions were incubated at 37°C. After 30 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at $530 \pm 12.5 \text{ nm}$ and detection at $590 \pm 17.5 \text{ nm}$. A background of 54 fluorescence units was subtracted from each data point. The inset shows the assay's sensitivity and linearity at low enzyme concentrations.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- This substrate is used for peroxidase-coupled detection in our Amplex® Red Assay Kits.
- Peroxidase-catalyzed reaction of the Amplex® UltraRed reagent (A36006) with H₂O₂ yields a fluorescent product with Abs = 568 nm (EC = 57,000 cm⁻¹M⁻¹), Em = 581 nm in pH 7.5 buffer.
- Dihydrofluorescein diacetates are colorless and nonfluorescent until both of the acetate groups are hydrolyzed and the products are subsequently oxidized to fluorescein derivatives. The materials contain less than 0.1% of oxidized derivative when initially prepared. The oxidation products of C400, C2938, C6827, D399 and D2935 are 2',7'-dichlorofluorescein derivatives with spectra similar to C368.
- Difluorodihydrofluorescein diacetates are colorless and nonfluorescent. Acetate hydrolysis and subsequent oxidation generate a fluorescent 2',7'-difluorofluorescein derivative with spectra similar to O6146.
- This compound emits chemiluminescence upon oxidation in basic aqueous solutions. Emission peaks are at 425 nm (L8455) and 470 nm (L6868).
- Peroxidase-catalyzed oxidation of NBD methylhydrazine generates fluorescent *N*-methyl-4-amino-7-nitrobenzofurazan, Abs = 470 nm, Em = 547 nm in aqueous buffer (pH 5.8). (*Angew Chem Int Ed Engl* (2000) 39:1453)
- Generates chemiluminescence (Em = 455 nm) upon reaction with superoxide.

PRODUCT LIST 10.5 SUBSTRATES FOR OXIDASES, INCLUDING AMPLEX® RED KITS

Cat. No.	Product	Quantity
A33851	Amplex® ELISA Development Kit for Mouse IgG *with Amplex® UltraRed reagent* *500 assays*	1 kit
A33852	Amplex® ELISA Development Kit for Rabbit IgG *with Amplex® UltraRed reagent* *500 assays*	1 kit
A12217	Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit *500 assays*	1 kit
A22180	Amplex® Red Catalase Assay Kit *400 assays*	1 kit
A12216	Amplex® Red Cholesterol Assay Kit *500 assays*	1 kit
A22179	Amplex® Red Galactose/Galactose Oxidase Assay Kit *400 assays*	1 kit
A22189	Amplex® Red Glucose/Glucose Oxidase Assay Kit *500 assays*	1 kit
A12221	Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit *200 assays*	1 kit
A22188	Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit *500 assays*	1 kit
A12214	Amplex® Red Monoamine Oxidase Assay Kit *500 assays*	1 kit
A22178	Amplex® Red Neuraminidase (Sialidase) Assay Kit *400 assays*	1 kit
A12218	Amplex® Red Phosphatidylcholine-Specific Phospholipase C Assay Kit *500 assays*	1 kit
A12219	Amplex® Red Phospholipase D Assay Kit *500 assays*	1 kit
A12222	Amplex® Red reagent	5 mg
A22177	Amplex® Red reagent *packaged for high-throughput screening*	10 x 10 mg
A12220	Amplex® Red Sphingomyelinase Assay Kit *500 assays*	1 kit
A22181	Amplex® Red Uric Acid/Uricase Assay Kit *400 assays*	1 kit
A22182	Amplex® Red Xanthine/Xanthine Oxidase Assay Kit *400 assays*	1 kit
A33855	Amplex® Red/UltraRed stop reagent *500 tests* *set of 5 vials*	1 set
A36006	Amplex® UltraRed reagent	5 x 1 mg
C13293	5-(and-6)-carboxy-2',7'-difluorodihydrofluorescein diacetate (carboxy-H ₂ DFFDA) *mixed isomers*	5 mg
C400	5-(and-6)-carboxy-2',7'-dichlorodihydrofluorescein diacetate (carboxy-H ₂ DCFDA) *mixed isomers*	25 mg
D22185	Diaminobenzidine (DAB) Histochemistry Kit #1 *with goat anti-mouse IgG–HRP*	1 kit
D22187	Diaminobenzidine (DAB) Histochemistry Kit #3 *with streptavidin–HRP*	1 kit
D399	2',7'-dichlorodihydrofluorescein diacetate (2',7'-dichlorofluorescein diacetate; H ₂ DCFDA)	100 mg
D23805	dihydrocalcein, AM *special packaging*	20 x 50 µg
E33856	EnzChek® Myeloperoxidase (MPO) Activity Assay Kit *400 assays* *for myeloperoxidase chlorination and peroxidation activity*	1 kit
E33701	EnzChek® Ultra Phytase Assay Kit *500 assays*	1 kit
G21040	goat anti-mouse IgG (H+L), horseradish peroxidase conjugate	1 mg
L8455	luminol (3-aminophthalhydrazide)	25 g
M20490	N-methyl-4-hydrazino-7-nitrobenzofurazan (NBD methylhydrazine)	25 mg
M23800	2-methyl-6-(4-methoxyphenyl)-3,7-dihydroimidazo[1,2-a]pyrazin-3-one, hydrochloride (MCLA)	5 mg
P21041	protein G, horseradish peroxidase conjugate	1 mg
Z33857	Zen™ Myeloperoxidase (MPO) ELISA Kit *200 assays*	1 kit

10.6 Substrates for Microsomal Dealkylases, Acetyltransferases, Luciferases and Other Enzymes

Fluorogenic substrates that detect glycosidases (Section 10.2) and phosphatases (Section 10.3) have been by far the dominant probes for measuring enzymatic activity. Exactly the same fluorophores and chromophores—fluoresceins, resorufins and umbelliferones (7-hydroxycoumarins)—can be used to prepare substrates for other hydrolytic enzymes and ether-metabolizing microsomal dealkylase enzymes or peroxidases. In addition, we offer substrates for chloramphenicol acetyltransferase (CAT), luciferase and β -lactamase, which are usually not widely expressed in cells. These substrates are important tools for detecting cells transfected with reporter genes that encode these enzymes. We also have available several reagents that are substrates for detecting enzyme-catalyzed chemical reduction associated with cells, including the tetrazolium salts MTT and XTT¹ (M6494, X6493; Section 15.2) and resazurin (R12204), which is useful for quantitatively measuring cell-mediated cytotoxicity,² cell proliferation^{3,4} and mitochondrial metabolic activity in isolated neural tissue.⁵

Microsomal Dealkylases

Metabolic oxidation of chemical compounds, including many pollutants, is the function of the cytochrome-mediated monooxygenase or mixed-function oxidase system. Several enzymes are involved, including cytochrome P448 monooxygenase (aryl hydrocarbon hydroxylase), which is induced by carcinogenic polyaromatic hydrocarbons. Cytochrome P450 (CYP) is a useful marker of endoplasmic reticulum membranes.⁶ The very low turnover rate of these enzymes can be followed using various fluorogenic alkyl ether derivatives of coumarin,⁷ resorufin⁸ and fluorescein,⁹ all of which yield cleavage products with longer-wavelength spectral properties than the parent substrates.

Resorufin-Based Microsomal Dealkylase Substrates

Resorufin ether-based substrates (R352, R441, R1147), which all yield red-fluorescent resorufin (R363, Section 10.1; excitation/emission maxima ~571/585 nm), have been extensively used to differentiate isozymes of cytochrome P450.^{8,10–16} Ethoxyresorufin *O*-deethylase (EROD) and total protein concentration have been simultaneously assayed in a fluorescence microplate reader using ethoxyresorufin (resorufin ethyl ether, R352) and fluorescamine¹⁷ (F2332, F20261; Section 9.2).

Coumarin-Based Microsomal Dealkylase Substrates

Fluorescence detection of the deethylation of 3-cyano-7-ethoxycoumarin^{10,18} (C684) is reported to be 50–100 times more sensitive than that of ethoxyresorufin, primarily because of the faster turnover rate of 3-cyano-7-ethoxycoumarin;^{19,20} however, ethoxyresorufin exhibits lower fluorescence background due to its more favorable spectral shifts. The deethylase product of 3-cyano-7-ethoxycoumarin, 3-cyano-7-hydroxycoumarin (C183, Section 10.1), has a lower pK_a than that of 7-ethoxycoumarin,^{21,22} allowing continuous measurements of enzyme activity at pH 7.

The cytochrome P450 substrate 7-ethoxy-4-trifluoromethylcoumarin (E2882) yields a product with a fluorescence emission that is distinct

from that of the substrate and of NADPH, making this substrate useful for the direct measurement of enzymatic activity.^{23–26} Researchers have shown that this substrate is cleaved by at least the 1A2, 2E1 and 2B1 isozymes of cytochrome P450.^{24,27}

EnzChek® Epoxide Hydrolase Substrate

The EnzChek® epoxide hydrolase substrate (E33956) is ideal for studying the epoxide hydrolase family of enzymes, including the arachidonic epoxide hydrolases (implicated in the regulation of inflammation and blood pressure) and microsomal epoxide hydrolases (reported to detoxify epoxides into diols), and their respective inhibitors. This substrate permits accurate detection of epoxide hydrolase activity in solution, with better sensitivity than colorimetric epoxide hydrolase substrates. In the presence of epoxide hydrolases, the nonfluorescent EnzChek® epoxide hydrolase substrate produces a bright blue-fluorescent product with excitation and emission maxima of ~358 nm and 452 nm, respectively. Furthermore, the blue-fluorescent product of the EnzChek® epoxide hydrolase substrate exhibits pH-insensitive spectra in the physiological pH range and is compatible with optics used for coumarin detection in fluorimeters.

Lipases

Lipases play an essential role in the transfer of lipids in cell signaling and metabolism and generally include glycerol ester hydrolases and cholesterol esterases. Phospholipase A selectively hydrolyzes lipophilic esters of phospholipids. Because of their importance to the process of signal transduction in cells, our extensive selection of substrates and other probes for phospholipases is discussed in Section 17.4.

EnzChek® Lipase Substrate

The triacylglycerol-based EnzChek® lipase substrate (E33955) offers higher throughput and better sensitivity than chromogenic (TLC or HPLC) assays, and a visible wavelength–detection alternative to pyrene-based fluorescent substrates. In the presence of lipases, the nonfluorescent EnzChek® lipase substrate produces a bright, green-fluorescent product (excitation/emission maxima of ~505/515 nm) that enables the accurate and sensitive detection of lipase activity in solution. Furthermore, the green-fluorescent product of the EnzChek® lipase substrate exhibits pH-insensitive spectra in the physiological pH range and is compatible with optics used for fluorescein detection in fluorimeters.

Coumarin-Based Lipase Substrates

The fluorogenic substrate *O*-pivaloyloxymethyl umbelliferone (C-POM, P35901) was developed to deliver optimal performance in assays of lipase activity. Standard lipase substrates

may exhibit high levels of undesirable nonspecific reactivity, either through spontaneous hydrolysis or direct reaction of the substrate with noncatalytic proteins such as BSA.²⁸ C-POM is much less prone to these unwanted side reactions, and the resulting low level of background fluorescence yields a better signal-to-noise ratio, providing a more accurate measure of lipase catalysis. Enzymatic conversion of the essentially nonfluorescent C-POM yields a bright blue-fluorescent reaction product (excitation/emission ~360/460 nm). C-POM has been shown to serve as a substrate for a variety of lipases and displays excellent stability in solution, making it an ideal substrate for specific lipases or for general or high-throughput screening.

Unlike lipase substrates that are esters of 7-hydroxy-4-methylcoumarin (β -methylumbelliferone, H189; Section 10.1) 6,8-difluoro-4-methylumbelliferyl octanoate (DiFMU octanoate, D12200) can be used for the continuous *in vitro* assay of lipases at a pH greater than or equal to 6;²⁹ the blue-fluorescent hydrolysis product of DiFMU octanoate, 6,8-difluoro-7-hydroxy-4-methylcoumarin (DiFMU, D6566; Section 10.1), has a pK_a of 4.9.³⁰

Cholesterol Esterase Assay

The cholesterol produced by cholesterol esterases is readily quantitated using the Amplex[®] Red Cholesterol Assay Kit (A12216), which is discussed in Section 10.5 and Section 13.3. The Amplex[®] Red cholesterol assay can be adapted to continuously measure cholesterol generated by the activity of cholesterol esterases.

Chloramphenicol Acetyltransferase (CAT)

Because of the close correlation between its transcript levels and enzymatic activity and the excellent sensitivity of the enzyme assay, the chloramphenicol acetyltransferase (CAT) reporter gene system has proven to be a powerful tool for investigating transcriptional elements in animal^{31,32} and plant cells.^{33,34} Most conventional CAT assays require incubation of cell extracts with radioactive substrates, typically ¹⁴C chloramphenicol or ¹⁴C acetyl CoA, followed by organic extraction and autoradiography or scintillation counting.³⁵⁻³⁷ The FAST CAT[®] Chloramphenicol Acetyltransferase Assay Kits contain unique BODIPY[®] chloramphenicol fluorescent substrates that take advantage of the exquisite sensitivity of fluorescence techniques, thus eliminating the need for hazardous radiochemicals, film, scintillation counters and expensive radioactive waste disposal.^{38,39} The original FAST CAT[®] Kit and our FAST CAT[®] Green and Yellow (deoxy) Kits provide detection limits similar to those achieved with conventional radioactive methods and yield results that are easily visualized using a hand-held UV lamp.

FAST CAT[®] Chloramphenicol Acetyltransferase Assay Kit

The green-fluorescent BODIPY[®] FL chloramphenicol substrate in our original FAST CAT[®] Chloramphenicol Acetyltransferase Assay Kit (F2900) has a K_M for purified CAT of 7.4 μ M and a V_{max} of 375 picomoles/unit/minute, values that are similar to those of ¹⁴C-labeled chloramphenicol^{39,40} ($K_M = 12 \mu$ M and $V_{max} = 120$ picomole/unit/minute). To perform the assay, cell extracts are simply incubated

with BODIPY[®] FL chloramphenicol and acetyl coenzyme A. After a suitable incubation period, the products and remaining substrate are extracted and separated by thin-layer chromatography (TLC). The brightly fluorescent, well-resolved spots can be immediately visualized with a hand-held UV lamp or quantitated with a laser scanner or CCD camera. Alternatively, quantitation can be accomplished using a fluorometer or spectrophotometer after a simple extraction. HPLC analysis of the fluorescent products has also been used to further enhance the assay's sensitivity.^{41,42}

These attributes have enabled researchers to use this FAST CAT[®] substrate to measure CAT activity in crude cellular extracts of transfected ovarian granulosa cells.⁴⁰ The FAST CAT[®] Chloramphenicol Acetyltransferase Assay Kit has also been employed to study hormonal regulation of prodynorphin gene expression^{43,44} and to measure the rate of hair growth in single follicles of transgenic mice.⁴²

Each FAST CAT[®] Chloramphenicol Acetyltransferase Assay Kit (F2900) is available in a 100-test size and includes:

- BODIPY[®] FL chloramphenicol substrate
- Mixture of the 1- and 3-acetyl and 1,3-diacetyl BODIPY[®] FL derivatives, which serve as a reference standard for the fluorescent products
- Detailed protocols

FAST CAT[®] (Deoxy) Chloramphenicol Acetyltransferase Assay Kits

The FAST CAT[®] (deoxy) Chloramphenicol Acetyltransferase Assay Kits (F6616, F6617; Figure 10.6.1) contain substrates that greatly simplify the quantitation of chloramphenicol acetyltransferase (CAT) activity and extend the linear detection range of the original Molecular Probes[®] FAST CAT[®] assay.⁴⁵ The BODIPY[®] FL chloramphenicol substrate in our original FAST CAT[®] kit contains two acetylation sites, only one of which is acetylated by the CAT enzyme. Once the CAT enzyme adds an acetyl group to this position, the acetyl group can be nonenzymatically transferred to the second site, leaving the original position open for another enzymatic acetylation.⁴⁶⁻⁴⁸ Therefore, enzyme

Figure 10.6.1 Chloramphenicol acetyltransferase (CAT) assays using our FAST CAT[®] Yellow (deoxy) Chloramphenicol Acetyltransferase Assay Kit (F6617). Decreasing amounts of purified CAT enzyme (2-fold dilutions) were incubated with the corresponding deoxy substrate in the presence of acetyl CoA; the reaction mixture was then separated with standard thin-layer chromatography (TLC) methods and visualized with 366 nm epi-illumination. The bottom row of fluorescent spots in each TLC represents the substrate; the top, the monoacetylated reaction product.

acetylation of our original BODIPY® FL FAST CAT® substrate produces three products—one diacetylated and two monoacetylated chloramphenicols—thus complicating the quantitative analysis of CAT gene activity. More importantly, because the nonenzymatic transacetylation is the rate-limiting step, the rate of product accumulation may not accurately reflect CAT activity.^{46,49,50}

To overcome this limitation, we have modified the original FAST CAT® substrate, producing reagents that undergo a single acetylation reaction (Figure 10.6.2). The green-fluorescent BODIPY® FL deoxy-chloramphenicol and yellow-fluorescent BODIPY® 543/569 deoxy-chloramphenicol substrates in the FAST CAT® Green and FAST CAT® Yellow (deoxy) Chloramphenicol Acetyltransferase Assay Kits (F6616, F6617) are acetylated at a single position, yielding only one fluorescent product^{45,50} (Figure 10.6.2). This simplified reaction scheme is designed to provide a straightforward and reliable measure of CAT activity and to extend the linear detection range of our original FAST CAT® assay.

The FAST CAT® Green and FAST CAT® Yellow (deoxy) Chloramphenicol Acetyltransferase Assay Kits are available in a 100-test size and include:

- BODIPY® FL 1-deoxychloramphenicol substrate (in Kit F6616) or BODIPY® TMR 1-deoxychloramphenicol substrate (in Kit F6617)
- 3-Acetyl BODIPY® FL derivative (in Kit F6616) or BODIPY® TMR derivative (in Kit F6617), which serves as a reference standard for the fluorescent product
- Detailed protocols

Figure 10.6.2 The green-fluorescent BODIPY® FL 1-deoxychloramphenicol substrate in our FAST CAT® Green (deoxy) Chloramphenicol Acetyltransferase Assay Kit (F6616). CAT-mediated acetylation of this substrate and of the BODIPY® TMR 1-deoxychloramphenicol in our FAST CAT® Yellow (deoxy) Chloramphenicol Acetyltransferase Assay Kit (F6617) results in single fluorescent products because these substrates contain only one hydroxyl group that can be acetylated. In contrast, the BODIPY® FL chloramphenicol substrate in our original FAST CAT® Kit (F2900) contains a second hydroxyl group at the 1-position (indicated by the labeled arrow). This hydroxyl group undergoes a nonenzymatic transacetylation step, restoring the original hydroxyl for a second acetylation. CAT-mediated acetylation of this chloramphenicol substrate produces three fluorescent products, thus complicating the analysis.

The CAT substrate in our FAST CAT® Green (deoxy) Chloramphenicol Acetyltransferase Assay Kit (F6616) is spectrally identical to the green-fluorescent BODIPY® FL chloramphenicol substrate in our original FAST CAT® Kit. The FAST CAT® Yellow (deoxy) Chloramphenicol Acetyltransferase Assay Kit (F6617) contains a red-orange-fluorescent BODIPY® TMR derivative. The availability of two spectrally distinct CAT substrates allows researchers to choose the optimal fluorophore for a particular excitation source or multicolor labeling experiment.

Luciferases

Firefly luciferase (*Photinus-luciferin:oxygen 4-oxidoreductase* or luciferin 4-monooxygenase, EC 1.13.12.7) produces light by the ATP-dependent oxidation of luciferin (Figure 10.6.3). The 560 nm chemiluminescence from this reaction peaks within seconds, with light output that is proportional to luciferase concentration when substrates are present in excess.⁵¹ The *luc* gene, which encodes the 62,000-dalton firefly luciferase, is a popular reporter gene for plants,^{33,52–55} bacteria^{56,57} and mammalian cells^{58,59} and for monitoring baculovirus gene expression in insects.^{60,61} Chemiluminescent techniques are virtually background-free, making the *luc* reporter gene ideal for detecting low-level gene expression.⁶²

Luciferin

The substrate for firefly luciferase, D-(–)-2-(6'-hydroxy-2'-benzothiazolyl)thiazoline-4-carboxylic acid, commonly known as luciferin, was first isolated by Bitler and McElroy.⁶³ In the firefly, spent luciferin (oxyluciferin) is recycled back to luciferin.⁶⁴ We prepare synthetic luciferin (L2911) and its water-soluble sodium (L2912) and potassium (L2916) salts. The physical properties of these derivatives are identical to those of the natural compound. Typically, luciferase expression is measured by adding the substrates ATP and luciferin to cell lysates and then analyzing light production with a luminometer. As little as 0.02 pg (250,000 molecules) of luciferase can be reliably measured using a standard scintillation counter.⁶⁵ Moreover, a CCD-based imaging method of detecting *luc* gene expression in single cells has been developed.⁶⁶

NovaBright™ β-Galactosidase and Firefly Luciferase Dual Enzyme Reporter Gene Chemiluminescent Detection Kit

The NovaBright™ β-Galactosidase and Firefly Luciferase Dual Enzyme Reporter Gene Chemiluminescent Detection Kit (200 assays, N10561; 600 assays, N10562) allows rapid and sensitive sequential detection of firefly luciferase and β-galactosidase, enabling experimental and control reporter gene enzymes to be measured in the same cell extract sample.⁶⁷

This kit employs the chemiluminescent luciferase substrate luciferin and the chemiluminescent β-galactosidase substrate Galacton-Plus for the detection of 1 fg to 20 ng and 10 fg to 20 ng of purified luciferase and β-galactosidase, respectively. Cell lysate is mixed with assay buffer for the luciferase reaction, and the luciferase signal is measured immediately after the injection of substrate dilution buffer, which contains both luciferin and Galacton-Plus substrates. The enhanced luciferase reaction produces a light signal that decays with a half-life of approximately 1 minute. Light signal from the β-galactosidase reaction is negligible due to lack of enzyme turnover time, low pH (7.8) and absence

of enhancer. After a 30–60 minute incubation, light signal from the accumulated product of the β -galactosidase/Galacton-Plus reaction is initiated by adding the accelerator, which raises the pH and provides the Sapphire™-II luminescence enhancer to increase light intensity. Light emission from the β -galactosidase reaction exhibits glow kinetics with a half-life of 180 minutes. Residual light from the luciferase reaction is minimal, due to rapid kinetic signal decay and quenching by accelerator. Generally, only very high luciferase concentrations (ng levels of enzyme) interfere with detection of β -galactosidase. A longer delay after the addition of accelerator prior to measurement results in decreased residual luciferase signal when extremely high levels are present. It is important, however, to maintain consistent timing for the addition of substrate dilution buffer and the measurement of the β -galactosidase signal after adding accelerator.

Each NovaBright™ β -Galactosidase and Firefly Luciferase Dual Enzyme Reporter Gene Chemiluminescent Detection Kit provides:

- Lysis buffer
- Assay buffer
- Substrate dilution buffer
- Galacton-Plus substrate
- Accelerator
- Detailed protocols

Chemiluminescent 1,2-dioxetane substrates for β -galactosidase, including the Galacton-Plus substrate described here and the Galacton-Star® substrate provided in the NovaBright™ β -Galactosidase Enzyme Reporter Gene Chemiluminescent Detection Kits (N10563, N10564, N10565, N10566; Section 10.2) permit highly sensitive enzyme detection and have been utilized extensively in reporter assays in mammalian cell and tissue extracts.

Luciferin–Luciferase Assays for ATP, Anesthetics and Hormones

Luciferin has been used in an exquisitely sensitive and specific ATP assay,^{68,69} which allows the detection of femtomolar quantities of ATP.⁷⁰ This bioluminescent ATP assay has been employed to determine cell proliferation and cytotoxicity in both bacteria^{71,72} and mammalian cells.^{73,74} We provide all the reagents needed for this important assay in the ATP Determination Kit (A22066, Section 10.3). Researchers have also adapted the luciferin–luciferase ATP assay system for detecting single base changes in a solid-phase DNA sequencing method.⁷⁵ In addition, amphipathic and hydrophobic substances, including certain anesthetics and hormones, compete with luciferin for the hydrophobic site on the luciferase molecule, providing a convenient method to assay subnanomolar concentrations of these substances.⁷⁶ A protein A–luciferase fusion protein has been developed that can be used in bioluminescence-based immunoassays.^{77,78}

Figure 10.6.3 Reaction scheme for bioluminescence generation via luciferase-catalyzed conversion of luciferin (L2911, L2912, L2916) to oxyluciferin.

Caged Luciferin

Although luciferase activity is sometimes measured in live cells,^{66,79} *in vivo* quantitation appears to be limited by the difficulty in delivering luciferin into intact cells.⁸⁰ Molecular Probes® DMNPE-caged luciferin (L7085) readily crosses cell membranes. Once the caged luciferin is inside the cell, active luciferin can be released either instantaneously by a flash of UV light or continuously by the action of endogenous intracellular esterases, which are found in many cell types. This probe facilitates *in vivo* luciferase assays in two important ways. First, caged luciferin improves the sensitivity and quantitative analysis of these assays by allowing more efficient delivery of luciferin into intact cells. Second, hydrolysis by intracellular esterases provides a continuous supply of active luciferin, permitting long-term measurements and reducing the need for rapid mixing protocols and costly injection devices. Moreover, DMNPE-caged luciferin may make it easier to follow dynamic changes in gene expression in live cells. We also offer DMNPE-caged ATP (A1049, Section 5.3), which can be used in conjunction with DMNPE-caged luciferin for *in vivo* luciferase assays.⁸¹

Coelenterazines for *Renilla* Luciferase

Coelenterazine and its analogs are substrates for the bioluminescent *Renilla* luciferase.^{82,83} We offer coelenterazine (C2944) and several synthetic coelenterazine analogs, including coelenterazine *cp*, *f* and *h* (C14260, C6779, C6780; Section 19.5; Table 19.4). Luciferin and coelenterazine have been used together for dual detection of firefly and *Renilla* luciferases in live mice.⁸⁴ Coelenterazine analogs have been characterized for their effectiveness in measuring *Renilla* luciferase in both live cells and live animals.⁸⁵

β -Lactamases

Fluorocillin™ Green 495/525 β -Lactamase Substrate

Fluorocillin™ Green 495/525 substrate (F33952) is a robust reporter for ELISA protocols that employ TEM-1 β -lactamase conjugates. Upon cleavage, Fluorocillin™ Green 495/525 reagent is converted to a green-fluorescent soluble product (excitation/emission maxima ~495/525 nm). Fluorocillin™ Green 495/525 reagent has a broad dynamic range of fluorescence signal, is more sensitive than common colorimetric substrates such as nitrocefin and displays only modest hydrolysis when incubated for extended periods from pH 5.5 to 8.0. Additionally, Fluorocillin™ Green 495/525 reagent consistently reports β -lactamase activity in the presence of EDTA, many detergents, salts and sodium azide. Fluorocillin™ Green 495/525 reagent is available as a dry powder, packaged in five vials each containing 100 μ g (F33952), and as a component of the SensiFlex™ ELISA Development Kits (S33853, S33854; Section 7.2).

Figure 10.6.4 Detection of dead and dying cells using the Vybrant® Cytotoxicity Assay Kit (V23111). Jurkat cells were treated with 10 μM camptothecin for 6 hours, then assayed for glucose 6-phosphate dehydrogenase release. An untreated control sample is shown for comparison. The fluorescence was measured in a microplate reader (excitation/emission ~530/590 nm). A background of 55 fluorescence units was subtracted from each value.

Figure 10.6.5 6-Chloro-9-nitro-5-oxo-5H-benzoaphenoxazine (CNOB, C22220).

Fluorocillin™ Green 345/530 β-Lactamase Substrate

Fluorocillin™ Green 345/530 β-lactamase substrate (F33951) was developed as a precipitating dye generally compatible with a variety of β-lactamase enzymes and corresponding antibody conjugates. We have demonstrated the utility of this reagent in immunohistochemistry applications, and it may also prove useful as a marker for endogenous β-lactamase activity in prokaryotes, possibly detected by microscopy or even flow cytometry. It is important to note, however, that in its precipitated form, Fluorocillin™ Green 345/530 β-lactamase substrate produces a crystal size incompatible with immunocytochemical analysis. This form of β-lactamase substrate is also incompatible with TEM-1 β-lactamase and its conjugates, but can, for example, be cleaved by P99 β-lactamase.

Dehydrogenases

Resazurin (R12204), which under the name alamarBlue® dye has been reported to be useful for quantitatively measuring cell-mediated cytotoxicity,² cell proliferation^{3,4} and mitochondrial metabolic activity in isolated neural tissue, is also a useful substrate for measuring the dehydrogenase activity or a wide variety of dehydrogenase enzymes *in vitro*.

Among the assays reported are the use of resazurin to detect:

- Argininosuccinate lyase and NADPH by a coupled diaphorase–resazurin reaction sequence⁸⁶
- Bile acids in human urine, feces and serum using NAD⁺ 3α-hydroxysteroid dehydrogenase^{87–91}
- Glucose 6-phosphate dehydrogenase (G6PD) activity⁹²
- NADH and bile acids with NADH oxidoreductase^{93,94}
- Serum formate using formate dehydrogenase and NAD⁺⁹⁵
- Triacylglycerols with glycerol dehydrogenase⁹⁶
- Urinary acylcarnitines in an immobilized enzyme reactor^{97,98}

Our Vybrant® Cytotoxicity Assay Kit (V23111, Section 15.3) employs the resazurin dehydrogenase substrate to monitor the release of G6PD from the cytosol of damaged cells into the surrounding medium (Figure 10.6.4); this method, however, also provides an extremely sensitive and specific assay for G6PD in cell-free extracts. The dehydrogenase substrate in our Vybrant® Cell Metabolic Assay Kit and LIVE/DEAD® Cell Vitality Assay Kit (V23110, L34951; Section 15.3) is dodecylresazurin, a more lipophilic version of resazurin. Because this substrate readily penetrates the membranes of live cells and its fluorescent reduction product (dodecylresorufin) is better retained in cells, it is preferred for both microscopy and flow cytometry assays.

Nitroreductase and Nitrate Reductase

We have developed a unique fluorogenic substrate that can detect the enzymatic activity of certain enzymes that reduce nitro compounds to amines or inorganic nitrate to nitrite. 6-Chloro-9-nitro-5-oxo-5H-benzoaphenoxazine (CNOB, C22220; Figure 10.6.5) is reduced to an aminophenoxazine dye that absorbs maximally at ~620 nm and has an emission maximum near 630 nm. We have shown that CNOB is a good substrate for at least some bacterial nitroreductases but apparently is not a good substrate for a mammalian nitroreductase. The utility of CNOB for detection of nitroreductase activity or detection of hypoxia in tumor cells has not yet been tested; however, it is known that some nitroimidazoles and other nitroaromatic compounds are reduced to amines under highly reducing conditions.⁹⁹

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Enzymatic reduction of C22220 yields a fluorescent aminobenzophenoxazine derivative (Abs = 617 nm, Em = 625 nm).
- Acetylation by chloramphenicol acetyltransferase (CAT) yields a mixture of 1-acetyl-, 3-acetyl- and 1,3-diacetyl chloramphenicol derivatives. Spectroscopic properties of these products are similar to the substrate.
- Data represent the substrate component of this kit.
- Acetylation by chloramphenicol acetyltransferase (CAT) yields a 3-acetyl-1-deoxychloramphenicol derivative with similar spectroscopic properties to the substrate.
- ATP-dependent oxidation of luciferin by luciferase results in bioluminescence (Em = 560 nm) at neutral and alkaline pH. Bioluminescence is red-shifted (Em = 617 nm) under acidic conditions. (J Am Chem Soc (1966) 88:2015)
- All photoactivatable probes are sensitive to light. They should be protected from illumination except when photolysis is intended.
- L7085 is converted to bioluminescent luciferin (L2911) upon ultraviolet photoactivation.
- Enzymatic cleavage of this substrate yields 7-hydroxycoumarin (umbelliferone), which has similar spectroscopic properties to H189.

PRODUCT LIST 10.6 SUBSTRATES FOR MICROSOMAL DEALKYLASES, ACETYLTRANSFERASES, LUCIFERASES AND OTHER ENZYMES

Cat. No.	Product	Quantity
R441	benzyloxoresorufin (resorufin benzyl ether)	10 mg
C22220	6-chloro-9-nitro-5-oxo-5H-benzoaphenoxazine (CNOB)	1 mg
C2944	coelenterazine	250 µg
C14260	coelenterazine <i>cp</i>	250 µg
C6779	coelenterazine <i>f</i>	250 µg
C6780	coelenterazine <i>h</i>	250 µg
C684	3-cyano-7-ethoxycoumarin	10 mg
D12200	6,8-difluoro-4-methylumbelliferyl octanoate (DiFMU octanoate)	10 mg
E33956	EnzChek® epoxide hydrolase substrate	100 µg
E33955	EnzChek® lipase substrate *green fluorescent, 505/515*	100 µg
R352	ethoxyresorufin (resorufin ethyl ether)	5 mg
E2882	7-ethoxy-4-trifluoromethylcoumarin	25 mg
F2900	FAST CAT® Chloramphenicol Acetyltransferase Assay Kit *100 assays*	1 kit
F6616	FAST CAT® Green (deoxy) Chloramphenicol Acetyltransferase Assay Kit *100 assays*	1 kit
F6617	FAST CAT® Yellow (deoxy) Chloramphenicol Acetyltransferase Assay Kit *100 assays*	1 kit
F33951	Fluorocillin™ Green 345/530 β-lactamase substrate *precipitating product*	5 mg
F33952	Fluorocillin™ Green 495/525 β-lactamase substrate *soluble product*	5 x 100 µg
L7085	D-luciferin, 1-(4,5-dimethoxy-2-nitrophenyl)ethyl ester (DMNPE-caged luciferin)	5 mg
L2911	D-luciferin, free acid	25 mg
L2916	D-luciferin, potassium salt	25 mg
L2912	D-luciferin, sodium salt	25 mg
N10561	NovaBright™ β-galactosidase and Firefly Luciferase Dual Enzyme Reporter Gene Chemiluminescent Detection Kit *200 assays*	1 kit
N10562	NovaBright™ β-galactosidase and Firefly Luciferase Dual Enzyme Reporter Gene Chemiluminescent Detection Kit *600 assays*	1 kit
R1147	pentoxyresorufin (resorufin pentyl ether)	5 mg
P35901	O-pivaloyloxymethyl umbelliferone (C-POM) *lipase substrate* *special packaging*	5 x 100 µg
R12204	resazurin, sodium salt	10 mg

CHAPTER 11

Probes for Cytoskeletal Proteins

11.1 Probes for Actin	479
Fluorescent Actin	479
Alexa Fluor® Actin and Unlabeled Actin	479
GFP- and RFP-Labeled Actin	479
CellLight® Null Control Reagent	480
Phallotoxins for Labeling F-Actin	480
Properties of Phallotoxin Derivatives	482
Alexa Fluor® Phalloidins	482
Oregon Green® Phalloidins	483
BODIPY® Phallotoxins	484
Rhodamine Phalloidin and Other Red-Fluorescent Phalloidins	484
Other Labeled Phallotoxins	484
DNase I Conjugates for Staining G-Actin	484
Probes for Actin Quantitation, Actin Polymerization and Actin-Binding Proteins	485
Assays for Quantitating F-Actin and G-Actin Polymerization	485
Jasplakinolide: A Cell-Permeant F-Actin Probe	486
Latrunculin A and Latrunculin B: Cell-Permeant Actin Antagonists	486
Assays for Actin-Binding Proteins	486
Data Table 11.1 Probes for Actin	487
Product List 11.1 Probes for Actin	488
11.2 Probes for Tubulin and Other Cytoskeletal Proteins	489
Paclitaxel Probes	489
Paclitaxel	489
TubulinTracker™ Green Reagent	489
Fluorescent Paclitaxel Conjugates	489
Tubulin-Selective Probes	490
GFP- and RFP-Labeled Tubulin and MAP4	490
Anti- α -Tubulin Monoclonal Antibody	491
BODIPY® FL Vinblastine	492
Other Probes for Tubulin	492
Probes for Other Cytoskeletal Proteins	492
GFP- and RFP-Labeled Talin	492
Anti-Glial Fibrillary Acidic Protein (GFAP) Antibody	492
Anti-Desmin Antibody	493
Anti-Synapsin I Antibody	493
Data Table 11.2 Probes for Tubulin and Other Cytoskeletal Proteins	494
Product List 11.2 Probes for Tubulin and Other Cytoskeletal Proteins	494

Rhodamine Red™ goat anti-rabbit IgG, Alexa Fluor® 488 goat anti-mouse IgG and Hoechst 33258.

11.1 Probes for Actin

The cytoskeleton is an essential component of a cell's structure and one of the easiest to label with fluorescent reagents. This section describes Molecular Probes® labeling reagents for both monomeric actin (G-actin) and filamentous actin (F-actin); reagents for staining tubulin and other cytoskeletal proteins are described in Section 11.2.

Fluorescent Actin

Alexa Fluor® Actin and Unlabeled Actin

Fluorescently labeled actin (Figure 11.1.1) is an important tool for investigating the structural dynamics of the cytoskeleton.¹⁻³ We offer highly purified actin from rabbit muscle (A12375), as well as fluorescent actin conjugates labeled with four of our brightest and most photostable dyes. The green-fluorescent Alexa Fluor® 488 actin conjugate (A12373) has excitation and emission maxima similar to fluorescein actin, but it is brighter and more photostable, and its spectra are much less pH dependent. The red-orange-fluorescent Alexa Fluor® 568 (A12374, Figure 11.1.2), red-fluorescent Alexa Fluor® 594 (A34050) and far-red-fluorescent Alexa Fluor® 647 (A34051) actin conjugates are more fluorescent than the spectrally similar Lissamine rhodamine B, Texas Red® and Cy5 conjugates, respectively.

Our fluorescent actin conjugates are prepared by reacting amine residues of polymerized F-actin with the succinimidyl ester of the appropriate dye using a modification of the method described by Alberts and co-workers.⁴ After labeling, the conjugates are subjected to depolymerization and subsequent polymerization to help ensure that the actin conjugates are able to assemble properly. The labeled actin that polymerizes is then separated from remaining monomeric actin by centrifugation, depolymerized and packaged in monomeric form.

GFP- and RFP-Labeled Actin

The requirement for intracellular delivery of Alexa Fluor® dye-labeled actin conjugates by microinjection typically limits their applications for live-cell imaging to experiments involving no more than a few (<10) cells. For applications such as high-content screening (HCS) assays requiring larger sample sizes, GFP-actin fusions are well-established probes for imaging cytoskeletal structure and dynamics.⁵ CellLight® Actin-GFP (C10582) and CellLight® Actin-RFP (C10583, Figure 11.1.3)

Figure 11.1.3 HeLa cell labeled with CellLight® Actin-RFP (C10583) and CellLight® MAP4-GFP (C10598) reagents and with Hoechst 33342 nucleic acid stain.

Figure 11.1.1 Ribbon diagram of the structure of uncomplexed actin in the ADP state. The four subdomains are represented in different colors, and ADP is bound at the center where the four subdomains meet. Four Ca^{2+} ions bound to the actin monomer are represented as gold spheres. In this structure, tetramethylrhodamine-5-maleimide (T6027) has been used to covalently attach the dye to a specific cysteine residue (Cys 374). Image provided by Roberto Dominguez, Boston Biomedical Research Institute, Watertown, Massachusetts. Reprinted with permission from Science (2001) 293:708. Copyright 2001 American Association for the Advancement of Science.

Figure 11.1.2 Chick embryo fibroblasts injected with the Alexa Fluor® 568 conjugate of actin from rabbit muscle (A12374). The cells were then fixed and permeabilized, and the filamentous actin was stained with coumarin phalloidin (C606). The double-exposure image was acquired using longpass filter sets appropriate for rhodamine and DAPI. Image contributed by Heiti Paves, Laboratory of Molecular Genetics, National Institute of Chemical Physics and Biophysics, Estonia.

expression vectors (Table 11.1) generate autofluorescent proteins fused to the N-terminus of human β -actin and incorporate all the generic advantages of BacMam 2.0 delivery technology (BacMam Gene Delivery and Expression Technology—Note 11.1). In particular, the viral dose can be readily adjusted to modulate expression levels if GFP- or RFP-dependent perturbation of cellular structural or functional properties is a concern.

CellLight® Null Control Reagent

The CellLight® Null (control) reagent (C10615), a suspension of baculovirus particles lacking mammalian genetic elements, is designed for use in parallel with our CellLight® reagents (Table 11.1). For example, microarray expression analysis on cells treated with the CellLight® Null (control) reagent can be used to assess down-regulation or up-regulation of host cell genes elicited by baculovirus infection.

Table 11.1 CellLight® reagents and their targeting sequences.

Target	Targeting Sequence	Ref	GFP (489/508 nm)*	RFP (555/584 nm)*	Handbook Section
Actin	Human actin	1	C10582	C10583	11.1
Tubulin	Human tubulin	2	C10613	C10614	11.2

Phallotoxins for Labeling F-Actin

We prepare a number of fluorescent and biotinylated derivatives of phalloidin and phalloidin for selectively labeling F-actin. Phallotoxins are bicyclic peptides isolated from the deadly *Amanita phalloides* mushroom⁶ (www.grzyby.pl/gatunki/Amanita_phalloides.htm). They can be used interchangeably in most applications and bind competitively to the same sites on F-actin. Table 11.2 lists the available phalloxin derivatives, along with their spectral properties.

A detailed staining protocol is included with each phalloxin derivative. One vial of the fluorescent phalloxin contains sufficient reagent for staining ~300 microscope slide preparations; one vial of biotin-XX phalloidin, which must be used at a higher concentration, contains sufficient reagent for ~50 microscope slide preparations. We also offer unlabeled phalloidin (P3457) for blocking F-actin staining by labeled phallotoxins and for promoting actin polymerization.

Table 11.2 Spectral characteristics of Molecular Probes® actin-selective probes.

Cat. No.	Actin-Selective Probe	Ex/Em *	Approximate MW

NOTE 11.1**BacMam Gene Delivery and Expression Technology****Baculovirus-Mediated Transduction of Mammalian Cells**

BacMam technology uses a modified insect cell baculovirus as a vehicle to efficiently deliver and express genes in mammalian cells with minimum effort and toxicity.¹⁻⁴ We have combined the BacMam gene delivery and expression system with genetically encoded Premo™ sensors as well as with genetically encoded CellLight® targeted fluorescent proteins to yield robust and easy-to-use cell-based assays (Figure 1).

BacMam particles carrying the biosensor or targeted fluorescent protein cDNA under the control of the CMV promoter are taken up by endocytosis. The viral DNA traffics to the nucleus where only the CMV promoter-driven gene is transcribed; baculovirus promoters are not recognized by the mammalian transcriptional machinery. Following transcription, the biosensor or targeted fluorescent protein mRNA is expressed in the cytosol and cells are soon ready to assay. This process begins within 4–6 hours after transduction and in many cell types is completed after an overnight period.

BacMam 2.0 vectors incorporated in our CellLight® reagents extend the applicability of BacMam-mediated transgene delivery and expression. Cells such as primary neurons that were not amenable to BacMam transduction with version 1.0 (used in the corresponding Organelle Lights™ and Cellular Lights™ reagents) can now be transduced quantitatively in a simple, one-step process. The improved performance is due to inclusion of a pseudotyped capsid protein for more efficient cell entry as well as genetic elements (enhanced CMV promoter and Woodchuck Post-Transcriptional Regulatory Element) that boost expression levels.

Inducible, division-arrested or transient expression systems such as the BacMam system are increasingly methods of choice to decrease variability of expression in cell-based assays. Constitutively expressed ion channels and other cell-surface proteins have been shown to contribute to cell toxicity in some systems, and they may also be subject to clonal drift and other inconsistencies that hamper successful experimentation and screening. Moreover, the BacMam gene delivery and expression system provides a method for simultaneously delivering multiple genes per cell, an important feature when expressing multisubunit proteins.¹

Advantages of the BacMam Delivery and Expression System

Baculoviruses have been used extensively for protein production in insect cells for over two decades; however, its use with mammalian cells is relatively new. BacMam technology has opened up new avenues for mammalian cell-based assays in drug discovery applications.^{3,5} In addition to producing ready-to-use viral stocks, BacMam delivery and expression

technology has many advantages when compared with lipids and other viral delivery methods:

- High transduction efficiency across a broad range of cell types, including primary and stem cells
- Minimal microscopically observable cytopathic effects
- Highly reproducible and titratable transient expression
- Biosafety level 1 rating (baculovirus is not pathogenic to vertebrates and does not replicate in mammalian cells)
- Ability to simultaneously deliver multiple genes

Furthermore, it is possible to divide the BacMam-transduced, homogeneous cell population into aliquots that can be stored frozen for use at a later time, approximating the consistency of a stable cell line in a transient expression format. More information is available at www.invitrogen.com/handbook/bacmam2.0.

Figure 1 Schematic representation of BacMam transgene delivery and expression as exemplified by Premo™ Halide Sensor (P10229).

Figure 11.1.4 Microtubules of fixed bovine pulmonary artery endothelial cells localized with mouse monoclonal anti- α -tubulin antibody (A11126), which was subsequently visualized with Alexa Fluor[®] 350 goat anti-mouse IgG antibody (A11045). Next, the F-actin was labeled with Alexa Fluor[®] 594 phalloidin (A12381). Finally, the cells were incubated with Alexa Fluor[®] 488 wheat germ agglutinin (W11261) to stain components of endosomal pathways. The superimposed and pseudocolored images were acquired sequentially using bandpass filter sets appropriate for DAPI, the Texas Red[®] dye and fluorescein, respectively.

Properties of Phallotoxin Derivatives

The fluorescent and biotinylated phallotoxin derivatives stain F-actin selectively at nanomolar concentrations and are readily water soluble, thus providing convenient labels for identifying and quantitating actin in tissue sections, cell cultures or cell-free preparations.^{7–11} F-actin in live neurons can be efficiently labeled using cationic liposomes containing fluorescent phallotoxins, such as BODIPY[®] FL phalloidin¹² (B607). This procedure permits the labeling of entire cell cultures with minimum disruption. Because fluorescent phalloidin conjugates are not permeant to most live cells, they can be used to detect cells that have compromised membranes. However, it has been reported that unlabeled phalloidin, and potentially dye-labeled phalloidins, can penetrate the membranes of certain hypoxic cells.¹³ An extensive study on visualizing the actin cytoskeleton with various fluorescent probes in cell preparations, as well as in live cells, has been published.⁷

Labeled phallotoxins have similar affinity for both large and small filaments and bind in a stoichiometric ratio of about one phallotoxin per actin subunit in both muscle and nonmuscle cells; they reportedly do not bind to monomeric G-actin, unlike some antibodies against actin.^{9,14} Phallotoxins have further advantages over antibodies for actin labeling, in that 1) their binding properties do not change appreciably with actin from different species, including plants and animals; and 2) their nonspecific staining is negligible; thus, the contrast between stained and unstained areas is high.

Phallotoxins shift actin's monomer/polymer equilibrium toward the polymer, lowering the critical concentration for polymerization as much as 30-fold.^{15,16} Furthermore, depolymerization of F-actin by cytochalasins, potassium iodide and elevated temperatures is inhibited by phallotoxin binding. Because the phallotoxin derivatives are relatively small, with approximate diameters of 12–15 Å and molecular weights below 2000 daltons, a wide variety of actin-binding proteins—including myosin, tropomyosin, troponin and DNase I—can still bind to actin after treatment with fluorescent phallotoxins. Even more significantly, phallotoxin-labeled actin filaments retain certain functional characteristics; labeled glycerinated muscle fibers still contract, and labeled actin filaments still move on solid-phase myosin substrates.^{17–19}

Alexa Fluor[®] Phalloidins

We have taken advantage of the outstanding fluorescence characteristics of our Alexa Fluor[®] dyes (Section 1.3) to create a series of Alexa Fluor[®] dye-labeled phalloidins (Figure 11.1.4, Figure 11.1.5, Figure 11.1.6, Figure 11.1.7), which are widely used F-actin stains for many applications

Figure 11.1.5 Actin filaments of the turbellarian flatworm *Archimonotresis* sp. stained with Alexa Fluor[®] 488 phalloidin (A12379) to reveal a meshwork of longitudinal, circular and diagonal muscles. The large, bright ring with muscle fibers radiating outward is the muscular pharynx, and the small, bright ring at the posterior is part of the reproductive system. This epifluorescence image was contributed by Matthew D. Hooge and Seth Tyler, University of Maine, Orono.

Figure 11.1.6 Subcellular structures in fixed and permeabilized bovine pulmonary artery endothelial cells visualized with several fluorescent dyes. Filamentous actin (F-actin) was identified with Alexa Fluor[®] 633 phalloidin (A22284), which is pseudocolored magenta. Intracellular membranes were stained with green-fluorescent DiOC₂(3) (D273). Finally, nuclei were counterstained with blue-fluorescent DAPI (D1306, D3571, D21490). The image was acquired using filters appropriate for fluorescein and DAPI and a special filter (courtesy of Omega[®] Optical) for the Alexa Fluor[®] 633 dye, consisting of a narrow band exciter (630DF10), dichroic (640DRLP) and emitter (660DF10).

Figure 11.1.7 FluoCells[®] prepared slide #4 (F24631) contains a section of mouse intestine stained with a combination of fluorescent stains. Alexa Fluor[®] 350 wheat germ agglutinin (W11263) is a blue-fluorescent lectin that was used to stain the mucus of goblet cells. The filamentous actin prevalent in the brush border was stained with red-orange-fluorescent Alexa Fluor[®] 568 phalloidin (A12380). Finally, the nuclei were stained with SYTOX[®] Green nucleic acid stain (S7020). This image is a composite of three digitized images obtained with filter sets appropriate for fluorescein, DAPI and tetramethylrhodamine.

across the full spectral range. The Alexa Fluor® phalloidin conjugates (Figure 11.1.8) provide researchers with fluorescent probes that are superior in brightness and photostability to other spectrally similar conjugates tested (Figure 11.1.9). For improved fluorescence detection of F-actin in fixed and permeabilized cells, we encourage researchers to try these fluorescent phalloidins in their actin-labeling protocols. A series of videos showing Alexa Fluor® 488 phalloidin-stained actin²⁰ is available at the *Journal of Cell Biology* web site (www.jcb.org/cgi/content/full/150/2/361/DC1).

Oregon Green® Phalloidins

Green-fluorescent actin stains are popular reagents for labeling F-actin in fixed and permeabilized cells. Unfortunately, the green-fluorescent fluorescein phalloidin and NBD phalloidin photobleach

rapidly, making their photography difficult. We have used two of our Oregon Green® dyes (Section 1.5) to prepare Oregon Green® 488 phalloidin (O7466, Figure 11.1.10) and the slightly longer-wavelength Oregon Green® 514 phalloidin (O7465). The excitation and emission spectra of the Oregon Green® 488 dye are virtually superimposable on those of fluorescein, and both the Oregon Green® 488 and Oregon Green® 514 dyes may be viewed with standard fluorescein optical filter sets. As shown in Figure 11.1.11, Oregon Green® 514 phalloidin is more photostable than fluorescein phalloidin, making it easier to visualize and photograph.

Figure 11.1.8 Alexa Fluor® 488 phalloidin (A12379).

Figure 11.1.10 Simultaneous visualization of F- and G-actin in a bovine pulmonary artery endothelial cell (BPAEC) using F-actin-specific Oregon Green® 488 phalloidin (O7466) and G-actin-specific Texas Red® deoxyribonuclease I. The G-actin appears as diffuse red fluorescence that is more intense in the nuclear region where the cell thickness is greater and stress fibers are less dense. The image was obtained by taking multiple exposures through bandpass optical filter sets appropriate for fluorescein and the Texas Red® dye.

Figure 11.1.9 Comparison of the photobleaching rates of the Alexa Fluor® 488 and Alexa Fluor® 546 dyes and the well-known fluorescein and Cy®3 fluorophores. The cytoskeleton of bovine pulmonary artery endothelial cells (BPAEC) was labeled with (top series) Alexa Fluor® 488 phalloidin (A12379) and mouse monoclonal anti- α -tubulin antibody (A11126) in combination with Alexa Fluor® 546 goat anti-mouse IgG antibody (A11003) or (bottom series) fluorescein phalloidin (F432) and the anti- α -tubulin antibody in combination with a commercially available Cy®3 goat anti-mouse IgG antibody. The pseudocolored images were taken at 30-second intervals (0, 30, 90 and 210 seconds of exposure). The images were acquired with bandpass filter sets appropriate for fluorescein and rhodamine.

Figure 11.1.11 Photostability comparison for Oregon Green® 514 phalloidin (O7465) and fluorescein phalloidin (F432). CRE BAG 2 fibroblasts were fixed with formaldehyde, permeabilized with acetone and then stained with the fluorescent phallotoxins. Samples were continuously illuminated and images were acquired every 5 seconds using a Star 1 CCD camera (Photometrics); the average fluorescence intensity in the field of view was calculated with Image-1 software (Universal Imaging Corp.) and expressed as a fraction of the initial intensity. Three data sets, representing different fields of view, were averaged for each labeled phalloidin to obtain the plotted time courses.

Figure 11.1.12 Permeabilized bovine pulmonary artery endothelial cells stained with SYTOX[®] Green nucleic acid stain (S7020) to label the nuclei and with BODIPY[®] TR-X phalloidin (B7464) to label the F-actin. The image was acquired by taking sequential exposures through bandpass optical filter sets appropriate for fluorescein and the Texas Red[®] dye.

Figure 11.1.13 Actin labeled with BODIPY[®] FL phalloidin (B607) and vinculin, a cytoskeletal focal adhesion protein, tagged with a monoclonal anti-vinculin antibody that was subsequently probed with Texas Red[®] goat anti-mouse IgG antibody (T862). The large triangular cell is a fibroblast containing green actin stress fibers terminating in red focal adhesions. The neighboring polygonal cell, a rat neonatal cardiomyocyte, contains green striated actin in the myofibrils terminating in the focal adhesions. The close apposition of the two stains results in a yellowish-orange color. Image contributed by Mark B. Snuggs and W. Barry VanWinkle, University of Texas, Houston.

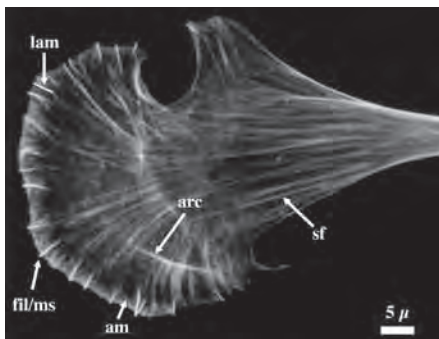

Figure 11.1.14 Actin filaments of chick heart fibroblasts stained with rhodamine phalloidin (R415). The subcompartments in the cytoskeleton are readily apparent and labeled as follows: *sf*, stress fiber; *lam*, lamellipodium; *fil/ms*, filopodium/microspike; *am*, actin meshwork; *arc*, dorsal arc. Figure reprinted from "Visualizing the Actin Cytoskeleton." J. Small *et al.* *Microscopy Research and Technique* (1999) 47:3. BODIPY[®] Phallotoxins

BODIPY[®] phalloxin conjugates (B607, B3475, B12382; Figure 11.1.12, Figure 11.1.13) have some important advantages over the conventional NBD, fluorescein and rhodamine phallotoxins. BODIPY[®] dyes are more photostable than these traditional fluorophores²¹ and have narrower emission bandwidths (Section 1.4), making them especially useful for double- and triple-labeling experiments. BODIPY[®] FL phalloidin (B607), which reportedly gives a signal superior to that of fluorescein phalloidin,²² has been used for quantitating F-actin and determining its distribution in cells.^{23,24}

The BODIPY[®] FL and BODIPY[®] 558/568 phallotoxins (B607, B3475) exhibit excitation and emission spectra similar to those of fluorescein and rhodamine B, respectively, and can be used with standard optical filter sets. BODIPY[®] 650/665 phalloidin (B12382) is the longest-wavelength BODIPY[®] phalloxin conjugate available, increasing the options for multicolor analysis. BODIPY[®] 650/665 phalloidin, Alexa Fluor[®] 647 phalloidin (A22287) and Alexa Fluor[®] 660 phalloidin (A22285) are among the few probes available that can be excited by the 647 nm spectral line of the Ar-Kr laser.

Rhodamine Phalloidin and Other Red-Fluorescent Phalloidins

Rhodamine phalloidin (R415, Figure 11.1.14) has been the standard for red-fluorescent phallotoxins.^{25–27} Rhodamine phalloidin is excited efficiently by the mercury-arc lamp in most fluorescence microscopes. However, our Alexa Fluor[®] 546, Alexa Fluor[®] 568, Alexa Fluor[®] 594 and Texas Red[®]-X phalloidins²⁸ (A22283, A12380, A12381, T7471; Figure 11.1.15, Figure 11.1.16) will be welcome replacements for rhodamine phalloidin in many multicolor applications because their emission spectra are better separated from those of the green-fluorescent Alexa Fluor[®] 488, Oregon Green[®] and fluorescein dyes.

Other Labeled Phallotoxins

The original yellow-green-fluorescent NBD phalloidin (N354) and green-fluorescent fluorescein phalloidin (F432) remain in use despite their relatively poor photostability (Figure 11.1.11). Photostability of fluorescein phalloidin and some other fluorescent phallotoxins can be considerably improved (Figure 11.1.17) by mounting the stained samples with our ProLong[®] Antifade Kit or ProLong[®] Gold antifade reagent (P7481, P36930, P36934; Section 23.1). We recommend the Alexa Fluor[®] 488, Oregon Green[®] 488, Oregon Green[®] 514 and BODIPY[®] FL phallotoxins for photostable, green-fluorescent actin staining. Alexa Fluor[®] 350 phalloidin (A22281) and coumarin phalloidin (C606, Figure 11.1.2) are the only blue-fluorescent phalloxin conjugates currently available for staining actin.²⁹

Biotin-XX phalloidin (B7474) permits detection of F-actin by electron microscopy and light microscopy techniques.³⁰ This biotin conjugate can be visualized with fluorophore- or enzyme-labeled avidin and streptavidin (Section 7.6) or with tyramide signal amplification (TSA[™]) technology (Section 6.2). Biotin-XX phalloidin, in conjunction with streptavidin or CaptAvidin[™] agarose (S951, C21386; Section 7.6), can be used to precipitate F-actin from the cytosolic anti-phosphotyrosine-reactive fraction in macrophages stimulated with colony-stimulating factor-1.³¹

DNase I Conjugates for Staining G-Actin

Bovine pancreatic deoxyribonuclease (DNase I, ~31,000 daltons) binds much more strongly to monomeric G-actin than to filamentous F-actin, with binding constants of $5 \times 10^8 \text{ M}^{-1}$ and $1.2 \times 10^4 \text{ M}^{-1}$, respectively.^{32–35} Because of this strong, selective binding to G-actin, fluorescent DNase I conjugates have proven very useful for detecting and quantitating the proportion of unpolymerized actin in a cell. We have triple-labeled endothelial cells with fluorescein DNase I, BODIPY[®] 581/591 phalloidin and a monoclonal anti-actin antibody detected with a Cascade Blue[®] dye-labeled secondary antibody³⁶ (C962, Section 7.2). We found that the monoclonal antibody, which binds to both G-actin and F-actin, colocalized with the DNase I and phalloidin conjugates, suggesting that these three probes recognize unique binding sites on the actin molecule. Researchers can choose DNase I conjugates labeled with either the green-fluorescent Alexa Fluor[®] 488 (D12371) or red-fluorescent Alexa Fluor[®] 594 (D12372) dyes, depending on their multicolor application and their detection instrumentation (Table 11.2).

Alexa Fluor® 488 and Alexa Fluor® 594 DNase I conjugates have been used in combination with fluorescently labeled phallotoxins to simultaneously visualize G-actin pools and filamentous F-actin^{37,38} and to study the disruption of microfilament organization in live nonmuscle cells.³⁹ Rhodamine phalloidin (R415) has been used in conjunction with Oregon Green® 488 DNase I to determine the F-actin:G-actin ratio in *Dictyostelium* using confocal laser-scanning microscopy.⁴⁰ A mouse fibroblast labeled with both Texas Red® DNase I and Oregon Green® 488 phalloidin (O7466) permitted visualization of the G-actin and the complex network of F-actin throughout the cytoplasm, as well as at the cell periphery (Figure 11.1.10). The influence of cytochalasins on actin structure in monocytes has been quantitated by flow cytometry using Texas Red® DNase I and BODIPY® FL phalloidin (B607) to stain the G-actin and F-actin pools, respectively.⁴¹ Fluorescent DNase I has also been used as a model system to study the interactions of nucleotides, cations and cytochalasin D with monomeric actin.⁴²

Probes for Actin Quantitation, Actin Polymerization and Actin-Binding Proteins

Assays for Quantitating F-Actin and G-Actin Polymerization

Quantitative assays for F-actin have employed fluorescein phalloidin,^{43,44} rhodamine phalloidin,⁴⁵ BODIPY® FL phalloidin²⁴ and NBD phalloidin.⁴⁶ An F-actin assay based on fluorescein phalloidin was used to demonstrate the loss of F-actin from cells during apoptosis.⁴⁷ The addition of propidium iodide (P1304MP, P3566, P21493; Section 8.1) to the cell suspensions enabled these researchers to estimate the cell-cycle distributions of both the apoptotic and nonapoptotic cell populations. The change in F-actin content in proliferating adherent cells has been quantitated using the ratio of rhodamine phalloidin fluorescence to ethidium bromide fluorescence.⁴⁸ The spectral separation of the signals in this assay may be improved by using a green-fluorescent stain for F-actin and a high-affinity red-fluorescent nucleic acid stain, such as the combination of Alexa Fluor® 488 phalloidin (A12379) and ethidium homodimer-1 (E1169, Section 8.1).

The fluorescence of actin monomers labeled with pyrene iodoacetamide (P29) has been demonstrated to change upon polymerization, making this probe an excellent tool for following the kinetics of actin polymerization and the effects of actin-binding proteins on polymerization.^{49–51}

Figure 11.17 Bovine pulmonary artery endothelial cells were labeled with fluorescein phalloidin (F432), which labels filamentous actin, and placed under constant illumination on the microscope with a FITC filter set using a 60x objective. Images were acquired at one-second intervals for 30 seconds. Under these illumination conditions, fluorescein photobleached to about 12% of its initial value in 30 seconds in PBS (left), but stayed at the initial value under the same illumination conditions when mounted using the reagents in the ProLong® Antifade Kit (right, P7481).

Figure 11.1.15 A section of mouse intestine stained with a combination of fluorescent stains. Fibronectin, an extracellular matrix adhesion molecule, was labeled using a chicken primary antibody against fibronectin and visualized using green-fluorescent Alexa Fluor® 488 goat anti-chicken IgG antibody (A11039). The filamentous actin (F-actin) prevalent in the brush border was stained with red-fluorescent Alexa Fluor® 568 phalloidin (A12380). Finally, the nuclei were stained with DAPI (D1306, D3571, D21490).

Figure 11.1.16 Confocal micrograph of the cytoskeleton of a mixed population of granule neurons and glial cells. The F-actin was stained with red-fluorescent Texas Red®-X phalloidin (T7471). The microtubules were detected with a mouse monoclonal anti-β-tubulin primary antibody and subsequently visualized with the green-fluorescent Alexa Fluor® 488 goat anti-mouse IgG antibody (A11001). The image was contributed by Jonathan Zmuda, Immunomatrix, Inc.

Figure 11.1.18 Jasplakinolide (J7473).

Figure 11.1.19 Latrunculin A (L12370).

Jasplakinolide: A Cell-Permeant F-Actin Probe

We offer jasplakinolide (J7473, Figure 11.1.18), a macrocyclic peptide isolated from the marine sponge *Jaspis johnstoni*.^{52–54} Jasplakinolide is a potent inducer of actin polymerization *in vitro* by stimulating actin filament nucleation^{55,56} and competes with phalloidin for actin binding⁵⁷ ($K_d = 15$ nM). Moreover, unlike other known actin stabilizers such as phalloidins and virotoxins, jasplakinolide appears to be somewhat cell permeant and therefore can potentially be used to manipulate actin polymerization in live cells. This peptide, which also exhibits fungicidal, insecticidal and antiproliferative activity,^{53,58–60} is particularly useful for investigating cell processes mediated by actin polymerization and depolymerization, including cell adhesion, locomotion, endocytosis and vesicle sorting and release. Jasplakinolide has been reported to enhance apoptosis induced by cytokine deprivation.⁶¹

Latrunculin A and Latrunculin B: Cell-Permeant Actin Antagonists

Latrunculins are powerful disruptors of microfilament organization. Isolated from a Red Sea sponge, these G-actin binding compounds inhibit fertilization and early embryological development,⁶² alter the shape of cells^{63,64} and inhibit receptor-mediated endocytosis.⁶⁵ Latrunculin A^{61,63,66} (L12370, Figure 11.1.19) binds to monomeric G-actin in a 1:1 ratio at submicromolar concentrations (Howard Petty, Wayne State University, personal communication) and is frequently used to establish the effects of F-actin disassembly on particular physiological functions such as ion transport⁶⁷ and protein localization.⁶⁸ The activity of latrunculin B (L22290) mimics that of latrunculin A in most applications.^{63,65,69–71}

Assays for Actin-Binding Proteins

Enhancement of the fluorescence of certain phallotoxins upon binding to F-actin can be a useful tool for following the kinetics and extent of binding of specific actin-binding proteins. We have used the change in fluorescence of rhodamine phalloidin (R415) to determine the dissociation constant of various phallotoxins.⁷² The enhancement of rhodamine phalloidin's fluorescence upon actin binding has also been used to measure the kinetics and extent of gelsolin severing of actin filaments.⁷³ The affinity and rate constants for rhodamine phalloidin binding to actin are not affected by saturation of actin with either myosin subfragment-1 or tropomyosin, indicating that these two actin-binding proteins do not bind to the same sites as the phalloidin.¹²

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. α -Bungarotoxin, EGF and phallotoxin conjugates have approximately 1 label per peptide.
2. Although this phallotoxin is water-soluble, storage in water is not recommended, particularly in dilute solution.
3. The value of EC listed for this phallotoxin conjugate is for the labeling dye in free solution. Use of this value for the conjugate assumes a 1:1 dye:peptide labeling ratio and no change of EC due to dye-peptide interactions.
4. In aqueous solutions (pH 7.0), Abs/Em = 625/645 nm for A22284, 633/648 nm for A34054, 649/666 nm for A22287, 661/689 nm for A22285 and 677/699 nm for A22286.
5. B7464 and B12382 are not directly soluble in H₂O. Aqueous dispersions can be prepared by dilution of a stock solution in MeOH.
6. Spectral data of the 2-mercaptoethanol adduct.
7. Iodoacetamides in solution undergo rapid photodecomposition to unreactive products. Minimize exposure to light prior to reaction.
8. This bicyclic peptide is very weakly fluorescent in aqueous solution (Em ~380 nm). (*Biochim Biophys Acta* (1983) 760:411)
9. In aqueous solutions (pH 7.0), Abs/Em = 554/573 nm for R415 and 591/608 nm for T7471.

PRODUCT LIST 11.1 PROBES FOR ACTIN

Cat. No.	Product	Quantity
A12375	actin from rabbit muscle	1 mg
A12373	actin from rabbit muscle, Alexa Fluor® 488 conjugate *in solution*	200 µg
A12374	actin from rabbit muscle, Alexa Fluor® 568 conjugate *in solution*	200 µg
A34050	actin from rabbit muscle, Alexa Fluor® 594 conjugate *in solution*	200 µg
A34051	actin from rabbit muscle, Alexa Fluor® 647 conjugate *in solution*	200 µg
A22281	Alexa Fluor® 350 phalloidin	300 U
A12379	Alexa Fluor® 488 phalloidin	300 U
A22282	Alexa Fluor® 532 phalloidin	300 U
A22283	Alexa Fluor® 546 phalloidin	300 U
A34055	Alexa Fluor® 555 phalloidin	300 U
A12380	Alexa Fluor® 568 phalloidin	300 U
A12381	Alexa Fluor® 594 phalloidin	300 U
A22284	Alexa Fluor® 633 phalloidin	300 U

B12382	BODIPY® 650/665 phalloidin	300 U
B607	BODIPY® FL phalloidin	300 U
C10582	CellLight® Actin-GFP *BacMam 2.0*	1 mL
C10583	CellLight® Actin-RFP *BacMam 2.0*	1 mL
C10615	CellLight® Null (control) *BacMam 2.0*	1 mL
C606	coumarin phalloidin	300 U
D12371	deoxyribonuclease I, Alexa Fluor® 488 conjugate	5 mg
D12372	deoxyribonuclease I, Alexa Fluor® 594 conjugate	5 mg
F432	fluorescein phalloidin	300 U
J7473	jasplakinolide	100 µg
L12370	latrunculin A	100 µg
L22290	latrunculin B	100 µg
N354	<i>N</i> -(7-nitrobenz-2-oxa-1,3-diazol-4-yl)phalloidin (NBD phalloidin)	300 U
O7466	Oregon Green® 488 phalloidin	300 U
O7465	Oregon Green® 514 phalloidin	300 U
P3457	phalloidin	1 mg
P29	<i>N</i> -(1-pyrene)iodoacetamide	100 mg
R415	rhodamine phalloidin	300 U
T7471	Texas Red®-X phalloidin	300 U

11.2 Probes for Tubulin and Other Cytoskeletal Proteins

Paclitaxel Probes

Paclitaxel

We offer paclitaxel (P3456) for *research purposes only* at a purity of >98% by HPLC. Paclitaxel, formerly referred to as taxol in some scientific literature, is the approved generic name for the anticancer pharmaceutical Taxol® (Bristol-Myers Squibb Co.). The diterpenoid paclitaxel is a potent anti-neoplastic agent^{1,2} originally isolated from the bark and needles of the western yew tree, *Taxus brevifolia*.^{3,4} The anti-mitotic and cytotoxic action of paclitaxel is related to its ability to promote tubulin assembly into stable aggregated structures that cannot be depolymerized by dilution, calcium ions, cold or a number of microtubule-disrupting drugs;⁵⁻⁷ paclitaxel also decreases the critical concentration of tubulin required for microtubule assembly. Cultured cells treated with paclitaxel are blocked in the G₂ (the "gap" between DNA synthesis and mitosis) and M (mitosis) phases of the cell cycle.⁸

TubulinTracker™ Green Reagent

TubulinTracker™ Green reagent (T34075) provides green-fluorescent staining of polymerized tubulin in live cells.⁹⁻¹¹ Also known as Oregon Green® 488 paclitaxel bis-acetate (a bi-acetylated version of Oregon Green® 488 paclitaxel (P22310), see below), TubulinTracker™ Green reagent is an uncharged, nonfluorescent compound (Figure 11.2.1) that easily passes through the plasma membrane of live cells. Once inside the cell, the lipophilic blocking group is cleaved by nonspecific esterases, resulting in a green-fluorescent, charged paclitaxel.

Figure 11.2.1 TubulinTracker™ Green (Oregon Green® 488 Taxol®, bis-acetate; T34075).

TubulinTracker™ Green reagent is provided as a set of two components: lyophilized TubulinTracker™ Green reagent and a 20% Pluronic® F-127 solution in dimethylsulfoxide (DMSO), a solubilizing agent for making stock solutions and facilitating cell loading. Please note that because paclitaxel binds polymerized tubulin, TubulinTracker™ Green reagent will inhibit cell division and possibly other functions utilizing polymerized tubulin in live cells.

Fluorescent Paclitaxel Conjugates

In addition to unlabeled paclitaxel and TubulinTracker™ Green reagent, we provide three fluorescent derivatives of paclitaxel: Oregon Green® 488 paclitaxel (Flutax-2, P22310), BODIPY® FL paclitaxel (P7500) and BODIPY® 564/570 paclitaxel (P7501). These fluorescent paclitaxel derivatives are promising tools for imaging microtubule formation and motility. Their fluorescent attributes should also make these conjugates useful reagents for screening compounds that affect microtubule assembly.

Oregon Green® 488 paclitaxel¹²⁻¹⁶ is an important probe for labeling tubulin filaments in live cells. The fluorescent label on this probe is attached by derivatizing the 7β-hydroxy group of native paclitaxel (Figure 11.2.2), a strategy that permits selective binding of the probe to microtubules with high affinity at 37°C¹⁶ ($K_d \sim 10^{-7}$ M). Oregon Green® 488 paclitaxel has been utilized in a high-throughput fluorescence polarization-based assay to screen for paclitaxel biomimetics.¹⁴ We have successfully used Oregon Green® 488 paclitaxel to label microtubules

Figure 11.2.2 Paclitaxel, Oregon Green® 488 conjugate (Oregon Green® 488 Taxol®, Flutax-2; P22310).

Figure 11.2.3 Microtubules were assembled, stabilized and visualized with the aid of green-fluorescent Oregon Green® 488 paclitaxel (P22310). Viable HeLa cells were incubated with the conjugate for 1 hour, followed by several washes with phosphate-buffered saline containing 2% bovine serum albumin. The image was acquired using a confocal laser-scanning microscope and a filter set appropriate for fluorescence.

Figure 11.2.4 Paclitaxel, BODIPY® FL conjugate (BODIPY® FL Taxol®, P7500).

of live HeLa (Figure 11.2.3), NIH 3T3, A-10 and BC3H1 cells. *Xenopus laevis*¹⁷ and bovine brain¹⁸ microtubules have also been stained with Oregon Green® 488 paclitaxel.

In the BODIPY® FL and BODIPY® 564/570 paclitaxel derivatives, the *N*-benzoyl substituent of the 3-phenylisoserine portion of native paclitaxel is replaced by a BODIPY® propionyl substituent (Figure 11.2.4). As an alternative to chemically modifying tubulin with a reactive fluorophore, a published method describes the use of these BODIPY® paclitaxel derivatives to generate fluorescent microtubules that are stable at room temperature for one week or longer.¹⁹ In contrast to the Oregon Green® 488 derivative, the BODIPY® FL and BODIPY® 564/570 paclitaxel derivatives do not appear to be suitable for labeling intracellular tubulin in most cases.

Tubulin-Selective Probes

GFP- and RFP-Labeled Tubulin and MAP4

GFP-tubulin fusions are well-established probes for imaging cytotokinesis and other dynamic rearrangements of microtubules in live cells.²⁰ CellLight® Tubulin-GFP and CellLight® Tubulin-RFP expression vectors (C10613, C10614; Table 11.1) generate autofluorescent proteins fused to the N-terminus of human β-tubulin and incorporate all the generic advantages of BacMam 2.0 delivery technology (BacMam Gene Delivery and Expression Technology—Note 11.1).

In context-specific instances where GFP-tubulin fusion protein incorporation into microtubules is inefficient, CellLight® expression vectors encoding GFP (C10598; Figure 11.2.5) or RFP (C10599) fused to the N-terminus of the mammalian microtubule-associated protein MAP4 provide a second option for microtubule visualization. However, because MAP4 stabilizes polymerized tubulin, CellLight® Tubulin-GFP and CellLight® Tubulin-RFP are generally preferable for molecular-level investigations of microtubule dynamic instability.

Figure 11.2.5 Human mesenchymal stem cell labeled with CellLight® MAP4-GFP (C10598) and CellLight® Histone 2B-RFP (C10595) reagents.

Figure 11.2.6 Microtubules of bovine pulmonary artery endothelial cells tagged with mouse monoclonal anti-α-tubulin antibody (A11126) and subsequently probed with: Alexa Fluor® 488 goat anti-mouse IgG antibody (A11001, left), Alexa Fluor® 546 goat anti-mouse IgG antibody (A11003, middle) or Alexa Fluor® 594 goat anti-mouse IgG antibody (A11005, right). These images were acquired using a fluorescein bandpass optical filter set, a rhodamine bandpass optical filter set and a Texas Red® bandpass optical filter set, respectively.

Anti- α -Tubulin Monoclonal Antibody

When used in conjunction with an anti-mouse IgG secondary immunoreagent (Section 7.2, Table 7.1), our anti- α -tubulin monoclonal antibody (A11126) enables researchers to visualize microtubules in fixed cells (Figure 11.2.6, Figure 11.2.7, Figure 11.2.8, Figure 11.2.9) and in fixed or frozen tissue sections from various species. This mouse monoclonal antibody, which recognizes amino acid residues 69–97 of the N-terminal structural domain, is also useful for detecting tubulin by ELISA or western blotting, for screening expression libraries and as a probe for the N-terminal domain of α -tubulin.

The anti- α -tubulin monoclonal antibody is available either unlabeled (A11126) or as a biotin-XX conjugate (A21371). For detecting the

biotinylated antibody, we carry a wide variety of fluorophore- and enzyme-labeled avidin, streptavidin and NeutrAvidin™ biotin-binding protein conjugates and NANOGOLD® and Alexa Fluor® FluoroNanogold™ streptavidin (Section 7.6, Table 7.9).

We have extensively utilized the mouse IgG₁ monoclonal anti- α -tubulin antibody during development and evaluation of our Zenon® technology (Section 7.3, Table 7.7), which allows labeling of submicrogram quantities of primary antibodies in minutes (Figure 11.2.10, Figure 11.2.11). A comprehensive listing of our primary antibodies for cytoskeletal proteins can be found at www.invitrogen.com/handbook/antibodies.

Figure 11.2.7 Microtubules of fixed bovine pulmonary artery endothelial cells were labeled with our mouse monoclonal anti- α -tubulin antibody (A11126), detected with the biotin-XX-conjugated F(ab')₂ fragment of goat anti-mouse IgG antibody (B11027) and visualized with Alexa Fluor® 488 streptavidin (S11223). The actin filaments were then labeled with orange-fluorescent Alexa Fluor® 568 phalloidin (A12380), and the cell was counterstained with blue-fluorescent Hoechst 33342 (H1399, H3570, H21492) to image the DNA, and red-fluorescent propidium iodide (P1304MP, P3566, P21493) to image the nucleolar RNA. The multiple-exposure image was acquired using bandpass filters appropriate for the Texas Red® dye, fluorescein and DAPI.

Figure 11.2.8 Bovine pulmonary artery endothelial cells were labeled with Alexa Fluor® 488 phalloidin (A12379) to stain F-actin and our mouse monoclonal anti- α -tubulin antibody (A11126) in combination with Alexa Fluor® 594 dye-conjugated F(ab')₂ fragment of goat anti-mouse IgG antibody (A11020) to stain microtubules. The multiple-exposure image was acquired using bandpass filter sets appropriate for Texas Red® dye and fluorescein.

Figure 11.2.9 A zebrafish cryosection incubated with the biotin-XX conjugate of mouse monoclonal anti- α -tubulin antibody (A21371). The signal was amplified with TSA™ Kit #22, which includes HRP-streptavidin and Alexa Fluor® 488 tyramide (T20932). The sample was then incubated with the mouse monoclonal FRet 6 antibody and was visualized with Alexa Fluor® 647 goat anti-mouse IgG (A21235), which is pseudocolored magenta. Finally, the nuclei were counterstained with SYTOX® Orange nucleic acid stain (S11368).

Figure 11.2.10 Fixed and permeabilized bovine pulmonary artery endothelial cells stained with Alexa Fluor® 350 phalloidin (A22281), an anti- α -tubulin antibody (A11126) and the anti-cdc6 peptide antibody (A21286). The anti- α -tubulin antibody was labeled with the Zenon® Alexa Fluor® 568 Mouse IgG₁ Labeling Kit (Z25006) and the anti-cdc6 peptide antibody was labeled with the Zenon® Alexa Fluor® 488 Mouse IgG₁ Labeling Kit (Z25002).

Figure 11.2.11 A prometaphase muntjac skin fibroblast stained with Alexa Fluor® 350 phalloidin (A22281), an anti- α -tubulin antibody (A11126) and an anti-cdc6 peptide antibody (A21286). The anti- α -tubulin antibody was pre-labeled with the Zenon® Alexa Fluor® 488 Mouse IgG₁ Labeling Kit (Z25002) and the anti-cdc6 peptide antibody was pre-labeled with the Zenon® Alexa Fluor® 647 Mouse IgG₁ Labeling Kit (Z25008).

BODIPY® FL Vinblastine

BODIPY® FL vinblastine (V12390, Figure 11.2.12), a fluorescent analog of the anticancer drug vinblastine, is a useful probe for labeling β -tubulin and for investigating drug-transport mechanisms.^{21,22} Vinblastine inhibits cell proliferation by capping microtubule ends, thereby suppressing mitotic spindle microtubule dynamics.²³ Another fluorescent vinblastine derivative, vinblastine 4'-anthranilate, reportedly binds to the central portion of the primary sequence of β -tubulin and inhibits polymerization.^{21,24–26}

In addition, intracellular accumulation of vinblastine has been associated with a vinblastine-specific modulating site on P-glycoprotein, a drug-efflux pump that is overexpressed in multidrug-resistant (MDR) cells²⁷ (Section 15.6). This highly lipophilic P-glycoprotein substrate has also been used to study the role of P-glycoprotein in drug penetration through the blood-brain barrier.²⁸ Fluorescently labeled vinblastine analogs, including BODIPY® FL vinblastine, have been employed to measure drug-transport kinetics in MDR cells.²⁹

Other Probes for Tubulin

The nuclear stain DAPI (D1306, D3571, D21490) binds tightly to purified tubulin *in vitro* without interfering with microtubule assembly or GTP hydrolysis. DAPI binds to tubulin at sites different from those of paclitaxel, colchicine and vinblastine, and its binding is accompanied by shifts in the absorption spectra and fluorescence enhancement. The affinity of DAPI for polymeric tubulin is 7-fold greater than for dimeric tubulin, making DAPI a sensitive tool for investigating microtubule assembly kinetics.^{30–33} DAPI has been used to screen for potential anti-microtubule drugs in a high-throughput assay.³⁴

Bis-ANS (B153) is a potent inhibitor of *in vitro* microtubule assembly.³⁵ This fluorescent probe binds to the hydrophobic clefts of proteins with an affinity approximately 10–100 times higher than that of 1,8-ANS (A47, Section 13.5) and exhibits a significant fluorescence enhancement upon binding. The bis-ANS binding site on tubulin lies near the critical contact region for microtubule assembly, but it is distinct from the binding sites for colchicine, vinblastine, podophyllo-toxin and maytansine.^{36–38} Bis-ANS was used to investigate structural changes in tubulin monomers and dimers during time- and temperature-dependent decay.^{39,40}

Figure 11.2.12 Vinblastine, BODIPY® FL conjugate (BODIPY® FL vinblastine, V12390).

DCVJ (4-(dicyanovinyl)julolidine; D3923), which binds to a specific site on the tubulin dimer,⁴¹ has been reported to be a useful probe for following polymerization of tubulin in live cells.⁴² DCVJ staining in live cells is mostly blocked by cytochalasin D.⁴³ Additionally, DCVJ emits strong green fluorescence upon binding to bovine brain calmodulin.⁴⁴ The hydrophobic surfaces of tubulin have also been investigated with the environment-sensitive probes Nile red⁴⁵ (N1142) and Prodan⁴⁶ (P248).

Probes for Other Cytoskeletal Proteins

GFP- and RFP-Labeled Talin

Talin is a cytoskeletal protein that is concentrated in focal adhesions, linking integrins to the actin cytoskeleton either directly or indirectly by interacting with vinculin and α -actinin. CellLight® Talin-GFP and CellLight® Talin-RFP expression vectors (C10611, C10612; Table 11.1; Figure 11.2.13) generate autofluorescent proteins fused to the C-terminal actin-binding domain of human talin and incorporate all the generic advantages of BacMam 2.0 delivery technology (BacMam Gene Delivery and Expression Technology—Note 11.1). These CellLight® reagents have potential applications in image-based high-content screening (HCS) assays of integrin-mediated cell adhesion, as well as for general-purpose labeling of cytoskeletal actin in live cells.

Anti-Glial Fibrillary Acidic Protein (GFAP) Antibody

The 50,000-dalton type-III intermediate filament protein known as glial fibrillary acidic protein (GFAP) is a major structural component of astrocytes and some ependymal cells.⁴⁷ GFAP associates with the calcium-binding protein annexin II2-p11(2) and S-100.^{48,49} Association with these proteins together with phosphorylation regulates GFAP polymerization. Astrocytes respond to brain injury by proliferation (astrogliosis); one of the first events to occur during astrocyte proliferation is increased GFAP expression. Our anti-GFAP antibody (A21282) and its Alexa Fluor® 488 and Alexa Fluor® 594 conjugates (A21294, A21295; Figure 11.2.14) can be used to aid in the identification of cells of glial lineage. Interestingly, antibodies to GFAP have been detected in

Figure 11.2.13 HeLa cell labeled with CellLight® Talin-GFP (C10611) and CellLight® Actin-RFP (C10583) reagents.

individuals with dementia.⁵⁰ In the central nervous system, anti-GFAP antibody stains both astrocytes and ependymal cells. In the peripheral nervous system, Schwann cells, satellite cells and enteric glial cells are stained; tumors of glial origin contain high amounts of GFAP. No positive staining is observed in skin, connective tissue, adipose tissue, lymphatic tissue, muscle, kidney, ureter, bladder or gastrointestinal tract, including liver and pancreas. Our anti-GFAP antibody does not cross-react with vimentin, which is frequently co-expressed in glioma cells and some astrocytes, nor does it cross-react with Bergmann glia cells, gliomas or other glial cell-derived tumors.

Anti-Desmin Antibody

Desmin, encoded by a gene belonging to the intermediate filament protein gene family,⁵¹⁻⁵³ is the main intermediate filament in mature skeletal, cardiac and smooth muscle cells. Both striated and smooth muscle cells can be labeled by an anti-desmin antibody, although not all muscle tissue contains desmin (e.g., aorta smooth muscle). Identification of desmin is useful in distinguishing habdomyosarcomas and leiomyosarcomas from other vimentin-positive sarcomas. We offer a mouse IgG₁ monoclonal anti-desmin antibody (A21283), which can be used with our fluorescent secondary antibodies (Section 7.2, Figure 11.2.15) as a marker for typing soft tissue sarcomas. Anti-desmin immunohistochemical staining in cell-block preparations may also be helpful in distinguishing mesothelial cells from carcinoma.⁵⁴

Anti-Synapsin I Antibody

Synapsin I, an actin-binding protein, is localized exclusively to synaptic vesicles and thus serves as an excellent marker for synapses in brain and other neuronal tissues.^{55,56} Synapsin I inhibits neurotransmitter release, an effect that is abolished upon its phosphorylation by Ca²⁺/calmodulin-dependent protein kinase II. For assaying the localization and abundance of synapsin I by western blot analysis, immunohistochemistry (Figure 11.2.16), enzyme-linked immunosorbent assay (ELISA) or immunoprecipitation, we offer a polyclonal rabbit anti-synapsin I antibody as an affinity-purified IgG fraction (A6442). Although raised against bovine synapsin I, this antibody also recognizes human, rat and mouse synapsin I; it has little or no activity against synapsin II.

Figure 11.2.16 Peripheral neurons in mouse intestinal cryosections were labeled with rabbit anti-synapsin I antibody (A6442) and detected using Alexa Fluor® 488 goat anti-rabbit IgG antibody (A11008). This tissue was counterstained with DAPI (D1306, D3571, D21490).

Figure 11.2.14 Rat brain cryosections were labeled with the red-fluorescent Alexa Fluor® 594 conjugate of anti-glial fibrillary acidic protein antibody (A21295). Nuclei were counterstained with TOTO®-3 iodide (T3604, pseudocolored blue).

Figure 11.2.15 The intermediate filaments in bovine pulmonary artery endothelial cells, localized using our anti-desmin antibody (A21283), which was visualized with the Alexa Fluor® 647 goat anti-mouse IgG antibody (A21235). Endogenous biotin in the mitochondria was labeled with Alexa Fluor® 546 streptavidin (S11225) and DNA in the cell was stained with blue-fluorescent DAPI (D1306, D3571, D21490).

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- B153 is soluble in water at 0.1–1.0 mM after heating.
- Bis-ANS (B153) bound to tubulin has Abs = 392 nm, Em = 490 nm and a fluorescence quantum yield of 0.23. (Biochemistry (1994) 33:11900)
- DAPI undergoes an approximately 9-fold fluorescence enhancement on binding to polymerized tubulin. Abs = 345 nm, Em = 446 nm. (J Biol Chem (1985) 260:2819)
- The absorption and fluorescence emission maxima of DCVJ (D3923) bound to tubulin are essentially the same as in methanol. (Biochemistry (1989) 28:6678)
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- The fluorescence emission maximum of Nile red (N1142) bound to tubulin is 623 nm. (J Biol Chem (1990) 265:14899)
- The fluorescence emission maximum of prodan (P248) bound to tubulin is ~450 nm. (Eur J Biochem (1992) 204:127)

PRODUCT LIST 11.2 PROBES FOR TUBULIN AND OTHER CYTOSKELETAL PROTEINS

Cat. No.	Product	Quantity
A21283	anti-desmin, mouse IgG ₁ , monoclonal 131-15014 *1 mg/mL*	100 µL
A21282	anti-GFAP (anti-glia fibrillary acidic protein, mouse IgG ₁ , monoclonal 131-17719) *1 mg/mL*	100 µL
A21294	anti-GFAP, Alexa Fluor® 488 conjugate (anti-glia fibrillary acidic protein, mouse IgG ₁ , monoclonal 131-17719, Alexa Fluor® 488 conjugate) *1 mg/mL*	50 µL
A21295	anti-GFAP, Alexa Fluor® 594 conjugate (anti-glia fibrillary acidic protein, mouse IgG ₁ , monoclonal 131-17719, Alexa Fluor® 594 conjugate) *1 mg/mL*	50 µL
A6442	anti-synapsin I (bovine), rabbit IgG fraction *affinity purified*	10 µg
A11126	anti-α-tubulin (bovine), mouse IgG ₁ , monoclonal 236-10501	50 µg
A21371	anti-α-tubulin (bovine), mouse IgG ₁ , monoclonal 236-10501, biotin-XX conjugate	50 µg
B153	bis-ANS (4,4'-dianilino-1,1'-binaphthyl-5,5'-disulfonic acid, dipotassium salt)	10 mg
C10598	CellLight® MAP4-GFP *BacMam 2.0*	1 mL
C10599	CellLight® MAP4-RFP *BacMam 2.0*	1 mL
C10611	CellLight® Talin-GFP *BacMam 2.0*	1 mL
C10612	CellLight® Talin-RFP *BacMam 2.0*	1 mL
C10613	CellLight® Tubulin-GFP *BacMam 2.0*	1 mL
C10614	CellLight® Tubulin-RFP *BacMam 2.0*	1 mL
D3923	DCVJ (4-(dicyanovinyl)julolidine)	25 mg
D1306	4',6-diamidino-2-phenylindole, dihydrochloride (DAPI)	10 mg
D21490	4',6-diamidino-2-phenylindole, dihydrochloride (DAPI) *FluoroPure™ grade*	10 mg
D3571	4',6-diamidino-2-phenylindole, dilactate (DAPI, dilactate)	10 mg
N1142	nile red	25 mg
P3456	paclitaxel (Taxol® equivalent) *for use in research only*	5 mg
P7501	paclitaxel, BODIPY® 564/570 conjugate (BODIPY® 564/570 Taxol®)	10 µg
P7500	paclitaxel, BODIPY® FL conjugate (BODIPY® FL Taxol®)	10 µg
P22310	paclitaxel, Oregon Green® 488 conjugate (Oregon Green® 488 Taxol®; Flutax-2)	100 µg
P248	prodan (6-propionyl-2-dimethylaminonaphthalene)	100 mg
T34075	TubulinTracker™ Green (Oregon Green® 488 Taxol®, bis-acetate) *for live-cell imaging*	1 set
V12390	vinblastine, BODIPY® FL conjugate (BODIPY® FL vinblastine)	100 µg

MitoTracker® Red CMXRos and DAPI.

12.1 A Diverse Selection of Organelle Probes

We offer a diverse array of cell-permeant fluorescent stains that selectively associate with the mitochondria, lysosomes, endoplasmic reticulum, Golgi apparatus and nucleus in live cells (Figure 12.1.1). These probes, which include our MitoTracker®, LysoTracker®, LysoSensor™, RedoxSensor™ and ER-Tracker™ organelle stains (Table 12.1), are compatible with most fluorescence instrumentation and provide researchers with powerful tools for investigating respiration, mitosis, apoptosis, multidrug resistance, substrate degradation and detoxification, intracellular transport and sorting and more. Importantly, unlike antibodies, these fluorescent probes can be used to investigate organelle structure and activity in live cells with minimal disruption of cellular function (Figure 12.1.2). The red-fluorescent organelle stains are particularly useful for demonstrating colocalization with Green Fluorescent Protein (GFP) expression (Using Organic Fluorescent Probes in Combination with GFP—Note 12.1).

In addition to these organelle-selective organic dyes, we offer CellLight® targeted fluorescent protein-based markers, comprising BacMam expression vectors encoding an autofluorescent protein fused to a site-selective targeting sequence. These reagents are available for labeling a variety of organelles—including mitochondria, lysosomes, endoplasmic reticulum, Golgi apparatus and nucleus, as well as several subcellular structures such as actin filaments and microtubules—in live mammalian cells (Table 11.1). In this chapter, we discuss the CellLight® reagents targeted specifically to organelles. CellLight® reagents incorporate all the customary advantages of BacMam delivery technology, including high transduction efficiency and long-lasting and titratable expression (BacMam Gene Delivery and Expression Technology—Note 11.1).

Fluorescent cytoskeleton probes, including CellLight® targeted fluorescent proteins, are discussed in Chapter 11. Fluorescent plasma membrane stains, as well as CellLight® membrane-targeted fluorescent proteins, are discussed in Section 14.4. A variety of probes for phagocytosis, endosomes and lysosomes—such as membrane markers, ligands for studying receptor-mediated endocytosis and CellLight® endosome-targeted fluorescent proteins—are discussed in Section 16.1. Our online Cell Staining Tool allows you to design your own multicolor experiments using these organelle probes; more information is available at www.invitrogen.com/handbook/cellstainingtool.

Figure 12.1.2 Euphyrene spermatozoa from the pupal testis of the gypsy moth (*Lymantria dispar*) that were incubated in a solution of MitoTracker® Red CMXRos (M7512). The sample was subsequently fixed and the nuclear material was counterstained with the blue-fluorescent dsDNA dye, DAPI (D1306, D3571, D21490). Image contributed by Laura K. Garvey, University of Connecticut.

NOTE 12.1**Using Organic Fluorescent Probes in Combination with GFP****Probes for Multiplexed Detection of GFP-Expressing Cells**

The Green Fluorescent Protein (GFP) reporter has added a new dimension to the analysis of protein localization, allowing real-time examination in live cells of processes that have conventionally been observed through immunocytochemical “snapshots” in fixed specimens.¹ Using spectrally distinct, organic fluorescent probes and markers (Table 1) adds extra data dimensions and reference points to these experiments (Figure 1).

The majority of the applications summarized in Table 1 involve live cells, tissues and organisms. There are many other instances where research objectives call for complementary use of immunochemical and GFP-based protein localization techniques. These experiments demand

Figure 1 The morphology of sporulating *Bacillus subtilis* in the early stages of forespore engulfment. The membranes and chromosomes of both the forespore and the larger mother cell are stained with FM® 4-64 (red; T3166, T13320) and DAPI (blue; D1306, D3571, D21490), respectively. The small green-fluorescent patch indicates the localization of a GFP fusion to SPoIII, a protein essential for translocation of the forespore chromosome that may also regulate membrane fusion events (see Proc Natl Acad Sci U S A (1999) 96: 14553). The background contains sporangia at various stages in the engulfment process stained with MitoTracker® Green FM® (green, M7514) and FM® 4-64 (red).

the combination of brightness, photostability and spectral separation provided by our Alexa Fluor® dye-labeled secondary detection reagents. For two-color combinations with GFP, we recommend the Alexa Fluor® 555, Alexa Fluor® 568 or Alexa Fluor® 594 dye-labeled secondary antibodies (Section 7.2, Table 7.1). The addition of Alexa Fluor® 635 or Alexa Fluor® 647 dye-labeled antibodies allows three-color detection. Some immunohistochemical procedures such as paraffin embedding of fixed tissue result in loss of the intrinsic fluorescence of GFP. In other cases, GFP expression levels may simply be too low for detection above background autofluorescence.² Antibodies to GFP provide remedies for these problems (Figure 2). We offer unlabeled mouse and rabbit monoclonal and rabbit and chicken polyclonal antibodies to GFP as well as Alexa Fluor® dye-labeled rabbit polyclonal antibodies to GFP (Section 7.5).

Alexa Fluor® Dyes: Highly Fluorescent FRET Acceptors

Proximity-dependent fluorescence resonance energy transfer (FRET) allows detection of protein-protein interactions with much higher spatial resolution than conventional diffraction-limited microscopy.³ Alexa Fluor® dyes with strong absorption in the 500–600 nm wavelength range are excellent FRET acceptors from GFP (Table 2). An assay to detect activation of GFP-GTPase fusions developed by researchers at Scripps Research Institute⁴ utilizes the GTPase-binding domain (PBD) of PAK1, a protein that binds to GTPases only in their activated GTP-bound form. GTPase activation is indicated by FRET from GFP to PDB labeled with Alexa Fluor® 546 C₅-maleimide at a single N-terminal cysteine residue. This assay has been used to determine the location and dynamics of rac and Cdc42 GTPase activation in live cells.^{4–6}

Normalizing Expression and Translation Signals

In 2002, researchers in Scott Fraser's laboratory at the California Institute of Technology reported a method of coinjecting Texas Red® dye-labeled 10,000 MW dextran and GFP vectors into sea urchin embryos. This method overcomes a multitude of problems inherent in making intra- and inter-embryo comparisons of gene expression levels using confocal microscopy. In particular, laser excitation and fluorescence collection efficiencies vary with the depth of the fluorescent protein in the embryo, and the orientation of different embryos on the coverslip varies relative to the microscope objective. Measuring the ratio of GFP fluorescence to Texas Red® dextran fluorescence corrects for these spatial factors, providing a gene expression readout that is 2–50 times more accurate than conventional confocal microscopy procedures depending on the localization of GFP within an embryo.⁷ A similar strategy was previously used to determine translation efficiencies of GFP-encoding mRNAs.⁸

Figure 2 HeLa cell transfected with pShooter™ pCMV/myc/mito/GFP, then fixed and permeabilized. Green Fluorescent Protein (GFP) localized in the mitochondria was labeled with mouse IgG_{2a} anti-GFP antibody (A11120) and detected with orange-fluorescent Alexa Fluor® 555 goat anti-mouse IgG antibody (A21422), which colocalized with the dim GFP fluorescence. F-actin was labeled with green-fluorescent Alexa Fluor® 488 phalloidin (A12379), and the nucleus was stained with blue-fluorescent DAPI (D1306, D3571, D21490). The sample was mounted using ProLong® Gold antifade reagent (P36930). Some GFP fluorescence is retained in the mitochondria after fixation (top), but immunolabeling and detection greatly improve visualization (bottom).

Table 2 R₀ values for FRET from EGFP to Alexa Fluor® dyes.

Acceptor Dye	R ₀ (Å)*
Alexa Fluor® 546 dye	57
Alexa Fluor® 555 dye	63
Alexa Fluor® 568 dye	54
Alexa Fluor® 594 dye	53

* R₀ values in angstroms (Å) represent the distance at which fluorescence resonance energy transfer from the donor dye to the acceptor dye is 50% efficient. Values were calculated from spectroscopic data as outlined (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2).

12.2 Probes for Mitochondria

Mitochondria are found in eukaryotic cells, where they make up as much as 10% of the cell volume. They are pleomorphic organelles with structural variations depending on cell type, cell-cycle stage and intracellular metabolic state. The key function of mitochondria is energy production through oxidative phosphorylation (OxPhos) and lipid oxidation.¹ Several other metabolic functions are performed by mitochondria, including urea production and heme, non-heme iron and steroid biogenesis, as well as intracellular Ca²⁺ homeostasis. Mitochondria also play a pivotal role in apoptosis—the genetically controlled ablation of cells during normal development^{2–4} (Section 15.5). For many of these mitochondrial functions, there is only a partial understanding of the components involved, with even less information on mechanism and regulation.

The morphology of mitochondria is highly variable. In dividing cells, the organelle can switch between a fragmented morphology with many ovoid-shaped mitochondria, as is often shown in textbooks, and a reticulum in which the organelle is a single, many-branched structure. The cell cycle- and metabolic state-dependent changes in mitochondrial morphology are controlled by a set of proteins that cause fission and fusion of the organelle mass. Mutations in these proteins are the cause of several human diseases, indicating the importance of overall morphology for cell functioning (Mitochondria in Diseases—Note 12.2). Organelle morphology is also controlled by cytoskeletal elements, including actin filaments and microtubules. In nondividing tissue, overall mitochondrial morphology is very cell-type dependent, with mitochondria spiraling around the axoneme in spermatozoa, and ovoid bands of mitochondria intercalating between actomyosin filaments. There is evidence of functionally significant heterogeneity of mitochondrial forms within individual cells.

The abundance of mitochondria varies with cellular energy level and is a function of cell type, cell-cycle stage and proliferative state. For example, brown adipose tissue cells,⁵ hepatocytes⁶ and certain renal epithelial cells⁷ tend to be rich in active mitochondria, whereas quiescent immune-system progenitor or precursor cells show little staining with mitochondrion-selective dyes.⁸ The number of mitochondria is reduced in Alzheimer disease and their proteins and nucleic acids are susceptible to damage by reactive oxygen species, including nitric oxide^{9–11} (Chapter 18).

We have a range of mitochondrion-selective dyes with which to monitor mitochondrial morphology and organelle functioning. The uptake of most mitochondrion-selective dyes is dependent on the mitochondrial membrane potential. These dyes thereby enable researchers to probe mitochondrial activity, localization and abundance,^{9,12,13} as well as to monitor the effects of some pharmacological agents that alter mitochondrial function.¹⁴

MitoTracker® Probes: Fixable Mitochondrion-Selective Probes

Although conventional fluorescent stains for mitochondria, such as rhodamine 123 and tetramethylrosamine, are readily sequestered by functioning mitochondria, they are subsequently washed out of

the cells once the mitochondrion's membrane potential is lost. This characteristic limits their use in experiments in which cells must be treated with aldehyde-based fixatives or other agents that affect the energetic state of the mitochondria. To overcome this limitation, we have developed MitoTracker® probes—a series of mitochondrion-selective stains that are concentrated by active mitochondria and well retained during cell fixation.¹⁵ Because the MitoTracker® Orange, MitoTracker® Red and MitoTracker® Deep Red probes are also retained following permeabilization, the sample retains the fluorescent staining pattern characteristic of live cells during subsequent processing steps for immunocytochemistry, *in situ* hybridization or electron microscopy. In addition, MitoTracker® reagents eliminate some of the difficulties of working with pathogenic cells because, once the mitochondria are stained, the cells can be treated with fixatives before the sample is analyzed.

NOTE 12.2

Mitochondria in Diseases

Given the multiple functions and numerous proteins present in the mitochondria, it is not surprising that genetically inherited defects of mitochondrial function are a major cause of morbidity and mortality in humans.¹ In particular, there are several human diseases that have known defects in the proteins responsible for oxidative phosphorylation (OxPhos) in cells. Typically, such defects produce lactic acidemia, exercise intolerance or neurological disorders.

Diseases of OxPhos are notoriously difficult to diagnose, and it is even more difficult to correlate their phenotype-genotype relationships. A subset of OxPhos defects is maternally inherited. These defects result from mutations in mitochondrial DNA (mtDNA), a small, 16-kb genome present in hundreds to thousands of copies per cell.^{2,3} mtDNA, which encodes 13 polypeptides of the OxPhos machinery, differs from the nuclear genome in its absence of histones, poor repair mechanisms and very limited recombination frequencies. As a result, mtDNA in somatic cells builds up mutations over time due to errors in replication that are not repaired and physical insult from a variety of toxins.⁴ Such accumulated mutations are implicated in a number of neurodegenerative diseases⁵—notably Parkinson disease and Alzheimer disease—where the mutation load triggers premature apoptotic or necrotic cell death. For example, a strong link has been established between exposure to the pesticide rotenone, a well-defined and specific inhibitor of OxPhos, and Parkinson disease. mtDNA mutations function by reducing energy production within the cell and are thought to contribute to cancer and aging. Likewise, mutations in the nuclear-encoded subunits of OxPhos have been found to regulate the life span in flies and worms. Many of the products listed in this section are useful tools for studying degenerative conditions.^{6–9}

Figure 12.2.2 MitoTracker® Red CMXRos (M7512).

Figure 12.2.3 Live NIH 3T3 cells labeled with probes for mitochondria, Golgi and the nucleus. Mitochondria were labeled with MitoTracker® Red FM® (M22425), Golgi with BODIPY® FL ceramide (D3521, B22650), and the nucleus with Hoechst 33342 (H1399, H3570, H21492).

Figure 12.2.4 Mitochondria of live bovine pulmonary artery endothelial cells stained with the MitoTracker® Deep Red FM® dye (M22426).

Properties of MitoTracker® Probes

MitoTracker® probes are cell-permeant mitochondrion-selective dyes that contain a mildly thiol-reactive chloromethyl moiety. The chloromethyl group appears to be responsible for keeping the dye associated with the mitochondria after fixation.¹⁶ To label mitochondria, cells are simply incubated in submicromolar concentrations of the MitoTracker® probe, which passively diffuses across the plasma membrane and accumulates in active mitochondria. Once their mitochondria are labeled, the cells can be treated with aldehyde-based fixatives to allow further processing of the sample; with the exception of MitoTracker® Green FM®, subsequent permeabilization with cold acetone does not appear to disturb the staining pattern of the MitoTracker® dyes.

We offer seven MitoTracker® reagents that differ in spectral characteristics, oxidation state and fixability (Table 12.2). MitoTracker® probes are provided in specially packaged sets of 20 vials, each containing 50 µg for reconstitution as required.

Orange-, Red- and Infrared-Fluorescent MitoTracker® Dyes

We offer MitoTracker® derivatives of the orange-fluorescent tetramethylrosamine (MitoTracker® Orange CMTMRos, M7510; Figure 12.2.1) and the red-fluorescent X-rosamine (MitoTracker® Red CMXRos, M7512; Figure 12.2.2), as well as MitoTracker® Red FM® and MitoTracker® Deep Red FM® probes (M22425, M22426; Figure 12.2.3, Figure 12.2.4). Because the MitoTracker® Red CMXRos, MitoTracker® Red FM® and MitoTracker® Deep Red FM® probes produce longer-wavelength fluorescence that is well resolved from the fluorescence of green-fluorescent dyes, they are suitable for multicolor labeling experiments^{17,18} (Figure 12.2.5, Figure 12.2.6, Figure 12.2.7). Also available are chemically reduced forms of the tetramethylrosamine (MitoTracker® Orange CM-H₂TMRos, M7511; Figure 12.2.8) and X-rosamine (MitoTracker® Red CM-H₂XRos, M7513; Figure 12.2.9) MitoTracker® probes. Unlike MitoTracker® Orange CMTMRos and MitoTracker® Red CMXRos, the reduced versions of these probes do not fluoresce until they enter an actively respiring cell, where they are oxidized to the fluorescent mitochondrion-selective probe and then sequestered in the mitochondria¹⁹ (Figure 12.2.10, Figure 12.2.11, Figure 12.2.12).

Figure 12.2.5 Bovine pulmonary artery endothelial cells (BPAEC) incubated with the fixable, mitochondrion-selective MitoTracker® Red CMXRos (M7512). After staining, the cells were formaldehyde-fixed, acetone-permeabilized, treated with DNase-free RNase and counterstained using SYTOX® Green nucleic acid stain (S7020). Microtubules were labeled with a mouse monoclonal anti-β-tubulin antibody, biotin-XX goat anti-mouse IgG antibody (B2763) and Cascade Blue® NeutrAvidin™ biotin-binding protein (A2663). This photograph was taken using multiple exposures through bandpass optical filters appropriate for Texas Red® dye, fluorescein and DAPI using a Nikon® Labophot 2 microscope equipped with a Quadfluor epi-illumination system.

Figure 12.2.6 A bovine pulmonary artery endothelial cell (BPAEC) stained with mouse monoclonal anti-β-tubulin in conjunction with Oregon Green® 514 goat anti-mouse IgG antibody (O6383), MitoTracker® Red CMXRos (M7512) and DAPI (D1306, D3571, D21490).

Images were obtained by taking single and multiple exposures through bandpass optical filter sets appropriate for fluorescein, the Texas Red® dye and DAPI.**Figure 12.2.8** MitoTracker® Orange CM-H₂TMRos (M7511).**Figure 12.2.9** MitoTracker® Red CM-H₂XRos (M7513).**Figure 12.2.11** Live bovine pulmonary artery endothelial cells stained with ER-Tracker™ Blue-White DPX (E12353) and MitoTracker® Red CM-H₂XRos (M7513). The endoplasmic reticulum appears green and the mitochondria appear orange. The image was acquired using a fluorescence microscope equipped with a triple-bandpass filter set appropriate for DAPI, fluorescein and Texas Red® dyes.**Figure 12.2.10** Intracellular reactions of our fixable, mitochondrion-selective MitoTracker® Orange CM-H₂TMRos (M7511). When this cell-permeant probe enters an actively respiring cell, it is oxidized to MitoTracker® Orange CMTMRos and sequestered in the mitochondria, where it can react with thiols on proteins and peptides to form aldehyde-fixable conjugates.**Figure 12.2.12** The mitochondria of bovine pulmonary artery endothelial cells stained with MitoTracker® Red CM-H₂XRos (M7513). The cells were subsequently fixed, permeabilized and treated with RNase. Then the nuclei were stained with SYTOX® Green nucleic acid stain (S7020). The multiple-exposure photomicrograph was acquired using a fluorescence microscope equipped with bandpass filter sets appropriate for fluorescein and Texas Red® dyes.

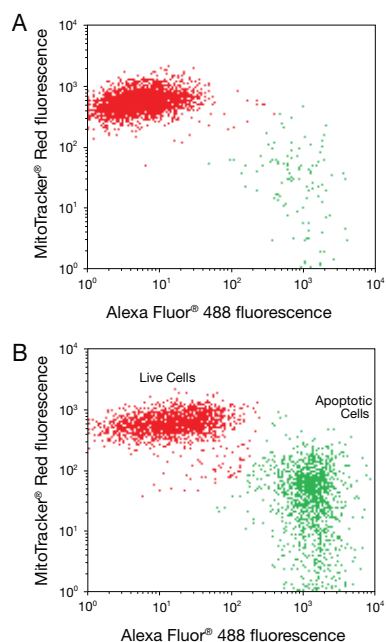

Figure 12.2.13 Flow cytometric analysis of Jurkat cells using the Mitochondrial Membrane Potential/Annexin V Apoptosis Kit (V35116). Jurkat human T-cell leukemia cells in complete medium were **B**) first exposed to 10 μ M camptothecin for 4 hours or **A**) left untreated. Both cell populations were then treated with the reagents in the Mitochondrial Membrane Potential/Annexin V Apoptosis Kit and analyzed by flow cytometry. Note that the apoptotic cells show higher reactivity for annexin V and lower MitoTracker[®] Red dye fluorescence than do live cells.

Figure 12.2.14 MitoTracker[®] Green FM[®] (M7514).

Our Mitochondrial Membrane Potential/Annexin V Apoptosis Kit (V35116, Section 15.5) utilizes MitoTracker[®] CMXRos in combination with Alexa Fluor[®] 488 annexin V in a two-color assay of apoptotic cells (Figure 12.2.13). Following fixation, the oxidized forms of the tetramethylrosamine and X-rosamine MitoTracker[®] dyes can be detected directly by fluorescence or indirectly with either anti-tetramethylrhodamine or anti-Texas Red[®] dye antibodies (A6397, A6399; Section 7.4).

MitoTracker[®] Green FM[®] Dye

Mitochondria in cells stained with nanomolar concentrations of MitoTracker[®] Green FM[®] dye (M7514, Figure 12.2.14) exhibit bright green, fluorescein-like fluorescence (Figure 12.2.15, Figure 12.2.16, Figure 12.2.17). The MitoTracker[®] Green FM[®] probe has the added advantage that it is essentially nonfluorescent in aqueous solutions and only becomes fluorescent once it accumulates in the lipid environment of mitochondria. Hence, background fluorescence is negligible, enabling researchers to clearly visualize mitochondria in live cells immediately following addition of the stain, without a wash step.

Unlike MitoTracker[®] Orange CMTMRos and MitoTracker[®] Red CMXRos, the MitoTracker[®] Green FM[®] probe appears to preferentially accumulate in mitochondria regardless of mitochondrial membrane potential in certain cell types, making it a possible tool for determining mitochondrial mass.²⁰ Furthermore, the MitoTracker[®] Green FM[®] dye is substantially more photostable than the widely used rhodamine 123 fluorescent dye and produces a brighter, more mitochondrion-selective signal at lower concentrations. Because its emission maximum is blue-shifted approximately 10 nm relative to the emission maximum of rhodamine 123, the MitoTracker[®] Green FM[®] dye produces a fluorescent staining pattern that should be better resolved from that of red-fluorescent probes in double-labeling experiments. The mitochondrial proteins that are selectively labeled by the MitoTracker[®] Green FM[®] reagent have been separated by capillary electrophoresis.¹⁶

Image-iT[®] LIVE Mitochondrial and Nuclear Labeling Kit

The Image-iT[®] LIVE Mitochondrial and Nuclear Labeling Kit (I34154) provides two stains—red-fluorescent MitoTracker[®] Red CMXRos dye (excitation/emission maxima ~578/599 nm) and blue-fluorescent Hoechst 33342 dye (excitation/emission maxima when bound to DNA ~350/461 nm)—for highly selective mitochondrial and nuclear staining, respectively, in live, Green Fluorescent Protein (GFP)-transfected cells. These dyes can be combined into one staining solution using the protocol provided, saving labeling time and wash steps while still providing optimal staining. Both dyes are retained after formaldehyde fixation and permeabilization. The Image-iT[®] LIVE Mitochondrial and Nuclear Labeling Kit contains:

- MitoTracker[®] CMXRos dye
- Hoechst 33342 dye
- Dimethylsulfoxide (DMSO)
- Labeling protocols

Figure 12.2.15 Bull sperm pre-labeled with MitoTracker[®] Green FM[®] (M7514) and used for *in vitro* fertilization of bovine oocytes. After fertilization, eggs with bound or incorporated sperm were fixed in 2% formaldehyde, made permeable with Triton X-100 and labeled with an anti-tubulin antibody followed by a tetramethylrhodamine-labeled secondary antibody and counterstained with DAPI (D1306, D3571, D21490). Image contributed by Peter Sutovsky, University of Wisconsin.

Figure 12.2.16 Bovine pulmonary artery endothelial cells (BPAEC) incubated simultaneously with 50 nM LysoTracker[®] Red DND-99 (L7528) and 75 nM MitoTracker[®] Green FM[®] (M7514) at 37°C for 30 minutes. Both dyes showed excellent cellular retention, even after cells were fixed in 3% glutaraldehyde for 30 minutes. The image was deconvolved using Huygens software (Scientific Volume Imaging, <http://www.svi.nl/>).

Each kit provides enough staining solution for 500 assays using the protocol provided for labeling live, cultured cells that are adhering to coverslips.

Fluorescent Protein–Based Markers for Mitochondria

CellLight® Mitochondria-GFP (C10600, Figure 12.2.18) and CellLight® Mitochondria-RFP (C10601) are BacMam expression vectors encoding GFP or RFP²¹ fused to the leader sequence of E1 α pyruvate dehydrogenase. These CellLight® reagents (Table 11.1) incorporate all the customary advantages of BacMam delivery technology including high transduction efficiency and long-lasting and titratable expression (BacMam Gene Delivery and Expression Technology—Note 11.1). In contrast to MitoTracker® Red CMXRos, TMRE, rhodamine 123 and other cationic dyes, mitochondrial localization of fluorescent protein–based markers is not driven by membrane potential.²² They can therefore be used in combination with cationic dye probes to investigate relationships between mitochondrial morphology and membrane potential.

MitoSOX™ Red Mitochondrial Superoxide Indicator

Mitochondrial superoxide is generated as a by-product of oxidative phosphorylation. In an otherwise tightly coupled electron transport chain, approximately 1–3% of mitochondrial oxygen consumed is incompletely reduced; these “leaky” electrons can quickly interact with molecular oxygen to form superoxide anion, the predominant reactive oxygen species in mitochondria.^{23,24} Increases in cellular superoxide production have been implicated in cardiovascular diseases, including hypertension, atherosclerosis and diabetes-associated vascular injuries,²⁵ as well as in neurodegenerative diseases such as Parkinson disease, Alzheimer disease and amyotrophic lateral sclerosis (ALS).²⁴

MitoSOX™ Red mitochondrial superoxide indicator (M36008) is a cationic derivative of dihydroethidium (also known as hydroethidine; see below) designed for highly selective detection of superoxide in the mitochondria of live cells (Figure 12.2.19). The cationic triphenylphosphonium substituent of MitoSOX™ Red indicator is responsible for the electrophoretically driven uptake of the probe in actively respiring mitochondria. Oxidation of MitoSOX™ Red indicator (or dihydroethidium) by superoxide results in hydroxylation at the 2-position (Figure 12.2.20). 2-Hydroxyethidium (and the corresponding derivative of MitoSOX™ Red indicator) exhibit a fluorescence excitation

Figure 12.2.17 The morphology of sporulating *Bacillus subtilis* in the early stages of forespore engulfment. The membranes and chromosomes of both the forespore and the larger mother cell are stained with FM® 4-64 (red; T3166, T13320) and DAPI (blue, D1306, D3571, D21490), respectively. The small green-fluorescent patch indicates the localization of a GFP fusion to SP0IIIe, a protein essential for translocation of the forespore chromosome that may also regulate membrane fusion events (Proc Natl Acad Sci USA (1999) 96:14553). The background contains sporangia at various stages in the engulfment process stained with MitoTracker® Green FM® (green, M7514) and FM® 4-64 (red).

Figure 12.2.18 HeLa cell labeled with CellLight® Mitochondria-GFP (C10600) and CellLight® Talin-RFP (C10612) reagents and with Hoechst 33342 nucleic acid stain.

Figure 12.2.19 Detection of superoxide in live cells using MitoSOX™ Red superoxide indicator (M36008). Live 3T3 cells were treated with FeTCP, a superoxide scavenger, (right) or left untreated (left). Cells were then labeled with MitoSOX™ Red reagent, which fluoresces when oxidized by superoxide, and nuclei were stained with blue-fluorescent Hoechst 33342. The mitochondria of untreated cells exhibited red fluorescence, indicating the presence of superoxide, whereas the mitochondria of treated cells showed minimal fluorescence.

Figure 12.2.20 Oxidation of MitoSOX™ Red mitochondrial superoxide indicator to 2-hydroxy-5-(triphenylphosphonium)heylethidium by superoxide (O_2^-).

peak at ~400 nm²⁶ that is absent in the excitation spectrum of the ethidium oxidation product generated by reactive oxygen species other than superoxide. Thus, fluorescence excitation at 400 nm with emission detection at ~590 nm provides optimum discrimination of superoxide from other reactive oxygen species^{26–28} (Figure 12.2.21).

Measurements of mitochondrial superoxide generation using MitoSOX™ Red indicator in mouse cortical neurons expressing caspase-cleaved tau microtubule-associated protein have been correlated with readouts from fluorescent indicators of cytosolic and mitochondrial calcium and mitochondrial membrane potential.²⁹ The relationship of mitochondrial superoxide generation to dopamine transporter activity, measured using the aminostyryl dye substrate 4-Di-1-ASP (D288, see below), has been investigated in mouse brain astrocytes.³⁰ MitoSOX™ Red indicator has been used for confocal microscopy analysis of reactive oxygen species (ROS) production by mitochondrial NO synthase (mtNOS) in permeabilized cat ventricular myocytes³¹ and, in combination with Amplex® Red reagent, for measurement of mitochondrial superoxide and hydrogen peroxide production in rat vascular endothelial cells.³² In addition to imaging and microscope photometry measurements, several flow cytometry applications of MitoSOX™ Red have also been reported. Detailed protocols for simultaneous measurements of mitochondrial superoxide generation and apoptotic markers APC annexin V (A35110, Section 15.5) and SYTOX® Green (S7020, Section 8.1) in human coronary artery endothelial cells by flow cytometry have been published by Mukhopadhyay and co-workers.³³

RedoxSensor™ Red CC-1 Stain

RedoxSensor™ Red CC-1 stain (2,3,4,5,6-pentafluorotetramethyl-dihydrosamine, R14060; Figure 12.2.22) passively enters live cells and is subsequently oxidized in the cytosol to a red-fluorescent product (excitation/emission maxima ~540/600 nm), which then accumulates in the mitochondria. Alternatively, this nonfluorescent probe may be transported to the lysosomes where it is oxidized.

Figure 12.2.21 Selectivity of the MitoSOX™ Red mitochondrial superoxide indicator (M36008). Cell-free systems were used to generate a variety of reactive oxygen species (ROS) and reactive nitrogen species (RNS); each oxidant was then added to a separate 10 μM solution of MitoSOX™ Red reagent and incubated at 37°C for 10 minutes. Excess DNA was added (unless otherwise noted) and the samples were incubated for an additional 15 minutes at 37°C before fluorescence was measured. The Griess Reagent Kit (G7921) (for nitric oxide, peroxynitrite, and nitrite standards only; blue bars) and dihydrorhodamine 123 (DHR 123, (D632); green bars) were employed as positive controls for oxidant generation. Superoxide dismutase (SOD), a superoxide scavenger, was used as a negative control for superoxide. The results show that the MitoSOX™ Red probe (red bars) is readily oxidized by superoxide but not by the other oxidants.

The differential distribution of the oxidized product between mitochondria and lysosomes appears to depend on the redox potential of the cytosol.^{34–36} In proliferating cells, mitochondrial staining predominates; whereas in contact-inhibited cells, the staining is primarily lysosomal (Figure 12.2.23).

JC-1 and JC-9: Dual-Emission Potential-Sensitive Probes

The green-fluorescent JC-1 probe (5,5',6,6'-tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarbocyanine iodide, T3168; Figure 12.2.24) exists as a monomer at low concentrations or at low membrane potential. However, at higher concentrations (aqueous solutions above 0.1 μM) or higher potentials, JC-1 forms red-fluorescent “J-aggregates” that exhibit a broad excitation spectrum and an emission maximum at ~590 nm (Figure 12.2.25, Figure 12.2.26, Figure 12.2.27). Thus, the emission of this cyanine dye can be used as a sensitive measure of mitochondrial membrane potential. Various types of ratio measurements are possible by combining signals from the green-fluorescent JC-1 monomer (absorption/emission maxima ~514/529 nm in water) and the J-aggregate (emission maximum 590 nm), which can be effectively excited anywhere between 485 nm and its absorption maximum at 585 nm (Figure 12.2.28). The ratio of red-to-green JC-1 fluorescence is dependent only on the membrane potential and not on other factors that may influence single-component fluorescence signals, such as mitochondrial size, shape and density. Optical filters designed for fluorescein and

Figure 12.2.22 RedoxSensor™ Red CC-1 (R14060).

Figure 12.2.23 Cellular proliferation state determines the distribution of the oxidized product of RedoxSensor™ Red CC-1 (R14060). Normal rat kidney (NRK) cells in different growth states were stained with RedoxSensor™ Red CC-1. In proliferating cells (left), the oxidized dye accumulates in mitochondria. In quiescent cells (right), the oxidized product localizes in the lysosomes.

tetramethylrhodamine can be used to separately visualize the monomer and J-aggregate forms, respectively. Alternatively, both forms can be observed simultaneously using a standard fluorescein longpass optical filter set. Chen and colleagues have used JC-1 to investigate mitochondrial potentials in live cells by ratiometric techniques^{37–39} (Figure 12.2.29).

Figure 12.2.24 5,5',6,6'-Tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarbocyanine iodide (JC-1, T3168).

Figure 12.2.25 Potential-dependent staining of mitochondria in CCL64 fibroblasts by JC-1 (T3168). The mitochondria were visualized by epifluorescence microscopy using a 520 nm longpass optical filter. Regions of high mitochondrial polarization are indicated by red fluorescence due to J-aggregate formation by the concentrated dye. Depolarized regions are indicated by the green fluorescence of the JC-1 monomers. The image was contributed by Lan Bo Chen, Dana Farber Cancer Institute, Harvard Medical School.

Figure 12.2.26 NIH 3T3 fibroblasts stained with JC-1 (T3168), showing the progressive loss of red J-aggregate fluorescence and cytoplasmic diffusion of green monomer fluorescence following exposure to hydrogen peroxide. Images show the same field of cells viewed before H₂O₂ treatment and 5, 10 and 20 minutes after treatment. The images were contributed by Ildo Nicoletti, Perugia University Medical School.

Figure 12.2.27 Cultured human pre-adipocytes loaded with the ratiometric mitochondrial potential indicator JC-1 (T3168) at 5 μ M for 30 minutes at 37°C. In live cells, JC-1 exists either as a green-fluorescent monomer at depolarized membrane potentials or as an orange-fluorescent J-aggregate at hyperpolarized membrane potentials. Cells were then treated with 50 nM FCCP, a protonophore, to depolarize the mitochondrial membrane. Approximately 10 minutes after the addition of the uncoupler, the cells were illuminated at 488 nm and the emission was collected between 515–545 nm and 575–625 nm. Image contributed by Bob Terry, Bioluminescence A/S, Denmark.

Figure 12.2.33 Tetramethylrosamine chloride (T639).

Figure 12.2.34 Rhodamine 6G chloride (R634).

JC-1 has been combined with Alexa Fluor® 647 annexin V (A23204, Section 15.5) to permit simultaneous assessment of phosphatidylserine externalization and mitochondrial function by flow cytometry.⁴⁰ We also offer JC-1 as part of the MitoProbe™ JC-1 Assay Kit for flow cytometry (M34152, Section 22.3). We have discovered another mitochondrial marker, JC-9 (3,3'-dimethyl- β -naphthoxazolium iodide, D22421; Figure 12.2.30), with a different chemical structure (Figure 12.2.31) but similar potential-dependent spectroscopic properties. However, the green fluorescence of JC-9 is essentially invariant with membrane potential, whereas the red fluorescence is significantly increased at hyperpolarized membrane potentials.

Mitochondrion-Selective Rhodamines and Rosamines

Rhodamine 123

Rhodamine 123 (R302, R22420; Figure 12.2.32) is a cell-permeant, cationic, fluorescent dye that is readily sequestered by active mitochondria without inducing cytotoxic effects.⁴¹ Uptake and equilibration of rhodamine 123 is rapid (a few minutes) compared with dyes such as DASPMI (4-Di-1-ASP, D288), which may take 30 minutes or longer.⁴² Viewed through a fluorescein longpass optical filter, fluorescence of the mitochondria of cells stained by rhodamine 123 appears yellow-green. Viewed through a tetramethylrhodamine longpass optical filter, however, these same mitochondria appear red. Unlike the lipophilic rhodamine and carbocyanine dyes, rhodamine 123 apparently does not stain the endoplasmic reticulum.

Rhodamine 123 has been used with a variety of cell types such as astrocytes, neurons,^{43,44} live bacteria,⁴⁵ plants^{46,47} and human spermatozoa.⁴⁸ Using flow cytometry, researchers employed rhodamine 123 in combination with Hoechst 33342 (H1399, H3570, H21492; Section 12.5) for the characterization of hematopoietic stem cells.⁴⁹ Rhodamine 123 is widely used as a substrate for functional assays of ATP-binding cassette (ABC) drug transporters⁵⁰ (Section 15.6).

Rosamines and Other Rhodamine Derivatives, Including TMRM and TMRE

Other mitochondrion-selective dyes include tetramethylrosamine (T639, Figure 12.2.33), whose fluorescence contrasts well with that of fluorescein for multicolor applications, and rhodamine 6G⁵¹⁻⁵⁴ (R634, Figure 12.2.34), which has an absorption maximum between that of rhodamine 123 and tetramethylrosamine. Tetramethylrosamine and rhodamine 6G have both been used to examine the efficiency of P-glycoprotein-mediated exclusion from multidrug-resistant cells⁵⁵ (Section 15.6). Rhodamine 6G has been employed to study microvascular reperfusion injury⁵⁶ and the stimulation and inhibition of F₁-ATPase from the thermophilic bacterium PS3.⁵⁷

At low concentrations, certain lipophilic rhodamine dyes selectively stain mitochondria in live cells.⁵⁸ We have observed that low concentrations of the hexyl ester of rhodamine B (R648MP) accumulate selectively in mitochondria (Figure 12.2.35) and appear to be relatively

Figure 12.2.30 A viable bovine pulmonary artery endothelial cell incubated with the ratiometric mitochondrial potential indicator, JC-9 (D22421). In live cells, JC-9 exists either as a green-fluorescent monomer at depolarized membrane potentials, or as a red-fluorescent J-aggregate at hyperpolarized membrane potentials.

nontoxic. We have included this probe in our Yeast Mitochondrial Stain Sampler Kit (Y7530, see below for description). At higher concentrations, rhodamine B hexyl ester and rhodamine 6G stain the endoplasmic reticulum of animal cells⁵⁸ (Section 12.4).

The accumulation of tetramethylrhodamine methyl and ethyl esters (TMRM, T668; TMRE, T669) in mitochondria and the endoplasmic reticulum has also been shown to be driven by their membrane potential^{59,60} (Section 22.3). Moreover, because of their reduced hydrophobic character, these probes exhibit potential-independent binding to cells that is 10 to 20 times lower than that seen with rhodamine 6G.⁶¹ Tetramethylrhodamine ethyl ester has been described as one of the best fluorescent dyes for dynamic and *in situ* quantitative measurements—better than rhodamine 123—because it is rapidly and reversibly taken up by live cells.^{62–64} TMRM and TMRE have been used to measure mitochondrial depolarization related to cytosolic Ca²⁺ transients⁶⁵ and to image time-dependent mitochondrial membrane potentials.⁶³ A high-throughput assay utilizes TMRE and our low-affinity Ca²⁺ indicator fluo-5N AM (F14204, Section 19.3) to screen inhibitors of the opening of the mitochondrial transition pore.⁶⁶ Researchers have also taken advantage of the red shift exhibited by TMRM, TMRE and rhodamine 123 upon membrane potential-driven mitochondrial uptake to develop a ratiometric method for quantitating membrane potential.⁶⁷

Reduced Rhodamines and Rosamines

Inside live cells, the colorless dihydrorhodamines and dihydrotetramethylrosamine are oxidized to fluorescent products that stain mitochondria.⁶⁸ However, the oxidation may occur in organelles other than the mitochondria. Dihydrorhodamine 123 (D632, D23806; Figure 12.2.36) reacts with hydrogen peroxide in the presence of peroxidases,⁶⁹ iron or cytochrome *c*⁷⁰ to form rhodamine 123. This reduced rhodamine has been used to monitor reactive oxygen intermediates in rat mast cells⁷¹ and to measure hydrogen peroxide in endothelial cells.⁷⁰ Dihydrorhodamine 6G (D633, Figure 12.2.37) is another reduced rhodamine that has been shown to be taken up and oxidized by live cells.^{72–74} Chloromethyl derivatives of reduced rosamines (MitoTracker® Orange CM-H₂TMRos, M7511; MitoTracker® Red CM-H₂XRos, M7513), which can be fixed in cells by aldehyde-based fixatives, have been described above.

Figure 12.2.36 Dihydrorhodamine 123 (D632).

Figure 12.2.37 Dihydrorhodamine 6G (D633).

Other Mitochondrion-Selective Probes

Carbocyanines

Most carbocyanine dyes with short (C₁–C₆) alkyl chains stain mitochondria of live cells when used at low concentrations (<100 nM); those with pentyl or hexyl substituents also stain the endoplasmic reticulum when used at higher concentrations (>1 μM). DiOC₆(3) (D273) stains mitochondria in live yeast^{75–78} and other eukaryotic cells,^{54,79} as well as sarcoplasmic reticulum in beating heart cells.⁸⁰ It has also been used to demonstrate mitochondria moving along microtubules.⁸¹ Photolysis of mitochondrion- or endoplasmic reticulum-bound

Figure 12.2.35 *Saccharomyces cerevisiae* stained sequentially with the red-fluorescent rhodamine B hexyl ester (R648MP), which selectively labels yeast mitochondria under these conditions, and the green-fluorescent yeast vacuole membrane marker MDY-64 (Y7536). These probes are also provided in our Yeast Mitochondrial Stain Sampler Kit (Y7530) and Yeast Vacuole Marker Sampler Kit (Y7531), respectively. Stained yeast were photographed in a single exposure through an Omega® Optical triple-bandpass filter set.

DiOC₆(3) specifically destroys the microtubules of cells without affecting actin stress fibers, producing a highly localized inhibition of intracellular organelle motility.⁸² We have included DiIC₁(5) and DiOC₂(3) in two of our MitoProbe™ Assay Kits for flow cytometry (M34151, M34150; Section 22.3). Several other potential-sensitive carbocyanine probes described in Section 22.3 also stain mitochondria in live cultured cells.⁵⁴ The carbocyanine DiOC₇(3) (D378), which exhibits spectra similar to those of fluorescein, is a versatile dye that has been reported to be a sensitive probe for mitochondria in plant cells.⁸³

Styryl Dyes

The styryl dyes DASPMI (4-Di-1-ASP, D288) and DASPEI (D426) can be used to stain mitochondria in live cells and tissues.^{84,85} These dyes have large fluorescence Stokes shifts and are taken up relatively slowly as a function of membrane potential. The kinetics of mitochondrial staining with styrylpyridinium dyes has been investigated using the concentration jump method.⁸⁶

Nonyl Acridine Orange

Nonyl acridine orange (A1372) is well retained in the mitochondria of live HeLa cells for up to 10 days, making it a useful probe for following mitochondria during isolation and after cell fusion.^{87–89} The mitochondrial uptake of this metachromatic dye is reported not to

depend on membrane potential. It is toxic at high concentrations⁹⁰ and apparently binds to cardiolipin in all mitochondria, regardless of their energetic state.^{91–94} This derivative has been used to analyze mitochondria by flow cytometry,⁹⁵ to characterize multidrug resistance⁹⁶ (Section 15.6) and to measure changes in mitochondrial mass during apoptosis in rat thymocytes.⁹⁷

Carboxy SNARF®-1 pH Indicator

A special cell-loading technique permits ratiometric measurement of intramitochondrial pH with our SNARF® dyes. Cell loading with 10 μM 5-(and 6-)carboxy SNARF®-1, acetoxymethyl ester, acetate (C1271, C1272; Section 20.2), followed by 4 hours of incubation at room temperature leads to highly selective localization of the carboxy SNARF®-1 dye in mitochondria (Figure 12.2.38), where it responds to changes in mitochondrial pH.⁹⁸

Lucigenin

The well-known chemiluminescent probe lucigenin (L6868) accumulates in mitochondria of alveolar macrophages.⁹⁹ Relatively high concentrations of the dye (~100 μM) are required to obtain fluorescent staining; however, low concentrations reportedly yield a chemiluminescent response to stimulated superoxide generation within the mitochondria.⁹⁹ Molecular Probes® lucigenin has been highly purified to remove a bright blue-fluorescent contaminant that is found in some commercial samples.

Figure 12.2.38 Selective loading of carboxy SNARF®-1 into mitochondria. BHK cells were loaded with 10 μM carboxy SNARF®-1, AM, acetate (C1271, C1272) for 10 minutes, followed by incubation for 4 hours at room temperature. **A)** Confocal image (488 nm excitation) of mitochondrial-selective loading of carboxy SNARF®-1 visualized through a 560–600 nm bandpass filter. **B)** Confocal image of the same cells as in **A**, but using a 605 nm dichroic mirror and a 610 nm longpass filter. **C)** Ratio image (**A** and **B**) of mitochondria in cells pseudocolored to represent different pH levels. **D)** Change in mitochondrial pH following the addition of 10 μM carbonyl cyanide m-chlorophenylhydrazone (CCCP), resulting in a decrease (acidification) of mitochondrial pH. Mitochondrial Transition Pore Assays

Image-iT® LIVE Mitochondrial Transition Pore Assay Kit for Fluorescence Microscopy

The mitochondrial permeability transition pore, a nonspecific channel formed by components from the inner and outer mitochondrial membranes, appears to be involved in the release of mitochondrial components during apoptotic and necrotic cell death. In a healthy cell, the inner mitochondrial membrane is responsible for maintaining the electrochemical gradient that is essential for respiration and energy production. As Ca²⁺ is taken up and released by mitochondria, a low-conductance permeability transition pore appears to flicker between open and closed states.¹⁰⁰ During cell death, the opening of the mitochondrial permeability transition pore dramatically alters the permeability of mitochondria. Continuous pore activation results from mitochondrial Ca²⁺ overload, oxidation of mitochondrial glutathione, increased levels of reactive oxygen species in mitochondria and other pro-apoptotic conditions.¹⁰¹ Cytochrome *c* release from mitochondria and loss of mitochondrial membrane potential are observed subsequent to continuous pore activation.

The Image-iT® LIVE Mitochondrial Transition Pore Assay Kit (I35103), based on published experimentation for mitochondrial transition pore opening,^{102,103} permits a more direct method of measuring mitochondrial permeability transition pore opening than assays relying on mitochondrial membrane potential alone. This assay employs the acetoxymethyl (AM) ester of calcein, a colorless and nonfluorescent ester substrate, and CoCl₂, a quencher of calcein fluorescence, to selectively label mitochondria. Cells are loaded with calcein AM, which passively diffuses into the cells and accumulates in cytosolic compartments, including the mitochondria. Once inside cells, calcein AM is

cleaved by intracellular esterases to liberate the very polar fluorescent dye calcein, which does not cross the mitochondrial or plasma membranes in appreciable amounts over relatively short periods of time. The fluorescence from cytosolic calcein is quenched by the addition of CoCl_2 , while the fluorescence from the mitochondrial calcein is maintained. As a control, cells that have been loaded with calcein AM and CoCl_2 can also be treated with a Ca^{2+} ionophore such as ionomycin (I24222, Section 19.8) to allow entry of excess Ca^{2+} into the cells, which triggers mitochondrial pore activation and subsequent loss of mitochondrial calcein fluorescence. This ionomycin response can be blocked with cyclosporine A, a compound reported to prevent mitochondrial transition pore formation by binding cyclophilin D.

The Image-iT® LIVE Mitochondrial Transition Pore Assay Kit has been tested with HeLa cells and bovine pulmonary artery endothelial cells (BPAEC). Each Image-iT® LIVE Mitochondrial Transition Pore Assay Kit provides sufficient reagents for 100 assays (based on 1 mL labeling volumes), including:

- Calcein AM
- MitoTracker® Red CMXRos, a red-fluorescent mitochondrial stain (excitation/emission maxima ~579/599 nm)
- Hoechst 33342, a blue-fluorescent nuclear stain (excitation/emission maxima ~350/461 nm)
- Ionomycin
- CoCl_2
- Dimethylsulfoxide (DMSO)
- Detailed protocols

MitoProbe™ Transition Pore Assay Kit for Flow Cytometry

The MitoProbe™ Transition Pore Assay Kit (M34153), based on published experimentation for mitochondrial transition pore opening,^{102,103} provides a more direct method of measuring mitochondrial permeability transition pore opening than assays relying on mitochondrial membrane potential alone (Figure 12.2.39). As with the Image-iT® LIVE mitochondrial transition pore assay described above, this assay employs the acetoxymethyl (AM) ester of calcein, a colorless and nonfluorescent esterase substrate, and CoCl_2 , a quencher of calcein fluorescence, to selectively label mitochondria. Cells are loaded with calcein AM, which passively diffuses into the cells and accumulates in cytosolic compartments, including the mitochondria. Once inside cells, calcein AM is cleaved by intracellular esterases to liberate the polar fluorescent dye calcein, which does not cross the mitochondrial or plasma membranes in appreciable amounts over relatively short periods of time. The fluorescence from cytosolic calcein is quenched by the addition of CoCl_2 , while the fluorescence from the mitochondrial calcein is maintained. As a control, cells that have been loaded with calcein AM and CoCl_2 can also be treated with a Ca^{2+} ionophore such as ionomycin (I24222, Section 19.8) to allow entry of excess Ca^{2+} into the cells, which triggers mitochondrial pore activation and subsequent loss of mitochondrial calcein fluorescence. This ionomycin response can be blocked with cyclosporine A, a compound reported to prevent mitochondrial transition pore formation by binding cyclophilin D.

The MitoProbe™ Transition Pore Assay Kit has been tested with Jurkat cells, MH1C1 cells and bovine pulmonary artery endothelial cells (BPAEC). Each MitoProbe™ Transition Pore Assay Kit provides sufficient reagents for 100 assays (based on 1 mL labeling volumes), including:

- Calcein AM
- CoCl_2
- Ionomycin
- Dimethylsulfoxide (DMSO)
- Detailed protocols

Figure 12.2.39 Flow cytometric analysis of Jurkat cells using the MitoProbe™ Transition Pore Assay Kit (M34153). Jurkat cells were incubated with the reagents in the MitoProbe™ Transition Pore Assay Kit and analyzed by flow cytometry. In the absence of CoCl_2 and ionomycin, fluorescent calcein is present in the cytosol as well as the mitochondria, resulting in a bright signal (A). In the presence of CoCl_2 , calcein in the mitochondria emits a signal, but the cytosolic calcein fluorescence is quenched; the overall fluorescence is reduced, as compared with calcein alone (B). When ionomycin, a Ca^{2+} ionophore, and CoCl_2 are added to the cells at the same time that calcein AM is added, the fluorescent signals from both the cytosol and mitochondria are largely abolished (C). The change in fluorescence between panels B and C indicates the continuous activation of mitochondrial permeability transition pores.

Yeast Mitochondrial Stain Sampler Kit

Because fluorescence microscopy has been extensively used to study yeast,¹⁰⁴ we offer a Yeast Mitochondrial Stain Sampler Kit (Y7530). This kit contains sample quantities of five

Figure 12.2.40 The intermediate filaments in bovine pulmonary artery endothelial cells, localized using our anti-desmin antibody (A21283), which was visualized with the Alexa Fluor® 647 goat anti-mouse IgG antibody (A21235). Endogenous biotin in the mitochondria was labeled with Alexa Fluor® 546 streptavidin (S11225) and DNA in the cell was stained with blue-fluorescent DAPI (D1306, D3571, D21490).

Figure 12.2.41 The cytoskeleton of a fixed and permeabilized bovine pulmonary artery endothelial cell detected using mouse monoclonal anti- α -tubulin antibody (A11126), visualized with Alexa Fluor® 647 goat anti-mouse IgG antibody (A21235) and pseudocolored magenta. Endogenous biotin in the mitochondria was labeled with green-fluorescent Alexa Fluor® 488 streptavidin (S11223) and DNA was stained with blue-fluorescent DAPI (D1306, D3571, D21490).

different probes that have been found to selectively label yeast mitochondria. Both well-characterized and proprietary mitochondrion-selective probes are provided:

- Rhodamine 123^{105–108}
- Rhodamine B hexyl ester⁵⁸ (Figure 12.2.35)
- MitoTracker® Green FM*
- SYTO® 18 yeast mitochondrial stain¹⁰⁹
- DiOC₆(3)^{76–78,110–116}

The mitochondrion-selective nucleic acid stain included in this kit—SYTO® 18 yeast mitochondrial stain—exhibits a pronounced fluorescence enhancement upon binding to nucleic acids, resulting in very low background fluorescence even in the presence of dye. SYTO® 18 is an effective mitochondrial stain in live yeast but neither penetrates nor stains the mitochondria of higher eukaryotic cells. Several of the components of the Yeast Mitochondrial Stain Sampler Kit are also available separately.

Avidin Conjugates for Staining Mitochondria

Endogenously biotinylated proteins in mammalian cells, bacteria, yeast and plants—biotin carboxylase enzymes—are present almost exclusively in mitochondria, where biotin synthesis occurs; consequently, mitochondria can be selectively stained by almost any fluorophore- or enzyme-labeled avidin or streptavidin derivative (Section 7.6; Table 7.9; Figure 12.2.40, Figure 12.2.41) without applying any biotinylated ligand.^{117,118} This staining, which can complicate the use of avidin-biotin techniques in sensitive cell-based assays, can be blocked by the reagents in our Endogenous Biotin-Blocking Kit (E21390, Section 7.6).

DATA TABLE 12.2 PROBES FOR MITOCHONDRIA

Cat. No.	MW	Storage	Soluble	Abs	EC	Em	Solvent	Notes
A1372	472.51	L	DMSO, EtOH	495	84,000	519	MeOH	
D273	572.53	D,L	DMSO	484	154,000	501	MeOH	
D288	366.24	L	DMF	475	45,000	605	MeOH	1
D378	600.58	D,L	DMSO	482	148,000	504	MeOH	
D426	380.27	L	DMF	461	39,000	589	MeOH	1
D632	346.38	F,D,L,AA	DMF, DMSO	289	7100	none	MeOH	2, 3
D633	444.57	F,D,L,AA	DMF, DMSO	296	11,000	none	MeOH	2, 3
D22421	532.38	D,L	DMSO, DMF	522	143,000	535	CHCl ₃	4
D23806	346.38	F,D,L,AA	DMSO	289	7100	none	MeOH	3, 5
L6868	510.50	L	H ₂ O	455	7400	505	H ₂ O	6, 7
M7510	427.37	F,D,L	DMSO	551	102,000	576	MeOH	
M7511	392.93	F,D,L,AA	DMSO	235	57,000	none	MeOH	2, 3
M7512	531.52	F,D,L	DMSO	578	116,000	599	MeOH	
M7513	497.08	F,D,L,AA	DMSO	245	45,000	none	MeOH	2, 3
M7514	671.88	F,D,L	DMSO	490	119,000	516	MeOH	
M22425	724.00	F,D,L	DMSO	588	81,000	644	MeOH	
M22426	543.58	F,D,L	DMSO	640	194,000	662	MeOH	
M36008	759.71	F,F,L,AA	DMSO	356	10,000	410	MeCN	2, 8
R302	380.83	F,D,L	MeOH, DMF	507	101,000	529	MeOH	
R634	479.02	F,D,L	EtOH	528	105,000	551	MeOH	
R648MP	627.18	F,D,L	DMF, DMSO	556	123,000	578	MeOH	
R14060	434.41	F,D,L,AA	DMSO	239	52,000	none	MeOH	2, 9
R22420	380.83	F,D,L	MeOH, DMF	507	101,000	529	MeOH	10
T639	378.90	L	DMF, DMSO	550	87,000	574	MeOH	
T668	500.93	F,D,L	DMSO, MeOH	549	115,000	573	MeOH	
T669	514.96	F,D,L	DMSO, EtOH	549	109,000	574	MeOH	
T3168	652.23	D,L	DMSO, DMF	514	195,000	529	MeOH	11

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. Abs and Em of styryl dyes are at shorter wavelengths in membrane environments than in reference solvents such as methanol. The difference is typically 20 nm for absorption and 80 nm for emission, but varies considerably from one dye to another. Styryl dyes are generally nonfluorescent in water.
2. This compound is susceptible to oxidation, especially in solution. Store solutions under argon or nitrogen. Oxidation may be induced by illumination.
3. These compounds are essentially colorless and nonfluorescent until oxidized. Oxidation products (in parentheses) are as follows: D632 and D23806 (R302); D633 (R634); M7511 (M7510); M7513 (M7512).
4. JC-9 exhibits long-wavelength J-aggregate emission at ~635 nm in aqueous solutions and polarized mitochondria.
5. This product is supplied as a ready-made solution in DMSO with sodium borohydride added to inhibit oxidation.
6. L6868 has much stronger absorption at shorter wavelengths (Abs = 368 nm (EC = 36,000 cm⁻¹M⁻¹)).
7. This compound emits chemiluminescence at 470 nm upon oxidation in basic aqueous solutions.
8. The product generated by reaction of M36008 with superoxide has similar spectroscopic properties to E1305.
9. R14060 is colorless and nonfluorescent until oxidized. The spectral characteristics of the oxidation product (2,3,4,5,6-pentafluorotetramethylrosamine) are similar to those of T639.
10. This product is specified to equal or exceed 98% analytical purity by HPLC.
11. JC-1 forms J-aggregates with Abs/Em = 585/590 nm at concentrations above 0.1 μM in aqueous solutions (pH 8.0). (Biochemistry (1991) 30:4480)

PRODUCT LIST 12.2 PROBES FOR MITOCHONDRIA

Cat. No.	Product	Quantity
A1372	acridine orange 10-nonyl bromide (nonyl acridine orange)	100 mg
C10600	CellLight® Mitochondria-GFP *BacMam 2.0*	1 mL
C10601	CellLight® Mitochondria-RFP *BacMam 2.0*	1 mL
D378	3,3'-diheptyloxycarbocyanine iodide (DiOC7(3))	100 mg
D273	3,3'-dihexyloxycarbocyanine iodide (DiOC6(3))	100 mg
D632	dihydrorhodamine 123	10 mg
D23806	dihydrorhodamine 123 *5 mM stabilized solution in DMSO*	1 mL
D633	dihydrorhodamine 6G	25 mg
D426	2-(4-(dimethylamino)styryl)-N-ethylpyridinium iodide (DASPEI)	1 g
D288	4-(4-(dimethylamino)styryl)-N-methylpyridinium iodide (4-Di-1-ASP)	1 g
D22421	3,3'-dimethyl-α-naphthoxycarbocyanine iodide (JC-9; DiNOC1(3))	5 mg
I34154	Image-iT® LIVE Mitochondrial and Nuclear Labeling Kit *counterstains for GFP-expressing cells*	1 kit
I35103	Image-iT® LIVE Mitochondrial Transition Pore Assay Kit *for microscopy*	1 kit
L6868	lucigenin (bis-N-methylacridinium nitrate) *high purity*	10 mg
M34153	MitoProbe™ Transition Pore Assay Kit *for flow cytometry* *100 assays*	1 kit
M36008	MitoSOX™ Red mitochondrial superoxide indicator *for live-cell imaging*	10 x 50 μg
M22426	MitoTracker® Deep Red FM® *special packaging*	20 x 50 μg
M7514	MitoTracker® Green FM® *special packaging*	20 x 50 μg
M7511	MitoTracker® Orange CM-H2TMRos *special packaging*	20 x 50 μg
M7510	MitoTracker® Orange CMTMRos *special packaging*	20 x 50 μg
M7513	MitoTracker® Red CM-H2XRos *special packaging*	20 x 50 μg

PRODUCT LIST 12.2 PROBES FOR MITOCHONDRIA—continued

M7512	MitoTracker® Red CMXRos *special packaging*	20 x 50 µg
M22425	MitoTracker® Red FM* *special packaging*	20 x 50 µg
R14060	RedoxSensor™ Red CC-1 *special packaging*	10 x 50 µg
R302	rhodamine 123	25 mg
R22420	rhodamine 123 *FluoroPure™ grade*	25 mg
R634	rhodamine 6G chloride	1 g
R648MP	rhodamine B, hexyl ester, perchlorate (R 6)	10 mg
T3168	5,5',6,6'-tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarbocyanine iodide (JC-1; CBIC2(3))	5 mg
T669	tetramethylrhodamine, ethyl ester, perchlorate (TMRE)	25 mg
T668	tetramethylrhodamine, methyl ester, perchlorate (TMRM)	25 mg
T639	tetramethylrosamine chloride	25 mg
Y7530	Yeast Mitochondrial Stain Sampler Kit	1 kit

12.3 Probes for Lysosomes, Peroxisomes and Yeast Vacuoles

Molecular Probes® acidotropic reagents can be used to stain lysosomes and yeast vacuoles, as well as several other types of acidic compartments such as trans-Golgi vesicles, endosomes and subpopulations of coated vesicles in fibroblasts, secretory vesicles in insulin-secreting pancreatic β-cells, acrosomes of spermatozoa and plant vacuoles.¹ Lysosomes contain glycosidases, acid phosphatases, elastase, cathepsins, carboxypeptidases and a variety of other proteases. Chapter 10 describes a number of substrates for detecting the activity of these hydrolytic enzymes. An excellent compendium of human diseases that affect intracellular transport processes through lysosomes, Golgi and endoplasmic reticulum (ER) has been published.²

Like lysosomes, peroxisomes are single membrane-bound vesicles that contain digestive enzymes. The chief function of these basic organelles is to enzymatically oxidize fatty acids and to subsequently catalyze the breakdown of H₂O₂, a by-product of fatty acid degradation. Recently, interest in peroxisomes has increased, especially studies related to peroxisomal origin and maintenance.^{3,4} Morphological abnormalities in peroxisomes related to disease states and diet have also been the subject of current research.^{5,6} The SelectFX® Alexa Fluor® 488 Peroxisome Labeling Kit (S34201), described below, provides an antibody-based method for labeling peroxisomes in fixed cells.

LysoTracker® Probes: Acidic Organelle-Selective Cell-Permeant Probes

LysoTracker® Probes

Weakly basic amines selectively accumulate in cellular compartments with low internal pH and can be used to investigate the biosynthesis and pathogenesis of lysosomes.^{7,8} One frequently used probe for acidic organelles, DAMP (D1552), is not fluorescent and therefore must be used in conjunction with anti-DNP antibodies (Section 7.4) directly or indirectly conjugated to a fluorophore or enzyme in order to visualize the staining pattern.⁹ The fluorescent probes neutral red (N3246) and acridine orange (A1301, A3568) are also commonly used for staining acidic organelles, though they lack specificity.^{1,10}

These limitations have motivated us to search for alternative acidic organelle-selective probes, both for short-term and long-term tracking studies. The LysoTracker® probes are fluorescent acidotropic probes

for labeling and tracing acidic organelles in live cells. These probes have several important features, including high selectivity for acidic organelles and effective labeling of live cells at nanomolar concentrations. Furthermore, the LysoTracker® probes are available in several fluorescent colors (Table 12.3, Figure 12.3.1), making them especially suitable for multicolor applications.

The LysoTracker® probes, which comprise a fluorophore linked to a weak base that is only partially protonated at neutral pH, are freely permeant to cell membranes and typically concentrate in spherical organelles (Figure 12.3.2). We have found that the fluorescent LysoTracker® probes must be used at very low concentrations—usually about 50 nM—to achieve optimal selectivity. Their mechanism of retention has not been firmly established but is likely to involve protonation and retention in the organelles' membranes, although staining is generally not reversed by subsequent treatment of the cells with weakly basic cell-permeant compounds. Unfortunately, these lysosomal probes can exhibit an alkalinizing effect on the lysosomes, such that longer incubation with these probes can induce an increase in lysosomal pH. Therefore, we recommend incubating cells with these probes for only one to five minutes before imaging.

The larger acidic compartments of cells stained with LysoTracker® Red DND-99 (L7528; Figure 12.3.3, Figure 12.3.4) usually retain their staining pattern following fixation with aldehydes. Simultaneous staining of lysosomes by two LysoTracker® dyes—LysoTracker® Yellow HCK-123 (L12491) and LysoTracker® Red DND-99 (L7528)—yields identical staining patterns when viewed through either the bandpass filter set appropriate for fluorescein or a longpass filter set appropriate for rhodamine (Figure 12.3.5). The LysoTracker® probes were principally developed for fluorescence microscopy applications. The lysosomal fluorescence in LysoTracker® dye-stained cells may constitute only a portion of total cellular fluorescence due to cellular autofluorescence or nonspecific staining. Consequently, successful application of these probes for quantitating the number of lysosomes by flow cytometry or fluorometry will likely depend on the particular cell lines and staining protocols used.

LysoTracker® Green DND-26 (L7526) was used to identify acidic compartments in a study of a membrane protein that facilitates vesicular sequestration of zinc,¹¹ to visualize acidic organelles labeled with rhodamine B in denervated skeletal muscle¹² and to assess acrosomal

integrity in cryopreserved bovine spermatozoa.¹³ This LysoTracker® probe also proved useful in a continuous assay for the secretion of pulmonary surfactant by exocytosis of lamellar bodies.¹⁴ LysoTracker® Red DND-99 provided researchers with a probe for examining lysosome damage in *Trypanosoma brucei* after specific uptake of cytokine tumor necrosis factor- α ,¹⁵ for studying apoptosis in organogenesis-stage mouse embryos¹⁶ and for determining the subcellular localization of receptor and channel proteins.^{17–19}

Table 12.3 Summary of our LysoTracker® and LysoSensor™ probes.

Cat. No.	Probe	Abs* (nm)	Em* (nm)	pK _a
LysoTracker® Probes				
L7525	LysoTracker® Blue DND-22	373	422	ND
L12491	LysoTracker® Yellow HCK-123	465	535	ND
L7526	LysoTracker® Green DND-26	504	511	ND
L7528	LysoTracker® Red DND-99	577	590	ND
LysoSensor™ Probes				
L7533	LysoSensor™ Blue DND-167	373	425	5.1
L7535	LysoSensor™ Green DND-189	443	505	5.2
L7534	LysoSensor™ Green DND-153	442	505	7.5
L7545	LysoSensor™ Yellow/Blue DND-160	384 329	540 † 440 ‡	3.9
L22460	LysoSensor™ Yellow/Blue 10,000 MW dextran	381 335	521 † 452 ‡	4.2

* Absorption (Abs) and fluorescence emission (Em) maxima, determined in aqueous buffer or methanol; values may vary somewhat in cellular environments. † At pH 3. ‡ At pH 7; this dye has pH-dependent dual-excitation and dual-emission peaks. ND = Not determined.

Figure 12.3.1 Normalized fluorescence emission spectra of 1) LysoTracker® Blue DND-22 (L7525), 2) LysoTracker® Green DND-26 (L7526) and 3) LysoTracker® Red DND-99 (L7528) in aqueous solutions, pH 6.0.

Figure 12.3.3 Bovine pulmonary artery endothelial cells (BPAEC) incubated simultaneously with 50 nM LysoTracker® Red DND-99 (L7528) and 75 nM MitoTracker® Green FM® (M7514) at 37°C for 30 minutes. Both dyes showed excellent cellular retention, even after cells were fixed in 3% glutaraldehyde for 30 minutes. The image was deconvolved using Huygens software (Scientific Volume Imaging, <http://www.svi.nl/>).

Figure 12.3.2 Bovine pulmonary artery endothelial cells simultaneously stained with LysoTracker® Red DND-99 (L7528), a cell-permeant, fixable lysosomal stain, and with 5-(pentafluorobenzoylamino)fluorescein di- β -D-galactopyranoside (PFB-FDG, P11948), a fluorogenic substrate for β -galactosidase. PFB-FDG is nonfluorescent until enzymatically hydrolyzed to green-fluorescent PFB-F. The center image demonstrates colocalization of the LysoTracker® Red DND-99 dye and PFB-F to the lysosomes. The left image was acquired with a bandpass filter set appropriate for fluorescein, the right image was acquired with a bandpass filter set appropriate for Texas Red® dye, and the center image was acquired with a double bandpass optical filter set appropriate for fluorescein and the Texas Red® dye.

Figure 12.3.4 Live bovine pulmonary artery endothelial cells (BPAEC) were first stained with LysoTracker® Red DND-99 (L7528). Then, a solution of dihydrorhodamine 123 (D632, D23806) and Hoechst 33258 (H1398, H3569, H21491) was added and allowed to incubate with the cells for an additional 10 minutes before the cells were subsequently washed and visualized. The green-fluorescent oxidation product (rhodamine 123, R302) localized primarily to the mitochondria. The red-fluorescent LysoTracker® Red DND-99 stain accumulated in the lysosomes, and the blue-fluorescent Hoechst 33258 dye stained the nuclei. The image was acquired with filters appropriate for DAPI, fluorescein and the Texas Red® dye. The image was deconvolved using Huygens software (Scientific Volume Imaging, <http://www.svi.nl/>). 3D reconstruction was performed using Imaris software (Bitplane AG, <http://www.bitplane.com/>).

Figure 12.3.5 Rat fibroblasts stained with LysoTracker® Yellow HCK-123 (L12491) and LysoTracker® Red DND-99 (L7528). The lysosomes fluoresce green when visualized through a bandpass filter set appropriate for fluorescein (right image) and red when visualized through a longpass filter set appropriate for rhodamine (left image).

Figure 12.3.6 Live HeLa cells were transfected using pShooter™ vector pCMV/myc/mito/GFP and Lipofectamine® 2000 transfection reagent and stained with the reagents in the Image-iT® LIVE Lysosomal and Nuclear Labeling Kit (I34202). Lysosomes were stained with LysoTracker® Red DND-99. Cells were visualized using epifluorescence microscopy.

Image-iT® LIVE Lysosomal and Nuclear Labeling Kit

The Image-iT® LIVE Lysosomal and Nuclear Labeling Kit (I34202) provides two stains—red-fluorescent LysoTracker® Red DND-99 dye (excitation/emission maxima ~577/590 nm) and blue-fluorescent Hoechst 33342 dye (excitation/emission maxima when bound to DNA ~350/461 nm)—for highly selective staining of lysosomes and the nucleus, respectively, in live, Green Fluorescent Protein (GFP)–transfected cells (Figure 12.3.6). When used according to the sample protocol, cell-permeant LysoTracker® Red DND-99 dye provides highly selective lysosomal staining with minimal background. A significant amount of specific staining is retained after formaldehyde fixation, although some cytoplasmic background staining may be seen. Hoechst 33342 dye, a cell-permeant nucleic acid stain that is selective for DNA and spectrally similar to DAPI, is UV excitable and emits blue fluorescence when bound to DNA. This dye does not interfere with GFP fluorescence and is retained after fixation and permeabilization. It is not recommended that the dyes be combined into one staining solution; they should instead be used in separate labeling steps, with Hoechst 33342 staining first.

The Image-iT® LIVE Lysosomal and Nuclear Labeling Kit contains:

- LysoTracker® Red DND-99 dye
- Hoechst 33342 dye
- Labeling protocols

Each kit provides enough staining solution for 500 assays using the protocol provided for labeling live, cultured cells that are adhering to coverslips.

LysoSensor™ Probes: Acidic Organelle–Selective pH Indicators

LysoSensor™ Probes

For researchers studying the dynamic aspects of lysosome biogenesis and function in live cells, we have developed the LysoSensor™ probes—fluorescent pH indicators that partition into acidic organelles. The LysoSensor™ dyes are acidotropic probes that appear to accumulate in acidic organelles as the result of protonation. This protonation also relieves the fluorescence quenching of the dye by its weakly basic side chain, resulting in an increase in fluorescence intensity. Thus, the LysoSensor™ reagents exhibit a pH-dependent increase in fluorescence intensity upon acidification, in contrast to the LysoTracker® probes, which exhibit fluorescence that is not substantially enhanced at acidic pH.

We offer four LysoSensor™ reagents that differ in color and pK_a (Table 12.3). Because these probes may localize in the membranes of organelles, it is probable that the pK_a values listed in Table 12.3 will not be equivalent to those measured in cellular environments and that only qualitative and semiquantitative comparisons of organelle pH will be possible. The green-fluorescent LysoSensor™ probes are available with optimal pH sensitivity in either the acidic or neutral range

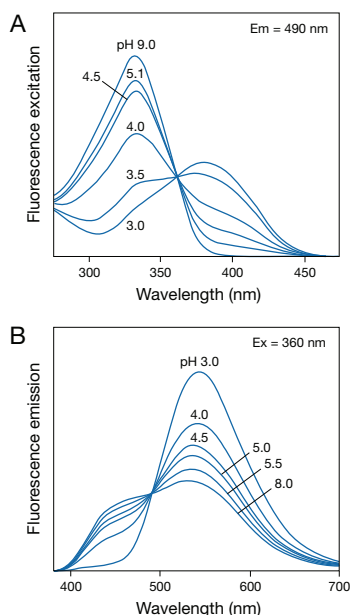

Figure 12.3.7 The pH-dependent spectral response of LysoSensor™ Yellow/Blue DND-160 (L7545): **A**) fluorescence excitation spectra and **B**) fluorescence emission spectra.

Figure 12.3.8 Dual-emission ratiometric measurement of lysosomal pH using LysoSensor™ Yellow/Blue DND-160 (L7545). Madin-Darby canine kidney cells were exposed to pH-calibration buffers (pH 4.5 or 7.0) in the presence of nigericin (N1495) and monensin. These pseudocolored images were constructed from two emission images at 450 ± 33 nm and 510 ± 20 nm, both excited at 365 ± 8 nm.

($pK_a \sim 5.2$ or ~ 7.5 in aqueous buffers). With their low pK_a values, LysoSensor™ Blue DND-167 (L7533) and LysoSensor™ Green DND-189 (L7535) are almost nonfluorescent except when inside acidic compartments, whereas LysoSensor™ Green DND-153 (L7534) is brightly fluorescent at neutral pH. LysoSensor™ Yellow/Blue DND-160 (PDMPO, L7545) is unique in that it exhibits both dual-excitation and dual-emission spectral peaks that are pH dependent (Figure 12.3.7, Figure 12.3.8).

LysoSensor™ Yellow/Blue DND-160 exhibits predominantly yellow fluorescence in acidic organelles, and in less acidic organelles it exhibits blue fluorescence. Dual-emission measurements facilitate ratio imaging of the pH in acidic organelles such as lysosomes,²⁰ myeloid leukemic cells²¹ and acidic vacuoles of plant cells.²² LysoSensor™ Yellow/Blue DND-160, frequently referred to by the acronym PDMPO, has been widely utilized as a tracer of silica deposition and transport in marine diatoms.^{23–26} Kinetic studies on the internalization of LysoSensor™ Yellow/Blue DND-160 indicate that the probe is taken up by live cells within seconds. Unfortunately, this lysosomal probe can exhibit an alkalinizing effect on the lysosomes, such that longer incubation with this probe can induce an increase in lysosomal pH. Therefore, it is a useful pH indicator only when incubation times are kept short; we recommend incubating cells for only one to five minutes before imaging.

The cell-permeant LysoSensor™ probes can be used singly or in combination to investigate the acidification of lysosomes and alterations of lysosomal function or trafficking that occur in cells. For example, lysosomes in some tumor cells have a lower pH than normal lysosomes,²⁷ whereas other tumor cells contain lysosomes with higher pH.²⁸ In addition, cystic fibrosis and other diseases result in defects in the acidification of some intracellular organelles, and the LysoSensor™ probes are useful in studying these aberrations.^{29,30} LysoSensor™ Green DND-189 has been used to selectively label acidic compartments within granule cell neurites³¹ and, along with LysoSensor™ Green DND-153, to examine the acidification of endosomes and lysosomes in a mutant CHO cell line.³² LysoSensor™ Yellow/Blue DND-160 was employed in a study that demonstrated the involvement of lysosomes in the acquired drug-resistance phenotype of a doxorubicin-selected variant of human U-937 myeloid leukemia cells.²¹

As with the LysoTracker® probes, the cell-permeant LysoSensor™ probes were originally developed for fluorescence microscopy applications. The lysosomal fluorescence in LysoSensor™ dye-stained cells may constitute only a portion of total cellular fluorescence due to cellular autofluorescence or nonspecific staining. Therefore, the successful application of these probes for quantitating the number of lysosomes or their pH by flow cytometry or fluorometry will likely depend on the particular cell lines and staining protocols used.

LysoSensor™ Yellow/Blue Dextran

We have prepared a 10,000 MW dextran conjugate of the LysoSensor™ Yellow/Blue dye (L22460). As this labeled dextran is taken up by the cells and moves through the endocytic pathway, the fluorescence of the LysoSensor™ dye changes from blue fluorescent in the near-neutral endosomes to longer-wavelength yellow fluorescent in the acidic lysosomes.³³ The greatest change in fluorescence emission occurs near the pK_a of the dye at pH ~ 3.9 . Unlike the cell-permeant LysoSensor™ dyes, LysoSensor™ Yellow/Blue dextran allows measurement of pH in lysosomes using either fluorescence microscopy (Figure 12.3.9) or flow cytometry.

Figure 12.3.9 Dual-emission ratiometric measurement of lysosomal pH using LysoSensor™ Yellow/Blue dextran (L22460). MDCK cells labeled with the fluorescent dextran were exposed to pH-calibration buffers (pH 3.5 or pH 6.0) in the presence of nigericin (N1495) and monensin. Pseudocolored images were constructed from two emission images at 450 ± 33 nm and 510 ± 20 nm, both excited at 365 ± 8 nm (Chem Biol (1999) 6:411).

Figure 12.3.10 *N*-(3-((2,4-dinitrophenyl)amino)propyl)-*N*-(3-aminopropyl)methylamine, dihydrochloride (DAMP, D1552).

DAMP and Other Lysosomotropic Probes

DAMP

The reagent DAMP (*N*-(3-((2,4-dinitrophenyl)amino)propyl)-*N*-(3-aminopropyl)methylamine, dihydrochloride; D1552; Figure 12.3.10) is a weakly basic amine that is taken up in acidic organelles of live cells. This cell-permeant acidotropic reagent can be detected with anti-DNP antibodies (Section 7.4), including those labeled with Alexa Fluor® 488 dye, biotin, Qdot® 655 nanocrystal or enzymes,⁹ making DAMP broadly applicable for detecting acidic organelles by electron and light microscopy. For example, DAMP has been used to investigate:

- Endocytic and secretory pathways^{34–36}
- Defective acidification of intracellular organelles in cells from cystic fibrosis patients³⁷
- Dependence on pH of the conversion of proinsulin to insulin in beta cells³⁸
- Development of autophagic vacuoles^{39,40}
- Location of intracellular acidic compartments during viral infection⁴¹

Figure 12.3.11 Cellular proliferation state determines the distribution of the oxidized product of RedoxSensor™ Red CC-1 (R14060). Normal rat kidney (NRK) cells in different growth states were stained with RedoxSensor™ Red CC-1. In proliferating cells (top panel), the oxidized dye accumulates in mitochondria. In quiescent cells (bottom panel), the oxidized product localizes in the lysosomes.

Figure 12.3.12 Viable bovine pulmonary artery endothelial cells simultaneously stained with BODIPY™ FL histamine (B22461), MitoTracker™ Red CMXRos (M7512) and Hoechst 33342 (H1399, H3570, H21492). Green-fluorescent BODIPY™ FL histamine localized to lysosomes, red-fluorescent MitoTracker™ Red CMXRos accumulated in the mitochondria, and the blue-fluorescent Hoechst 33342 dye stained the nuclei. This multiple-exposure image was acquired with bandpass filters appropriate for fluorescein, the Texas Red® dye and DAPI.

Figure 12.3.13 Dapoxyl® (2-aminoethyl)sulfonamide (D10460).

Figure 12.3.14 FUN® 1 cell stain (F7030).

As alternatives to DAMP, our cell-permeant fluorescent LysoTracker® and LysoSensor™ probes described above have significant potential in many of these applications. Because they can be visualized directly without any secondary detection reagents, the LysoTracker® and LysoSensor™ reagents enable researchers to study acidic organelles and follow their dynamic processes in live cells.

RedoxSensor™ Red CC-1 Stain

RedoxSensor™ Red CC-1 stain (2,3,4,5,6-pentafluorotetramethyldihydrosamine, R14060) passively enters live cells and is subsequently oxidized in the cytosol to a red-fluorescent product (excitation/emission maxima ~540/600 nm), which then accumulates in the mitochondria. Alternatively, this nonfluorescent probe may be transported to the lysosomes where it is oxidized. The differential distribution of the oxidized product between mitochondria and lysosomes appears to depend on the redox potential of the cytosol.^{42–44} In proliferating cells, mitochondrial staining predominates; whereas in contact-inhibited cells, the staining is primarily lysosomal (Figure 12.3.11). The best method we have found to quantitate the distribution of the oxidized product is to use the mitochondrion-selective MitoTracker® Green FM® stain (M7514) in conjunction with the RedoxSensor™ Red CC-1 stain.⁴⁴

Other Lysosomotropic Probes

BODIPY® FL histamine (B22461) combines the pH-insensitive, bright green-fluorescent BODIPY® FL dye with the weakly basic imidazole moiety of histamine. When used at low concentrations, this probe selectively stains lysosomes (Figure 12.3.12).

As with the LysoTracker® and LysoSensor™ probes, the weak basicity of the amine group in Dapoxyl® (2-aminoethyl)sulfonamide (D10460) leads to its accumulation in acidic organelles. Dapoxyl® (2-aminoethyl)sulfonamide⁴⁵ (Figure 12.3.13) uptake by the acidic lumen of the intact acrosome of mouse sperm is accompanied by significant enhancement of this probe's fluorescence.⁴⁶ The fluorescence of Dapoxyl® (2-aminoethyl)sulfonamide is considerably reduced upon loss of the pH gradient at the onset of the acrosome reaction.⁴⁶

Our high-purity neutral red (N3246) is a common lysosomal probe that stains lysosomes a fluorescent red.^{10,47} It has also been used to determine the number of adherent and nonadherent cells in a microplate assay⁴⁸ and to stain cells in brain tissue.^{49,50}

In addition, dansyl cadaverine^{51,52} (D113) and the DNA intercalator acridine orange^{10,53} (A1301, A3568) have been reported to be useful lysosomotropic reagents. Dansyl cadaverine has been shown to selectively label autophagic vacuoles, at least some of which had already fused with lysosomes; it did not, however, accumulate in early or late endosomes.⁵⁴

Cell-Permeant Probes for Yeast Vacuoles

Biogenesis of the yeast vacuole has been extensively studied as a model system for eukaryotic organelle assembly.^{55–58} Using a combination of genetic and biochemical approaches, researchers have isolated a large collection of yeast vacuolar protein sorting (*vps*) mutants⁵⁹ and characterized the vacuolar H⁺-ATPase (V-ATPase) responsible for compartment acidification.⁶⁰ To facilitate the investigation of yeast vacuole structure and function, we offer membrane-permeant reagents and a Yeast Vacuole Marker Sampler Kit (Y7531).

FUN® 1 Vital Cell Stain for Yeast

The FUN® 1 (Figure 12.3.14) vital cell stain (F7030) exploits endogenous biochemical processing mechanisms that appear to be well conserved among different species of yeast and other fungi.^{61,62} When used at micromolar concentrations, the FUN® 1 cell stain is freely taken up by several species of yeast and fungi and converted from a diffusely distributed pool of yellow-green-fluorescent intracellular stain into compact red-orange-fluorescent intravacuolar structures (Figure 12.3.15). This conversion requires both plasma membrane integrity and metabolic capability. Only metabolically active cells are marked clearly with fluorescent intravacuolar structures, while dead cells exhibit extremely bright, diffuse, yellow-green fluorescence^{63,64} (Figure 12.3.16, Figure 12.3.17). FUN® 1 staining has been used to detect antifungal activity against *Candida* species⁶⁵ and to measure susceptibility of fungi to fungicides by flow cytometry.^{66,67} The FUN® 1 cell stain is also available as a component in the LIVE/DEAD® Yeast Viability Kit (L7009, Section 15.3).

FM[®] 4-64 and FM[®] 5-95

One of our FM[®] styryl dyes, FM[®] 4-64, has been reported to selectively stain yeast vacuolar membranes with red fluorescence⁶⁸ (excitation/emission maxima ~515/640 nm). This styryl dye is proving to be an important tool for visualizing vacuolar organelle morphology and dynamics, for studying the endocytic pathway and for screening and characterizing yeast endocytosis mutants.^{69–74} We offer FM[®] 4-64 in 1 mg vials (T3166) or specially packaged in 10 vials of 100 µg each (T13320). The increasing number of successful applications for our FM[®] dyes has prompted us to synthesize FM[®] 5-95 (T23360), a slightly less lipophilic analog of FM[®] 4-64 with essentially identical spectroscopic properties.

Yeast Vacuole Marker Sampler Kit

The Yeast Vacuole Marker Sampler Kit (Y7531) contains sample quantities of a series of both novel and well-established vacuole marker probes that show promise for the study of yeast cell biology:

- 5-(and 6-)Carboxy-2',7'-dichlorofluorescein diacetate (carboxy-DCFDA)^{55,68,75–79}
- CellTracker™ Blue CMAC⁸⁰
- Aminopeptidase substrate Arg-CMAC (Figure 12.3.18)
- Dipeptidyl peptidase substrate Ala-Pro-CMAC
- Yeast vacuole membrane marker MDY-64⁸¹ (Figure 12.3.19)

Our experiments have demonstrated that several cell-permeant derivatives of 7-amino-4-chloromethylcoumarin (CMAC) are largely sequestered within yeast vacuoles. The corresponding 7-amino-4-methylcoumarin derivatives are known to be substrates for yeast vacuolar enzymes.^{82–84} This sampler kit's three coumarin-based vacuole markers selectively stain the lumen of the yeast vacuole. To complement the blue-fluorescent staining of the lumen, we provide a novel green-fluorescent membrane marker MDY-64 for staining the yeast vacuole membrane. Membrane staining can also be accomplished using the red-fluorescent probe FM[®] 4-64, as described above. The commonly used vacuole marker 5-(and 6-)carboxy-2',7'-dichlorofluorescein diacetate (carboxy-DCFDA) is supplied for use as a standard.^{55,76} Three of the components in the Yeast Vacuole Marker Sampler Kit—CellTracker™ Blue CMAC (C2110, Section 14.2), the proprietary yeast vacuole membrane marker MDY-64^{81,85} (Y7536) and carboxy-DCFDA (C369, Section 15.2)—are also available separately for those researchers who find that one of these dyes is well suited for their application.

Fluorescent Protein–Based Markers for Lysosomes, Peroxisomes and Endosomes

CellLight[®] reagents are BacMam expression vectors encoding site-selective autofluorescent protein fusions. These reagents incorporate all the customary advantages of BacMam delivery technology, including high efficiency transduction of mammalian cells and long-lasting, titratable expression (BacMam Gene Delivery and Expression Technology—Note 11.1). A complete list of our CellLight[®] reagents and their targeting sequences can be found in Table 11.1.

Figure 12.3.15 A culture of *Saccharomyces cerevisiae* incubated in medium containing the FUN[®] 1 viability indicator (F7030) and the counterstain Calcofluor White M2R, both of which are provided in our LIVE/DEAD[®] Yeast Viability Kit (L7009). Metabolically active yeast process the FUN[®] 1 dye, forming numerous red-fluorescent cylindrical structures within their vacuoles. Calcofluor stains the cell walls fluorescent blue, regardless of the yeast's metabolic state. The yeast were photographed in a single exposure through an Omega[®] Optical triple bandpass filter set.

Figure 12.3.16 Fluorescence emission spectra of a *Saccharomyces cerevisiae* suspension that has been stained with the FUN[®] 1 cell stain, which is available separately (F7030) or in the LIVE/DEAD[®] Yeast Viability Kit (L7009). After the FUN[®] 1 reagent was added to the medium, the fluorescence emission spectrum (excited at 480 nm) was recorded in a spectrofluorometer at the indicated times during a 30-minute incubation period. The shift from green (G) to red (R) fluorescence reflects the processing of FUN[®] 1 by metabolically active yeast cells.

Figure 12.3.17 *Saccharomyces cerevisiae* stained with the FUN[®] 1 dye, available separately (F7030) or in our LIVE/DEAD[®] Yeast Viability Kit (L7009). Metabolically active yeast process the FUN[®] 1 dye, forming numerous red fluorescent cylindrical structures within their vacuoles.

Figure 12.3.18 *Saccharomyces cerevisiae* vacuolar lumen stained with 7-amino-4-chloromethylcoumarin, L-arginine amide (Arg-CMAC), available in our Yeast Vacuole Marker Sampler Kit (Y7531). This kit contains three additional fluorescent vacuolar lumen stains plus a green-fluorescent vacuolar membrane stain. After staining, yeast were viewed by epifluorescence and DIC microscopy.

Figure 12.3.19 *Saccharomyces cerevisiae* vacuolar membranes stained with the yeast vacuole membrane marker MDY-64, which is available separately (Y7536) or in our Yeast Vacuole Marker Sampler Kit (Y7531). The kit contains four additional fluorescent vacuolar lumen stains.

Figure 12.3.20 Human aortic smooth muscle cells (HASMC) labeled with CellLight® Lysosomes-RFP (C10597) and CellLight® MAP4-GFP (C10598) reagents and with Hoechst 33342 nucleic acid stain.

Figure 12.3.21 Human aortic smooth muscle cells (HASMC) labeled with CellLight® Early Endosomes-GFP (C10586) and Organelle Lights™ Golgi-OPF reagents and with Hoechst 33342 nucleic acid stain.

Figure 12.3.22 HEK 293 cell labeled with CellLight® Peroxisomes-GFP (C10604) and CellLight® Plasma Membrane-CFP (C10606) reagents.

CellLight® Lysosomes-GFP (C10596) and CellLight® Lysosomes-RFP (C10597, Figure 12.3.20) are BacMam expression vectors encoding fusions of Green Fluorescent Protein (GFP) or Red Fluorescent Protein⁸⁶ (RFP) with the targeting sequence from Lamp1 (lysosomal-associated membrane protein 1). These CellLight® reagents generate lysosomally localized fluorescent labeling in live cells that is retained after fixation and permeabilization procedures—procedures that will dissipate LysoTracker® Red DND-99 staining.⁸⁷ The titratable expression capacity of BacMam vectors is a particularly useful feature in the context of the Lamp1-GFP fusion, as high levels of overexpression have sometimes been found to induce aberrant aggregation of late-endocytic organelles.⁸⁸

CellLight® Early Endosomes-GFP (C10586, Figure 12.3.21) and CellLight® Early Endosomes-RFP (C10587) reagents provide BacMam expression vectors encoding fusions of GFP or RFP with the small GTPase Rab5a. Rab5a fusions with autofluorescent proteins are sensitive and precise early endosome markers for real-time imaging of clathrin-mediated endocytosis in live cells.^{87,89,90}

CellLight® Peroxisome-GFP (C10604, Figure 12.3.22) is a BacMam expression vector encoding GFP C-terminally linked to a peroxisomal targeting sequence⁹¹ (GFP-PTS1). Live-cell imaging with the GFP-PTS1 fusion has provided many insights into normal and pathologically abnormal biogenesis and degradation of peroxisomes and the controlling influence of peroxisome proliferator-activated receptors (PPARs).

SelectFX® Alexa Fluor® 488 Peroxisome Labeling Kit

Peroxisomes, single membrane-bound vesicles found in most eukaryotic cells, function to enzymatically oxidize fatty acids and to subsequently catalyze the breakdown of H₂O₂, a by-product of fatty acid degradation. Peroxisomes are similar in size to lysosomes (0.5–1.5 μm). The SelectFX® Alexa Fluor® 488 Peroxisome Labeling Kit (S34201) provides all the reagents required for labeling peroxisomes in fixed cells, including cell fixation and permeabilization reagents. To specifically detect peroxisomes, this kit uses an antibody directed against peroxisomal membrane protein 70 (PMP 70), which is a high-abundance integral membrane protein in peroxisomes,⁶ and an Alexa Fluor® 488 dye-labeled secondary antibody (Figure 12.3.23). The Alexa Fluor® 488 dye exhibits bright green fluorescence that is compatible with filters and instrument settings appropriate for fluorescein. PMP 70 is significantly induced by administration of hypolipidemic agents, in parallel with peroxisome proliferation and the induction of peroxisomal fatty acid β-oxidation enzymes.⁶

Each SelectFX® Alexa Fluor® 488 Peroxisome Labeling Kit contains:

- Rabbit IgG anti-peroxisomal membrane protein 70 (PMP 70) antibody
- Highly cross-adsorbed Alexa Fluor® 488 goat anti-rabbit IgG antibody
- Concentrated fixative solution
- Concentrated phosphate-buffered saline (PBS)
- Concentrated permeabilization solution
- Concentrated blocking solution
- Detailed protocols for mammalian cell preparation and staining

Figure 12.3.23 Peroxisome labeling in fixed and permeabilized bovine pulmonary artery endothelial cells. Peroxisomes were labeled using an antibody directed at peroxisomal membrane protein 70 (PMP-70) and detected with Alexa Fluor® 488 dye-labeled goat anti-mouse IgG secondary antibody. Mitochondria were stained with MitoTracker® Red CMXRos (M7512) prior to fixation; nuclei were stained with blue-fluorescent DAPI (D1306, D3571, D21490).

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- F7030 is fluorescent when bound to DNA (Em = 538 nm). Uptake and processing of the dye by live yeast results in red-shifted fluorescence (Em ~590 nm).
- L7525 has structured absorption and fluorescence spectra with additional peaks at Abs = 394 nm and Em = 401 nm.
- The pK_a of the dimethylamino substituent of LysoTracker® Red DND-99 is 7.5. (J Biol Chem (2004) 279:32367) The absorption and fluorescence spectra of the dye are insensitive to protonation of this substituent.
- This LysoSensor™ dye exhibits increasing fluorescence as pH decreases with no spectral shift. L7533 has additional absorption and fluorescence emission peaks at Abs = 394 nm and Em = 401 nm.
- LysoSensor™ Yellow/Blue spectra are pH dependent. Abs and Em shift to shorter wavelengths at pH >5.
- The molecular weight is nominally as specified in the product name but may have a broad distribution.
- ND = not determined.
- Spectra of N3246 are pH dependent (pK_a ~6.7). Data reported are for 1:1 (v/v) EtOH/1% acetic acid.
- FM® 4-64 and FM® 5-95 are nonfluorescent in water. For two-color imaging in GFP-expressing cells, these dyes can be excited at 568 nm with emission detection at 690–730 nm. (Am J Physiol Cell Physiol (2001) 281:C624)
- Abs, EC and Em determined for dye bound to detergent micelles (20 mg/mL CHAPS in H₂O). These dyes are essentially nonfluorescent in pure water.

PRODUCT LIST 12.3 PROBES FOR LYSOSOMES, PEROXISOMES AND YEAST VACUOLES

Cat. No.	Product	Quantity
A1301	acridine orange	1 g
A3568	acridine orange *10 mg/mL solution in water*	10 mL
B22461	BODIPY® FL histamine	1 mg
C10586	CellLight® Early Endosomes-GFP *BacMam 2.0*	1 mL
C10587	CellLight® Early Endosomes-RFP *BacMam 2.0*	1 mL
C10596	CellLight® Lysosomes-GFP *BacMam 2.0*	1 mL
C10597	CellLight® Lysosomes-RFP *BacMam 2.0*	1 mL
C10604	CellLight® Peroxisome-GFP *BacMam 2.0*	1 mL
D10460	Dapoxyl® (2-aminoethyl)sulfonamide	10 mg
D113	5-dimethylaminonaphthalene-1-(<i>N</i> -(5-aminopentyl))sulfonamide (dansyl cadaverine)	100 mg
D1552	<i>N</i> -(3-(2,4-dinitrophenyl)amino)propyl)- <i>N</i> -(3-aminopropyl)methylamine, dihydrochloride (DAMP)	100 mg
F7030	FUN® 1 cell stain *10 mM solution in DMSO*	100 µL
I34202	Image-iT® LIVE Lysosomal and Nuclear Labeling Kit *counterstains for GFP-expressing cells*	1 kit
L7533	LysoSensor™ Blue DND-167 *1 mM solution in DMSO* *special packaging*	20 x 50 µL
L7534	LysoSensor™ Green DND-153 *1 mM solution in DMSO* *special packaging*	20 x 50 µL
L7535	LysoSensor™ Green DND-189 *1 mM solution in DMSO* *special packaging*	20 x 50 µL
L22460	LysoSensor™ Yellow/Blue dextran, 10,000 MW, anionic, fixable	5 mg
L7545	LysoSensor™ Yellow/Blue DND-160 (PDMPO) *1 mM solution in DMSO*	20 x 50 µL
L7525	LysoTracker® Blue DND-22 *1 mM solution in DMSO* *special packaging*	20 x 50 µL
L7526	LysoTracker® Green DND-26 *1 mM solution in DMSO* *special packaging*	20 x 50 µL
L7528	LysoTracker® Red DND-99 *1 mM solution in DMSO* *special packaging*	20 x 50 µL
L12491	LysoTracker® Yellow HCK-123 *1 mM solution in DMSO* *special packaging*	20 x 50 µL
N3246	neutral red *high purity*	25 mg
R14060	RedoxSensor™ Red CC-1 *special packaging*	10 x 50 µg
S34201	SelectFX® Alexa Fluor® 488 Peroxisome Labeling Kit *for fixed cells*	1 kit
T3166	<i>N</i> -(3-triethylammoniumpropyl)-4-(6-(4-(diethylamino)phenyl)hexatrienyl)pyridinium dibromide (FM® 4-64)	1 mg
T13320	<i>N</i> -(3-triethylammoniumpropyl)-4-(6-(4-(diethylamino)phenyl)hexatrienyl)pyridinium dibromide (FM® 4-64) *special packaging*	10 x 100 µg
T23360	<i>N</i> -(3-trimethylammoniumpropyl)-4-(6-(4-(diethylamino)phenyl)hexatrienyl)pyridinium dibromide (FM® 5-95)	1 mg
Y7531	Yeast Vacuole Marker Sampler Kit	1 kit
Y7536	yeast vacuole membrane marker MDY-64	1 mg

12.4 Probes for the Endoplasmic Reticulum and Golgi Apparatus

Figure 12.4.1 Fixed and permeabilized osteosarcoma cells simultaneously stained with the fluorescent lectins Alexa Fluor® 488 concanavalin A (Con A) (C11252) and Alexa Fluor® 594 wheat germ agglutinin (WGA) (W11262). Con A selectively binds α -glucopyranosyl residues, whereas WGA selectively binds sialic acid and *N*-acetylglucosaminyl residues. The nuclei were counterstained with blue-fluorescent Hoechst 33342 nucleic acid stain (H1399, H3570, H21492). The image was acquired using bandpass filter sets appropriate for the Texas Red® dye, fluorescein and AMCA.

The endoplasmic reticulum (ER) and Golgi apparatus are primarily responsible for the proper sorting of lipids and proteins in cells.¹ Consequently, most of the cell-permeant probes for these organelles are either lipids or chemicals that affect protein movement. Several of the most effective probes for the Golgi apparatus are fluorescent ceramides and sphingolipids, which are discussed below and in Section 13.3. Certain aspects of lipid trafficking through the ER and Golgi apparatus related to signal transduction are described in Section 17.4. In both live and fixed cells, the flattened membranous sacs of the ER and the Golgi apparatus can be stained with a variety of lipophilic probes and then distinguished by their morphology.

In addition to these fluorescent organelle stains, we offer several CellLight® reagents that comprise BacMam expression vectors encoding targeted autofluorescent proteins for visualizing the endoplasmic reticulum and Golgi apparatus in live mammalian cells. For labeling fixed-cell preparations, we offer the SelectFX® Alexa Fluor® 488 Endoplasmic Reticulum Labeling Kit (S34200), which contains an antibody directed against the ER-associated protein disulfide isomerase (PDI). Enzymes in the ER are also involved in synthesis of cholesterol and in the detoxification of hydrophobic drugs through the cytochrome P450 system (Section 10.6). Furthermore, some fluorescent lectins are useful markers for the Golgi apparatus because several enzymes in this organelle function to glycosylate lipids and proteins (Figure 12.4.1). Nissl bodies principally comprise ordered structures of alternate lamellae of rough endoplasmic reticulum and polyribosome arrays. Our NeuroTrace® fluorescent Nissl stains are described in Section 12.5. An excellent compendium of human diseases that affect intracellular transport processes through lysosomes, Golgi and ER has been published.²

ER-Tracker™ Dyes for Live-Cell Endoplasmic Reticulum Labeling

ER-Tracker™ dyes are cell-permeant, live-cell stains that are highly selective for the ER. These dyes rarely stain mitochondria, unlike the conventional ER stain DiOC₆(3) (D273), and staining at low concentrations does not appear to be toxic to cells. When cells are stained using the optimized protocol provided, staining patterns are retained after treatment with formaldehyde, although at reduced intensities.

ER-Tracker™ Blue-White DPX Dye

ER-Tracker™ Blue-White DPX (E12353, Figure 12.4.2) is a highly selective and photostable stain for the ER in live cells³⁻⁵ (Figure 12.4.3, Figure 12.4.4). ER-Tracker™ Blue-White DPX is a member of our Dapoxyl® dye family⁶ and thus exhibits an unusually large Stokes shift and long-wavelength emission with a high extinction coefficient and high quantum yield when in a hydrophobic environment. Its fluorescence is highly environment sensitive—with increasing solvent polarity, the fluorescence maximum shifts to longer wavelengths (Figure 12.4.5) and the quantum yield decreases—and peak fluorescence emission ranges from 430 nm to 640 nm; we recommend visualizing its ER staining with a standard DAPI or UV longpass optical filter set. The ER-Tracker™ Blue-White DPX dye is also readily visualized by two-photon microscopy.⁷

ER-Tracker™ Green and Red Dyes

ER-Tracker™ Green and ER-Tracker™ Red endoplasmic reticulum stains (E34251, E34250) are fluorescent sulfonylureas—BODIPY® FL glibenclamide (Figure 12.4.6) and BODIPY® TR glibenclamide—which exhibit excitation/emission maxima of ~504/511 nm and 587/615 nm, respectively. Glibenclamide binds to sulfonylurea (SUR) receptors of ATP-sensitive K⁺ channels, which are prominent on ER but may have more disseminated tissue- and cell type-dependent distributions.⁸ BODIPY® FL glibenclamide also generates SUR-independent labeling in some cases.⁹ Despite these mechanistic nuances, ER-Tracker™ Green (Figure 12.4.7) and ER-Tracker™ Red are effective and widely used endoplasmic reticulum markers in live-cell imaging applications.¹⁰⁻¹²

Figure 12.4.2 ER-Tracker™ Blue-White DPX (E12353).

Figure 12.4.3 Live bovine pulmonary artery endothelial cells (BPAEC) stained with ER-Tracker™ Blue-White DPX (E12353), a Dapoxyl® derivative. This image was acquired using a DAPI bandpass optical filter.

Figure 12.4.4 Live bovine pulmonary artery endothelial cells stained with ER-Tracker™ Blue-White DPX (E12353) and MitoTracker® Red CM-H₂XRos (M7513). The endoplasmic reticulum appears green and the mitochondria appear orange. The image was acquired using a fluorescence microscope equipped with a triple-bandpass filter set appropriate for DAPI, fluorescein and Texas Red® dyes.

Figure 12.4.7 Organelle staining of live bovine pulmonary artery endothelial cells. Endoplasmic reticulum was labeled with ER-Tracker™ Green (E34251); mitochondria were visualized with MitoTracker® Red CMXRos (M7512).

Figure 12.4.5 Normalized fluorescence emission spectra of Dapoxyl® (2-aminoethyl)sulfonamide (D10460) in 1) hexane, 2) chloroform, 3) acetone, 4) acetonitrile and 5) 1:1 acetonitrile:water.

Figure 12.4.6 ER-Tracker™ Green (BODIPY® FL glibenclamide, E34251).

with a fluorescein-like fluorescence; ER membranes can easily be distinguished by their characteristic morphology.²³ Caution must be exercised, however, in using the carbocyanines as probes for the ER. It has been reported that ER staining with DiOC₆(3) does not occur until the mitochondria round up and lose the fluorochrome.²⁴ Rhodamine 6G and the hexyl ester of rhodamine B (R634, R648MP; Section 12.2) appear to stain like DiOC₆(3), except they are apparently less toxic and they fluoresce orange, providing possibilities for multicolor labeling.^{23,25} When used at very low concentrations, these slightly lipophilic rhodamine dyes tend to stain only mitochondria of live cells.²⁶

Long-Chain Carbocyanine Dyes

Terasaki and Jaffe have used the long-chain carbocyanines DiIC₁₆(3) and DiIC₁₈(3) (D384, D282) to label ER membranes. They achieved selective labeling of the ER by microinjecting a saturated solution of DiI in oil into sea urchin eggs.^{27,28} This method has been successful in several other egg types but was not effective in molluscan or arthropod axons. As noted in the discussion of dialkylcarbocyanine and dialkylaminostyryl probes in Section 13.4, DiI diffuses only in continuous membranes.

Fluorescent Ceramide Analogs

NBD C₆-ceramide and BODIPY® FL C₅-ceramide (N1154, D3521), both of which can be used with fluorescein optical filter sets, are selective stains for the Golgi apparatus.^{29–31} With spectral properties similar to those of Texas Red® dye, BODIPY® TR ceramide^{32,33} (D7540) is especially useful for double-labeling in combination with Green Fluorescent Protein (GFP) fusion proteins³⁴ (Using Organic Fluorescent Probes in Combination with GFP—Note 12.1), as well as for staining cells and tissues that have substantial amounts of green autofluorescence. In addition, the BODIPY® TR fluorophore is ideal for imaging microscopy with CCD cameras or other red-sensitive detectors. Uptake of fluorescent ceramides, at least in *Paramecium* cells, appears to be an ATP-dependent process.³⁵

Figure 12.4.8 Selective staining of the Golgi apparatus using the green-fluorescent BODIPY® FL C₅-ceramide (D3521) (left). At high concentrations, the BODIPY® FL fluorophore forms excimers that can be visualized using a red longpass optical filter (right). The BODIPY® FL C₅-ceramide accumulation in the trans-Golgi is sufficient for excimer formation (J Cell Biol (1991) 113:1267). Images contributed by Richard Pagano, Mayo Foundation.

NBD Ceramide and NBD Sphingomyelin

NBD C₆-ceramide (N1154) and NBD C₆-ceramide complexed with defatted BSA (N22651) have been used extensively as a selective stain of the trans-Golgi in both live and fixed cells.^{36–43} Complexing fluorescent ceramides with bovine serum albumin (BSA) facilitates cell labeling without requiring the use of organic solvents to dissolve the probe.²⁹ Furthermore, the fluorescence of NBD C₆-ceramide is apparently sensitive to the cholesterol content of the Golgi apparatus, a phenomenon that is not observed with BODIPY® FL C₅-ceramide.⁴⁴ If NBD C₆-ceramide-containing cells are starved for cholesterol, the NBD C₆-ceramide that accumulates within the Golgi apparatus appears to be severely photolabile. However, this NBD photobleaching can be reduced by stimulation of cholesterol synthesis. Thus, NBD C₆-ceramide may be useful in monitoring the cholesterol content of the Golgi apparatus in live cells.⁴⁴

NBD C₆-ceramide's conversion to the NBD C₆-glycosyl ceramide and NBD C₆-sphingomyelin (N3524) has been observed *in vivo*.^{45–47} Metabolism of the probe in live Chinese hamster ovary (CHO) fibroblasts has been used to define lipid-transport pathways.^{45,48} Like NBD C₆-ceramide, NBD C₆-sphingomyelin has been used for the study of lipid trafficking between organelles.⁴⁹ Normal fibroblasts hydrolyze NBD C₆-sphingomyelin and process it through the Golgi apparatus.⁵⁰ However, in human skin fibroblasts from patients with Niemann–Pick disease, which is characterized by a lack of lysosomal sphingomyelinase activity, NBD C₆-sphingomyelin accumulates in the lysosomes.

BODIPY® Ceramides, BODIPY® Sphingomyelin and Related Derivatives

The green-fluorescent BODIPY® FL C₅-ceramide (D3521) is more fade-resistant and brighter than the NBD derivative and can likely be substituted for the NBD C₆-ceramide in many of its applications. The red-fluorescent BODIPY® TR ceramide (D7540) has proven useful for two-color immunofluorescence using a fluorescein-labeled antibody.⁵¹ As with NBD C₆-ceramide, we also offer BODIPY® FL C₅-ceramide and BODIPY® TR ceramide complexed with defatted BSA (B22650, B34400) to facilitate cell labeling without the use of organic solvents to dissolve the probe.²⁹

During normal resting intracellular transport, the kinetics of dye loading and transport may differ somewhat between the BODIPY® and NBD analogs.⁵² BODIPY® FL C₅-ceramide has proven to be an excellent structural marker for the Golgi apparatus, visualized either by fluorescence microscopy^{53,54} or, following diaminobenzidine (DAB) conversion, electron microscopy.^{55–57} BODIPY® FL C₅-ceramide has also been used to:

- Delineate the Golgi apparatus in the cytoarchitecture of size-excluding compartments in live cells⁵⁸
- Investigate both the inhibition of glycoprotein transport by ceramides⁵⁹ and the possible link between protein secretory pathways and sphingolipid biosynthesis⁶⁰
- Isolate mammalian secretion mutants⁶¹
- Study sphingolipid distribution during human keratinocyte differentiation⁶²
- Visualize tubovesicular membranes induced by *Plasmodium falciparum*^{63,64}

BODIPY® FL C₅-ceramide exhibits concentration-dependent fluorescence properties that provide additional benefits for imaging the Golgi apparatus. At high concentrations, the nonpolar BODIPY® FL

fluorophore forms excimers, resulting in a shift of the fluorophore's emission maximum from 515 nm (green) to ~620 nm (red). BODIPY® FL C₅-ceramide accumulation is sufficient for excimer formation in the trans-Golgi but not in the surrounding cytoplasm. Longpass optical filters that isolate the red emission can thus be used to selectively visualize the Golgi apparatus (Figure 12.4.8, Figure 12.4.9). Moreover, this two-color property can be used to quantitate BODIPY® FL C₅-ceramide accumulation by ratio imaging.^{30,60,65} Like BODIPY® FL C₅-ceramide, the red-fluorescent BODIPY® TR ceramide appears to form long-wavelength excimers when concentrated in the Golgi apparatus; in this case, however, the excimers exhibit infrared fluorescence. In an unexpected application, it has been shown that cells infected with some intracellular bacteria, including *Chlamydia psittaci*, accumulate BODIPY® FL C₅-ceramide (D3521) in their inclusion membranes rather than in the Golgi of the host cells.^{66,67} Certain CellTracker™ reagents (Section 14.2) that were used in combination with BODIPY® FL C₅-ceramide were also found to selectively label intracellular bacteria and parasites.⁶⁶

We also offer BODIPY® FL C₅-sphingomyelin (D3522)—the likely metabolic product of BODIPY® FL C₅-ceramide³⁰—as well as BODIPY® FL C₁₂-sphingomyelin⁶⁸ (D7711) and BODIPY® FL C₅-lactosylceramide (D13951, B34402). The concentration-dependent fluorescence shift of BODIPY® FL C₅-sphingomyelin from green to red has been used to follow the initial steps of lipid uptake and transport by early endosomes through the cytoplasm.⁶⁹ BODIPY® FL C₅-glucocerebroside is reportedly internalized by endocytic and nonendocytic pathways that are quite different from those governing the internalization of BODIPY® FL C₅-sphingomyelin⁷⁰ (D3522). Addition of BODIPY® FL C₅-lactosylceramide to the culture medium of cells from patients with sphingolipid-storage diseases (sphingolipidosis) results in fluorescent product accumulation in lysosomes, whereas this probe accumulates in the Golgi apparatus of normal cells and cells from patients with other storage diseases.^{71,72} Pagano and collaborators have published reviews of the use of BODIPY® ceramides and BODIPY® sphingolipids to study the endocytic pathway in mammalian cells.^{29,73}

Fluorescent Protein–Based Markers for the Endoplasmic Reticulum and Golgi Apparatus

CellLight® reagents are BacMam expression vectors encoding site-selective autofluorescent protein fusions. These CellLight® reagents incorporate all the customary advantages of BacMam delivery technology including high efficiency transduction of mammalian cells and long-lasting, titratable expression (BacMam Gene Delivery and Expression Technology—Note 11.1). A complete list of our CellLight® reagents and their targeting sequences can be found in Table 11.1.

The CellLight® ER and Golgi markers are generally useful for identification and demarcation of their respective target organelles in live-cell imaging investigations of protein trafficking. CellLight® ER-GFP (C10590, Figure 12.4.10) and CellLight® ER-RFP (C10591) are BacMam expression vectors encoding fusions of Green Fluorescent Protein (GFP) or Red Fluorescent Protein⁷⁴ (RFP) with the calreticulin ER insertion sequence and the KDEL tetrapeptide retention sequence. Because the localization of CellLight® ER-GFP and CellLight® ER-RFP is directed by cellular protein trafficking infrastructure, it is more specific than that of dyes such as DiOC₆(3), which is largely driven by simple hydrophobic partition.

CellLight® Golgi-GFP (C10592, Figure 12.4.11) and CellLight® Golgi-RFP (C10593) are BacMam expression vectors encoding fusions of GFP or RFP with the human Golgi-resident enzyme *N*-acetylgalactosaminyltransferase 2.⁷⁵

SelectFX® Alexa Fluor® 488 Endoplasmic Reticulum Labeling Kit

The SelectFX® Alexa Fluor® 488 Endoplasmic Reticulum Labeling Kit (S34200) provides all the reagents required to fix and permeabilize mammalian cells and then specifically label the ER. To achieve ER labeling, this kit employs a primary antibody directed against an ER-associated protein, protein disulfide isomerase (PDI), and an Alexa Fluor® 488 dye–labeled secondary antibody. The Alexa Fluor® 488 dye exhibits bright green fluorescence that is compatible with filters and instrument settings appropriate for fluorescein.

Figure 12.4.9 Viable Madin-Darby canine kidney (MDCK) cells sequentially stained with BODIPY® FL C₅-ceramide (D3521, B22650), LysoTracker® Red DND-99 (L7528) and Hoechst 33258 (H1398, H3569, H21491). Green-fluorescent BODIPY® FL C₅-ceramide localized to the Golgi apparatus, red-fluorescent LysoTracker® Red stain accumulated in the lysosomes, and the blue-fluorescent Hoechst 33258 dye stained the nuclei. The multiple-exposure image was acquired with bandpass filters appropriate for fluorescein, Texas Red® dye and DAPI.

Figure 12.4.10 U2OS osteosarcoma cells labeled with CellLight® ER-GFP reagent (C10590) and with Hoechst 33342 nucleic acid stain.

Figure 12.4.11 Human aortic smooth muscle cells (HASMC) labeled with CellLight® Golgi-GFP (C10592) and CellLight® Mitochondria-RFP (C10601) reagents and with Hoechst 33342 nucleic acid stain.

Each SelectFX® Alexa Fluor® 488 Endoplasmic Reticulum Labeling Kit contains:

- Mouse IgG_{2b} anti-protein disulfide isomerase (PDI) antibody
- Highly cross-adsorbed Alexa Fluor® 488 goat anti-mouse IgG antibody
- Concentrated fixative solution
- Concentrated phosphate-buffered saline (PBS)
- Concentrated permeabilization solution
- Concentrated blocking solution
- Detailed protocols for mammalian cell preparation and staining

Lectins for Staining the Golgi Apparatus

Wheat Germ Agglutinin and Concanavalin A

Various proteins and lipids found in the Golgi apparatus are glycosylated; consequently, lectin conjugates (Section 7.7) have been found to be particularly useful for staining Golgi structures in fixed-cell preparations (Figure 12.4.12). Wheat germ agglutinin (WGA) conjugates are commonly used as markers of the trans-Golgi.^{76–78} Fluorescent conjugates of concanavalin A (Con A) also stain the Golgi but with reduced specificity.⁷⁹ We prepare WGA and Con A conjugates whose fluorescence spans the entire visible and near-infrared spectrum (Table 7.10). Our Alexa Fluor® conjugates of these important lectins are particularly recommended for their enhanced brightness and photostability. We also offer a Wheat Germ Agglutinin Sampler Kit (W7024), which contains 1 mg quantities each of WGA conjugates of the Alexa Fluor® 350, Oregon Green® 488, tetramethylrhodamine and Texas Red®-X dyes.

Griffonia simplicifolia Lectin GS-II

Lectin GS-II from *Griffonia simplicifolia* is the only known lectin that binds with high selectivity to terminal, nonreducing α - and β -*N*-acetyl-D-glucosaminyl (GlcNAc) residues of glycoproteins. Because of the affinity of lectin GS-II for GlcNAc, conjugates of

this lectin are useful for staining intermediate-to-trans Golgi—the site of *N*-acetylglucosaminyltransferase activity.⁸⁰ The Golgi apparatus of oligodendrocytes and ganglion neurons are readily stained by fluorescent GS-II conjugates. We have prepared the green-fluorescent Alexa Fluor® 488 (L21415, Figure 12.4.13), red-fluorescent Alexa Fluor® 594 (L21416) and far-red-fluorescent Alexa Fluor® 647 (L32451) conjugates of lectin GS-II for use in Golgi staining.³⁴

Helix pomatia (Edible Snail) Agglutinin

Helix pomatia agglutinin (HPA) selectively binds to terminal α -*N*-acetylgalactosaminyl residues—an intermediate sugar added in *O*-linkage to serine and threonine residues in *cis*-Golgi cisternae and then substituted with galactose and sialic acid in the *trans*-Golgi.⁸¹ HPA conjugates are principally used as markers for the Golgi. Our fluorescent Alexa Fluor® 488 and Alexa Fluor® 647 conjugates of HPA (L11271, L32454) should be particularly useful for Golgi staining.

Brefeldin A

Isolated from from *Penicillium brefeldianum*, brefeldin A (BFA, B7450) has multiple targets in cells.⁸² Exposing cells to BFA causes a distortion in intracellular protein traffic from the ER to the Golgi apparatus and the eventual loss of Golgi apparatus morphology; removal of BFA completely reverses these effects.^{83–88} BFA also alters the morphology of endosomes and lysosomes.⁸⁹ BFA has been used to prevent retinoic acid potentiation of immunotoxins,⁹⁰ to study translocation of proteins in polarized epithelial cells⁹¹ and to investigate the regulation of ADP-ribosylation factor binding to the Golgi apparatus.⁹² BFA action can be monitored using fluorescent endosomal markers such as lucifer yellow CH⁸⁹ (L453, L682, L1177, L12926; Section 14.3) and tetramethylrhodamine-labeled transferrin⁹³ (T2872, Section 16.1). Researchers have also used BFA to detect the intracellular expression of cytokines.^{94,95} BFA disrupts Golgi-mediated intracellular transport and allows cytokines to accumulate, producing an enhanced cytokine signal that can be detected by flow cytometry.

Figure 12.4.12 Microtubules of fixed bovine pulmonary artery endothelial cells localized with mouse monoclonal anti- α -tubulin antibody (A11126), which was subsequently visualized with Alexa Fluor® 350 goat anti-mouse IgG antibody (A11045). Next, the F-actin was labeled with Alexa Fluor® 594 phalloidin (A12381). Finally, the cells were incubated with Alexa Fluor® 488 wheat germ agglutinin (W11261) to stain components of endosomal pathways. The superimposed and pseudocolored images were acquired sequentially using band-pass filter sets appropriate for DAPI, the Texas Red® dye and fluorescein, respectively.

Figure 12.4.13 Fixed and permeabilized NIH 3T3 cells were labeled with the Alexa Fluor® 488 conjugate of lectin GS-II from *Griffonia simplicifolia* (L21415) and counterstained with DAPI (D1306, D3571, D21490). The fluorescent images are shown overlaid with the differential interference contrast (DIC) image.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. Em for BODIPY® FL sphingolipids shifts to ~620 nm when high concentrations of the probe (>5 mol %) are incorporated in lipid mixtures. (*J Cell Biol* (1991) 113:1267)
2. This product is a lipid complexed with bovine serum albumin (BSA). Spectroscopic data are for the free lipid in MeOH.
3. Chloroform is the most generally useful solvent for preparing stock solutions of phospholipids (including sphingomyelins). Glycerophosphocholines are usually freely soluble in ethanol. Most other glycerophospholipids (phosphoethanolamines, phosphatidic acids and phosphoglycerols) are less soluble in ethanol, but solutions up to 1–2 mg/mL should be obtainable, using sonication to aid dispersion if necessary. Labeling of cells with fluorescent phospholipids can be enhanced by addition of cyclodextrins during incubation. (*J Biol Chem* (1999) 274:35359)
4. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
5. ER-Tracker™ Blue-White DPX Abs = 372 nm, Em = 556 nm bound to phospholipid bilayer membranes. The emission spectrum is extremely broad (~200 nm at half-maximum). Fluorescence in water is very weak.
6. Fluorescence of NBD and its derivatives in water is relatively weak. QY and τ increase and Em decreases in aprotic solvents and other nonpolar environments relative to water. (*Biochemistry* (1977) 16:5150, *Photochem Photobiol* (1991) 54:361)

PRODUCT LIST 12.4 PROBES FOR THE ENDOPLASMIC RETICULUM AND GOLGI APPARATUS

Cat. No.	Product	Quantity
B22650	BODIPY® FL C ₅ -ceramide complexed to BSA	5 mg
B34402	BODIPY® FL C ₅ -lactosylceramide complexed to BSA	1 mg
D7540	BODIPY® TR ceramide (<i>N</i> -((4-(4,4-difluoro-5-(2-thienyl)-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-yl)phenoxy)acetyl)sphingosine)	250 µg
B34400	BODIPY® TR ceramide complexed to BSA	5 mg
B7450	brefeldin A *from <i>Penicillium brefeldianum</i> *	5 mg
C10590	CellLight® ER-GFP *BacMam 2.0*	1 mL
C10591	CellLight® ER-RFP *BacMam 2.0*	1 mL
C10592	CellLight® Golgi-GFP *BacMam 2.0*	1 mL
C10593	CellLight® Golgi-RFP *BacMam 2.0*	1 mL
D7711	<i>N</i> -(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-dodecanoyl)sphingosyl phosphocholine (BODIPY® FL C ₁₂ -sphingomyelin) *1 mg/mL in DMSO*	250 µL
D3521	<i>N</i> -(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-pentanoyl)sphingosine (BODIPY® FL C ₅ -ceramide)	250 µg
D13951	<i>N</i> -(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-pentanoyl)sphingosyl 1-β-D-lactoside (BODIPY® FL C ₅ -lactosylceramide)	25 µg
D3522	<i>N</i> -(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-pentanoyl)sphingosyl phosphocholine (BODIPY® FL C ₅ -sphingomyelin)	250 µg
D384	1,1'-dihexadecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate (DiIC ₁₆ (3))	100 mg
D273	3,3'-dihexyloxycarbocyanine iodide (DiOC ₆ (3))	100 mg
D272	3,3'-dipentyloxycarbocyanine iodide (DiOC ₅ (3))	100 mg
D282	1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate ('DiI'; DiIC ₁₈ (3))	100 mg
E12353	ER-Tracker™ Blue-White DPX *for live-cell imaging* *1 mM solution in DMSO*	20 x 50 µL
E34251	ER-Tracker™ Green (BODIPY® FL glibenclamide) *for live-cell imaging*	100 µg
E34250	ER-Tracker™ Red (BODIPY® TR glibenclamide) *for live-cell imaging*	100 µg
L21415	lectin GS-II from <i>Griffonia simplicifolia</i> , Alexa Fluor® 488 conjugate	500 µg
L21416	lectin GS-II from <i>Griffonia simplicifolia</i> , Alexa Fluor® 594 conjugate	500 µg
L32451	lectin GS-II from <i>Griffonia simplicifolia</i> , Alexa Fluor® 647 conjugate	500 µg
L11271	lectin HPA from <i>Helix pomatia</i> (edible snail), Alexa Fluor® 488 conjugate	1 mg
L32454	lectin HPA from <i>Helix pomatia</i> (edible snail), Alexa Fluor® 647 conjugate	1 mg
N1154	NBD C ₆ -ceramide (6-((<i>N</i> -(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoyl)sphingosine)	1 mg
N22651	NBD C ₆ -ceramide complexed to BSA	5 mg
N3524	NBD C ₆ -sphingomyelin (6-((<i>N</i> -(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoyl)sphingosyl phosphocholine)	1 mg
S34200	SelectFX® Alexa Fluor® 488 Endoplasmic Reticulum Labeling Kit *for fixed cells*	1 kit
W11263	wheat germ agglutinin, Alexa Fluor® 350 conjugate	5 mg
W11261	wheat germ agglutinin, Alexa Fluor® 488 conjugate	5 mg
W32464	wheat germ agglutinin, Alexa Fluor® 555 conjugate	5 mg
W11262	wheat germ agglutinin, Alexa Fluor® 594 conjugate	5 mg
W21404	wheat germ agglutinin, Alexa Fluor® 633 conjugate	5 mg
W32466	wheat germ agglutinin, Alexa Fluor® 647 conjugate	5 mg
W32465	wheat germ agglutinin, Alexa Fluor® 680 conjugate	5 mg
W834	wheat germ agglutinin, fluorescein conjugate	5 mg
W6748	wheat germ agglutinin, Oregon Green® 488 conjugate	5 mg
W849	wheat germ agglutinin, tetramethylrhodamine conjugate	5 mg
W21405	wheat germ agglutinin, Texas Red®-X conjugate	1 mg
W7024	Wheat Germ Agglutinin Sampler Kit *four fluorescent conjugates, 1 mg each*	1 kit

12.5 Probes for the Nucleus

This section describes the use of Molecular Probes® nucleic acid stains for visualizing nuclei and chromosomes, as well as for analyzing chromosome banding patterns. The general chemical and spectroscopic properties of these nucleic acid stains are described in Section 8.1. The application of nucleic acid stains to the study of cell viability, cell proliferation and apoptosis is discussed in Chapter 15.

The counterstains described in this section are compatible with a wide range of cytological labeling techniques, including direct or indirect antibody-based detection methods, *in situ* hybridization and the detection of specific subcellular structures with fluorescent probes such as the mitochondrion-selective MitoTracker® reagents (Section 12.2), F-actin-selective phalloidin (Section 11.1) and autofluorescent proteins (Using Organic Fluorescent Probes in Combination with GFP—Note 12.1).

Nuclear Counterstains for Live Cells and Unfixed Tissues

Cell-permeant nucleic acid stains make it possible to stain live cells or tissues that have been minimally processed. Nuclear staining can reveal the natural location of cells in tissues and can provide a means to follow nuclear changes throughout processes such as mitosis and apoptosis (Section 15.5). Most of these dyes have little effect on cell function, allowing live cells to be traced as they move during development or as they infect other cells.

Cell-Permeant Blue-Fluorescent Counterstains

The membrane-permeant Hoechst 33342 dye (H1399, H3570, H21492) has been extensively used for staining the nuclei of live cells. Hoechst 33342 dye shows AT-selective staining, and Hoechst dye-stained cells and tissues show virtually no cytoplasmic staining. Hoechst 33342 is commonly used to distinguish the compact chromatin of apoptotic nuclei, in combination with BrdU labeling to identify replicating cells and to sort cells based on DNA content (Section 15.5).

While not all of the blue-fluorescent cell-permeant SYTO® dyes in Section 8.1 show selective nuclear staining, SYTO® 40 (S11351) shows excellent staining of the nuclei in a freshwater snail embryo (Figure 12.5.1). All of the blue-fluorescent SYTO® dyes listed in Table 8.3 are available individually as solutions in DMSO (Section 8.1) or in a sampler kit (S11350) to facilitate finding the best counterstain for a particular cell or tissue type.

Cell-Permeant Green-Fluorescent Counterstains

Some of the green-fluorescent cell-permeant SYTO® dyes (Table 8.3, Section 8.1) are excellent nuclear stains for live cells in culture (Figure 12.5.2) and for unfixed tissue sections. The green-fluorescent SYTO® 11 dye (S7573) has shown selective nuclear staining in heart tissue, vascular endothelium and cultured myocytes¹ and in cultured aortic vascular smooth muscle cells,² showing promise for broad use in noninvasive confocal laser-scanning microscope investigations. Staining with SYTO® 11 and SYTO® 13 (S7575) dyes facilitated counting cells in brain slices without disrupting the three-dimensional environment.³ Staining with SYTO® 11 dye was used to follow the movement of cells during development in whole-mount zebrafish embryos.⁴ SYTO® 11 dye has also been used to identify meiotic cells in developing brain tissue.⁵ *Trypanosoma cruzi* stained with SYTO® 11 dye can easily be detected within the cells they have infected.⁶ SYTO® 13 dye was used in a double-labeling experiment with BODIPY® 558/568 phalloidin (B3475, Section 11.1) to stain actin fibers, making it possible to look at nuclear changes and cytoskeletal changes concurrently in apoptotic cells.⁷ SYTO® 12 dye (S7574) was used to follow chromosome movement during meiosis in live maize myocytes,⁸ and SYTO® 14 dye (S7576) allowed researchers to follow RNA localization within live cells.^{9,10} SYTO® 16 dye (S7578) served as an effective nuclear counterstain in cultured cells¹¹ and has been used to stain nuclei in whole maize roots.¹²

The green-fluorescent SYTO® dyes listed in Table 8.3 are available individually as solutions in DMSO (Section 8.1) or as components in the SYTO® Green-Fluorescent Nucleic Acid Stain Sampler Kit (S7572). This SYTO® Stain Sampler Kit contains 50 µL each of eight different green-fluorescent SYTO® dyes to facilitate finding the best counterstain for a particular cell or tissue type.

Figure 12.5.1 The developing embryo of a freshwater snail stained with SYTO® 40 blue-fluorescent nucleic acid stain (S11351), a component of the SYTO® Blue Fluorescent Stain Sampler Kit (S11350). A series of z-plane images was acquired with a wide-field optical sectioning confocal microscope. A three-dimensional volume rendering was generated from the deconvolved image series. Image contributed by Bruce Roth and Paul Millard, Molecular Probes®, Inc., and Hillary MacDonald, Applied Precision, Inc.

Figure 12.5.2 Adherent cells from human peripheral blood stained with the SYTO® 13 dye (S7575), one of the six visible light-excitable cell-permeant nucleic acid stains in our SYTO® Green Fluorescent Nucleic Acid Stain Sampler Kit #1 (S7572). The multilobed nuclei of these polymorphonuclear leukocytes are particularly striking in this field of view.

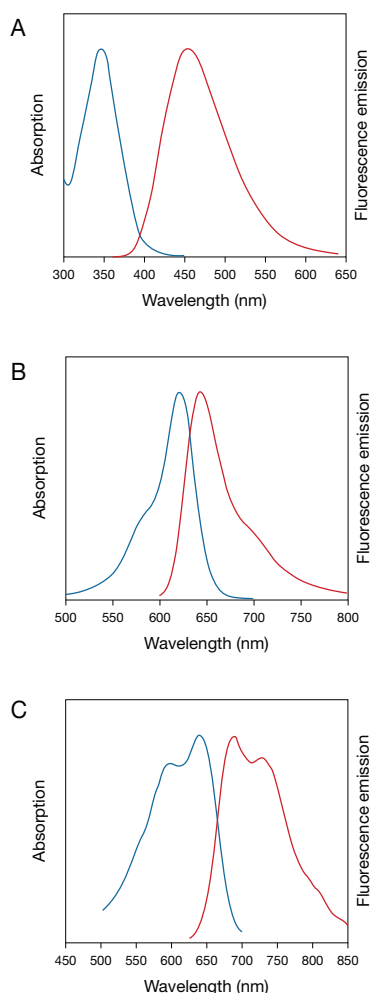

Figure 12.5.3 Absorption and fluorescence emission spectra of A) HCS NuclearMask™ Blue (H10325), B) HCS NuclearMask™ Red (H10326) and C) HCS NuclearMask™ Deep Red (H10294) stains.

Figure 12.5.4 DAPI-stained condensed chromatin in PtK2 cells during the later stages of mitosis. DAPI (D1306, D3571, D21490) binds to the minor groove of DNA with significant fluorescence enhancement.

Figure 12.5.5 Mitotic divisions in early *Drosophila* embryos. The spindles were labeled with an anti- α -tubulin primary antibody and probed with a secondary antibody labeled with Lissamine rhodamine B sulfonyle chloride (L20, L1908). After a brief RNase treatment to reduce background fluorescence, the chromosomes were counterstained with SYTOX® Green nucleic acid stain (S7020). The image was contributed by Tulle Hazelrigg and Amy MacQueen, Columbia University.

Figure 12.5.6 Microtubules of bovine pulmonary artery endothelial cells that have been labeled with mouse monoclonal anti- α -tubulin antibody (A11126), followed by biotin-XX goat anti-mouse IgG antibody (B2763), and then visualized with Marina Blue® streptavidin (S11221). The cells were next treated with RNase, and the chromosomes were labeled with TO-PRO®-3 iodide (T3605). A series of Z-plane images was acquired with a wide-field optical sectioning confocal laser-scanning microscope. A three-dimensional volume rendering was generated from the deconvolved image series.

Cell-Permeant Orange- and Red-Fluorescent Counterstains

The orange- and red-fluorescent cell-permeant SYTO® nucleic acid stains listed in Table 8.3 may also prove useful as nuclear counterstains for live cells. The red-fluorescent SYTO® 17 dye (S7579) was used as a nuclear counterstain for the green-fluorescent membrane stain DiOC₆(3) (D273, Section 12.4) and with fluorescein immunostaining, as well as with the TUNEL apoptosis assay using ChromaTide® fluorescein-12-dUTP (C7604, Section 15.4) to investigate chromatin degradation and denudation of lens tissue.^{13,14} *Leishmania* cells stained with SYTO® 17 dye could later be identified in cells they had infected.¹⁵ SYTO® 59 dye (S11341) has been used as a red-fluorescent nuclear counterstain in combination with the Green Fluorescent Protein (GFP) expressed in lymphoid cells¹⁶ and human embryonic kidney cells¹⁷ (Using Organic Fluorescent Probes in Combination with GFP—Note 12.1). SYTO® 59 dye has also proven very useful in the study of *Cryptosporidium* oocytes because the intensity of staining appears to be related to the infectivity of the oocytes.¹⁸

All of these orange- or red-fluorescent SYTO® dyes are available individually as solutions in DMSO (Section 8.1) or as components in the SYTO® Orange Fluorescent Stain Sampler Kit (S11360) or the SYTO® Red Fluorescent Stain Sampler Kit (S11340), which contain 50 μ L each of six different orange-fluorescent or seven different red-fluorescent SYTO® dyes to facilitate finding the best counterstain for a particular cell or tissue type.

HCS NuclearMask™ and HCS CellMask™ Stains

In image-based high-content screening (HCS) assays, cell or object identification is the first step of automated image acquisition and analysis. For many image analysis algorithms, the cell identification process begins with the detection of fluorescently stained nuclei.^{19–21} Using the position of the stained nucleus as a guide, the software then extrapolates to build a mask that marks the probable position of the cytoplasmic region.

The versatile HCS NuclearMask™ stains, which survive standard formaldehyde-based fixation and detergent-based permeabilization methods, can be applied to live or fixed cells. For additional flexibility in multiplexing experiments, HCS NuclearMask™ reagents are available in three fluorescent colors (Figure 12.5.3):

- HCS NuclearMask™ Blue stain (excitation/emission maxima ~350/461 nm, H10325)
- HCS NuclearMask™ Red stain (excitation/emission maxima ~622/645 nm, H10326)
- HCS NuclearMask™ Deep Red stain (excitation/emission maxima ~638/686 nm, H10294)

These three HCS NuclearMask™ stains leave the wavelength region from 500–600 nm clear for multiplexing with green- or orange-fluorescent probes. Sufficient quantities are provided to stain ten 96-well plates using an assay volume of 100 μ L per well.

In some HCS applications, cell identification based on nuclear staining alone is not adequate because the cytoplasmic region assigned by some image analysis algorithms does not accurately identify the actual cell boundaries. In addition to these HCS NuclearMask™ stains, we offer a series of HCS CellMask™ reagents that label the entire cell (i.e., cytoplasm and the nucleus), designed to provide an accurate backdrop against which to assess the features of interest:

- HCS CellMask™ Blue stain (excitation/emission maxima ~346/442 nm, H32720)
- HCS CellMask™ Green stain (excitation/emission maxima ~493/516 nm, H32714)
- HCS CellMask™ Orange stain (excitation/emission maxima ~556/572 nm, H32713)
- HCS CellMask™ Red stain (excitation/emission maxima ~588/612 nm, H32712)
- HCS CellMask™ Deep Red stain (excitation/emission maxima ~650/655 nm, H32721)

HCS CellMask™ stains are applied to cells immediately after fixation and permeabilization or after labeling with antibodies. Sufficient quantities are provided to stain ten 96-well plates using assay volumes of 100 µL per well.

Tracking Chromosomes through Mitosis

Many nucleic acid stains can be used to observe chromosomes caught in the act of cell division in fixed cells and tissues (Figure 12.5.4, Figure 12.5.5, Figure 12.5.6, Figure 12.5.7). Dimeric cyanine dyes (Table 8.2, Section 8.1) have been used to observe mitotic chromosome movement in live cells. For example, YOYO®-1 dye (Y3601) has been microinjected into cells in order to follow mitotic chromosomes through at least six cell cycles in fertilized sea urchin eggs (M. Terasaki and L. Jaffe, personal communication) (Figure 12.5.8).

Another useful technique for tracking chromosomes through mitosis involves metabolic incorporation of microinjected fluorescent nucleotides, including our fluorescein-12-dUTP (C7604, Section 8.2) by endogenous cellular enzymes into DNA. Incorporation of the fluorescent tracer does not interfere with subsequent progress through the cell cycle, and fluorescent strands of DNA can be followed as they assemble into chromosomes and segregate into daughters and granddaughters.^{22–24}

Fluorescent Protein–Based Markers for the Nucleus

GFP- and RFP-Labeled Nuclear Markers

CellLight® reagents are BacMam expression vectors encoding site-selective autofluorescent protein fusions. These reagents incorporate all the customary advantages of BacMam delivery technology, including high efficiency transduction of mammalian cells and long-lasting, titratable expression (BacMam Gene Delivery and Expression Technology—Note 11.1). A complete list of our CellLight® reagents and their targeting sequences can be found in Table 11.1.

CellLight® Nucleus-GFP (C10602) and CellLight® Nucleus-RFP (C10603) are BacMam expression vectors encoding fusions of Green Fluorescent Protein (GFP) or Red Fluorescent Protein (RFP) with the SV40 nuclear localization sequence (NLS). In addition to general purpose identification and demarcation of the nucleus in live-cell imaging experiments, SV40 NLS-GFP is extensively used for analysis of nucleocytoplasmic transport and nuclear envelope integrity.^{26,27}

CellLight® Histone 2B-GFP (C10594) and CellLight® Histone 2B-RFP (C10595, Figure 12.5.9) are BacMam expression vectors encoding fusions of GFP or RFP with histone 2B. Labeling with histone 2B-GFP is a well established and minimally invasive approach for visualization of chromatin in live cells²⁸ and is particularly useful for real-time imaging of mitotic cell division.

Figure 12.5.7 Mitotic spindles isolated from sea urchin eggs that are labeled with YOYO®-1 iodide (Y3601) and a monoclonal anti-β-tubulin antibody in conjunction with Texas Red® goat anti-rat IgG antibody (T6392). This image was generated by epifluorescence microscopy. Image contributed by John Murray, University of Pennsylvania.

Figure 12.5.8 Using the YOYO®-1 dye to follow cell division in a sea urchin egg. The YOYO®-1 dye (Y3601) was injected into an unfertilized sea urchin egg. The egg was fertilized and then observed by confocal laser-scanning microscopy. Images were obtained every 15 sec in this sequence. Every fourth image is shown in the first part, then every image is shown during chromosome separation. The image was contributed by Mark Terasaki, University of Connecticut Health Center.

Figure 12.5.9 Image montage sampled from a continuous 16-hour time-lapse illustrating cytoskeletal and histone dynamics during mitosis using U2OS osteosarcoma cells transduced with CellLight® Histone 2B-RFP (C10595) and CellLight® MAP4-GFP (C10598) reagents.

Figure 12.5.10 Absorption and fluorescence emission spectra of DAPI bound to DNA.

Figure 12.5.11 FluorCells[®] prepared slide #2 (F14781), which shows bovine pulmonary artery endothelial cells (BPAEC) that have been stained with an anti- β -tubulin mouse monoclonal antibody in conjunction with BODIPY[®] FL goat anti-mouse IgG (B2752) for labeling microtubules, Texas Red[®]-X phalloidin (T7471) for labeling F-actin and DAPI (D1306, D3571, D21490) for labeling nuclei. This multiple-exposure image was acquired using bandpass optical filter sets appropriate for DAPI, fluorescein and Texas Red[®] dye.

Figure 12.5.12 Mouse intestine cryosection showing basement membranes labeled with chicken IgY anti-fibronectin antibody and Alexa Fluor[®] 488 goat anti-chicken IgG antibody (A11039, green). Goblet cells and crypt cells were labeled with Alexa Fluor[®] 594 wheat germ agglutinin (W11262, red). The microvillar brush border and smooth muscle layers were visualized with Alexa Fluor[®] 680 phalloidin (A22286, pseudocolored purple). The section was counterstained with DAPI (D1306, D3571, D21490, blue).

Alexa Fluor[®] 488 Histone H1

The Alexa Fluor[®] 488 conjugate of the lysine-rich calf thymus histone H1 (H13188) is a useful probe for nuclear protein transport assays.²⁹ Nuclear-to-mitochondrial translocation of histone H1 is indicative of dsDNA strand breaks. Fluorescent histone H1 conjugates can also be used to detect membrane-surface exposure of acidic phospholipids such as phosphatidylserine.³⁰

Nuclear Counterstaining of Fixed Cells and Tissues

Blue-Fluorescent Counterstains

DAPI (D1306, D3571, D21490; Figure 12.5.10) is the classic nuclear and chromosome counterstain for identifying nuclei and observing chromosome-banding patterns. DAPI binds selectively to dsDNA and thus shows little to no background staining of the cytoplasm. Its relatively low-level fluorescence emission does not overwhelm signals from green- or red-fluorescent secondary antibodies or FISH probes. DAPI is semipermeant to live cells and can be used on unfixed cells or tissue sections (Figure 12.5.11, Figure 12.5.12). We also offer DAPI premixed with our *SlowFade*[®], *SlowFade*[®] Gold and ProLong[®] Gold antifade reagents (S36938, S36939, P36931, P36935; Section 23.1) for simultaneous nuclear staining and antifade protection.

The Hoechst 33342 dye (H1399, H3570, H21492) has been used widely for staining the nuclei of live cells. Hoechst dyes preferentially bind to AT regions, making them quite selective (but not specific) for DNA; Hoechst dye-stained cells and tissues show virtually no cytoplasmic staining (Figure 12.5.13). The Hoechst 33342 dye is commonly used in combination with labeling by 5-bromo-2'-deoxyuridine (BrdU, B23151; Section 8.2) to distinguish the compact chromatin of apoptotic nuclei, to identify replicating cells and to sort cells based on their DNA content (Section 15.4, Section 15.5).

The blue-fluorescent BOBO[™]-1 nucleic acid stain (B3582) emits a brighter fluorescence signal than does DAPI. BOBO[™]-1 has been used effectively as a counterstain for *Drosophila* chromosomes in combination with Cy³ dye- or fluorescein-labeled antibodies.³¹ SYTOX[®] Blue nucleic acid stain (S11348, S34857) also emits bright blue fluorescence upon binding to nucleic acids and

Figure 12.5.13 Endogenous alkaline phosphatase enzyme of osteosarcoma cells localized with the ELF[®] 97 Endogenous Phosphatase Detection Kit (E6601). Unlike other phosphatase substrates, the unique ELF[®] 97 phosphatase substrate forms a fluorescent precipitate at the site of enzymatic activity. The blue-fluorescent nucleic acid stain Hoechst 33342 (H1399, H3570, H21492) was used as a counterstain to the green fluorescence of the ELF[®] 97 alcohol precipitate. The double-exposure image was acquired using a bandpass filter set appropriate for ELF[®] 97 alcohol and a longpass filter set appropriate for DAPI.

Figure 12.5.14 Absorption and fluorescence emission spectra of SYTOX[®] Blue nucleic acid stain bound to DNA.

Figure 12.5.15 Absorption and fluorescence emission spectra of the SYTOX[®] Green nucleic acid stain bound to DNA.

is a very good nuclear counterstain. Fluorescence emission of the SYTOX® Blue complex with nucleic acids (Figure 12.5.14) somewhat overlaps the emission of fluorescein, Alexa Fluor® 488 and Oregon Green® 488 dyes and thus we recommend SYTOX® Blue dye only as a counterstain for orange- or red-fluorescent dyes.

Green-Fluorescent Counterstains

Some of our cyanine dyes (Table 8.1, Table 8.2, Table 8.3; Section 8.1) have been found to be useful as green-fluorescent nuclear counterstains. YO-PRO®-1 dye (Y3603) and SYTOX® Green stain (S7020, Figure 12.5.15) are excellent nuclear counterstains for cells in culture or for whole-mount tissues³²⁻³⁴ (Figure 12.5.16, Figure 12.5.17, Figure 12.5.18, Figure 12.5.19) and are useful counterstains for tissue sections as well. SYTOX® Green dye shows highly selective nuclear staining; YO-PRO®-1 dye shows more intense staining but also weakly stains the cytoplasm and nucleolus.^{32,33} SYTOX® Green dye has been used to follow changes in nuclear morphology in apoptotic cells (Figure 12.5.20) and is a component in some Molecular Probes® apoptosis assay kits (Section 15.5). SYTOX® Green stain has been used as a specific nuclear counterstain for multicolor labeling in *Drosophila* imaginal disc cells.³⁵ YO-PRO®-1, also a component in some of Molecular Probes® apoptosis assay kits (Section 15.5), is selectively permeant to apoptotic cells, enabling facile identification of this cell population by flow cytometry^{36,37} (Figure 12.5.21). Nuclear staining by YO-PRO®-1 dye has provided a method to identify individual cells within single live, perfused mesentery microvessels.³⁸

Figure 12.5.19 Human cheek epithelial cells labeled with Alexa Fluor® 350 wheat germ agglutinin (W11263) and stained with SYTOX® Green nucleic acid stain (S7020). This multiple-exposure image was acquired using bandpass filter sets appropriate for DAPI and fluorescein.

Figure 12.5.20 Nuclear deformation of an apoptotic cell visualized with the SYTOX® Green dye (S7020). Bovine pulmonary artery endothelial cells were treated with camptothecin for 24 hours, stained with the SYTOX® Green nucleic acid stain and photographed using a fluorescence microscope equipped with a bandpass filter set designed for fluorescein-like dyes.

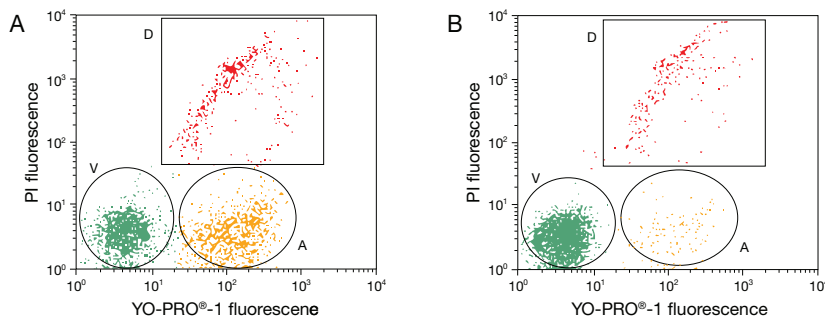

Figure 12.5.21 Flow cytometric analysis of Jurkat cells using the Membrane Permeability/Dead Cell Apoptosis Kit (V13243), which contains YO-PRO®-1 and propidium iodide. Jurkat human T-cell leukemia cells were first exposed to 10 μ M camptothecin for 4 hours (A) or left untreated (as control, B). Cells were then treated with the YO-PRO®-1 and propidium iodide (PI) dyes provided in the Membrane Permeability/Dead Cell Apoptosis Kit and analyzed by flow cytometry. Note that the camptothecin-treated cells (A) have a significantly higher percentage of apoptotic cells (indicated by an "A") than the basal level of apoptosis seen in the control cells (B). V = viable cells, D = dead cells.

Figure 12.5.16 Confocal micrograph illustrating sexual reproduction of the ciliate protist, *Tetrahymena thermophila*, 6 hours after mating. After fixation and permeabilization, the cytoskeleton was labeled with an anti-tubulin antibody and subsequently visualized with Texas Red®-X goat anti-mouse IgG antibody (T6390). The macro- and micronuclei were stained with SYTOX® Green nucleic acid stain (S7020). Image contributed by David Asai and Amy Walanski, Purdue University.

Figure 12.5.17 Macrophages cultured on a polymer surface that have fused to form a foreign-body giant cell following treatment with interleukin-4. Cells were fixed with 3.7% formaldehyde, treated with RNase A and stained with rhodamine phalloidin (R415) to visualize F-actin, and with YO-PRO®-1 iodide (Y3603) to visualize cell nuclei. Cells were imaged with a Bio-Rad® MRC600 confocal laser-scanning microscope. The image is a composite of optical sections taken through the Z-axis of the cell. F-actin (red) is restricted to the periphery of the multinucleated cell and surrounds a cluster of nuclei (green). Image contributed by Kristin DeFife and James M. Anderson, Institute of Pathology, Case Western Reserve University.

Figure 12.5.18 Permeabilized bovine pulmonary artery endothelial cells stained with SYTOX® Green nucleic acid stain (S7020) to label the nuclei and with BODIPY® TR-X phalloidin (B7464) to label the F-actin. The image was acquired by taking sequential exposures through bandpass optical filter sets appropriate for fluorescein and the Texas Red® dye.

Figure 12.5.22 Mouse brain section stained with NeuroTrace® 435/455 blue-fluorescent Nissl stain (N21479) and counterstained with nuclear yellow (N21485).

Figure 12.5.26 Day 10 of development of a *Drosophila* ovarian egg chamber assembly line. The nuclei of follicle and nurse cells were labeled with propidium iodide (P1304MP, P3566, P21493) and visualized by confocal laser-scanning microscopy using excitation by the 568 nm spectral line of an Ar-Kr laser. Image contributed by Sandra Orsulic, University of North Carolina at Chapel Hill.

Figure 12.5.27 Fluorescence excitation and emission spectra of SYTOX® Red nucleic acid stain bound to DNA.

Staining with the TOTO®-1 (T3600) and YOYO®-1 (Y3601) nucleic acid stains enables extremely sensitive flow cytometric analysis of nuclei and isolated human chromosomes.³⁹ In this study, YOYO®-1 dye staining produced more than 1000 times the fluorescence signal obtained with mithramycin; furthermore, histograms of both TOTO®-1 and YOYO®-1 on RNase-treated nuclei provided coefficients of variation that were at least as low as those found with propidium iodide or mithramycin. These researchers also found that when nuclei were simultaneously stained with the YOYO®-1 and Hoechst 33258 (H1398, H3569, H21491) dyes, the ratio of the fluorescence of these two dyes varied as a function of cell cycle. This observation suggests that our cyanine dyes might be useful for examining cell cycle-dependent changes that occur in chromatin structure. YOYO®-1 dye staining also permitted the detection of discrete ribosome-containing domains within the cytoplasm of mature cell axons, which are traditionally thought to contain no transcriptional activity.⁴⁰ In addition, YOYO®-1 dye has been used as a counterstain for immunofluorescent staining of chromatin in the nuclei of developing *Drosophila* embryos.³¹

Yellow-Fluorescent Counterstain

The long-wavelength tracer nuclear yellow (Hoechst S769121, N21485; Figure 12.5.22, Figure 12.5.23) is often combined with the popular retrograde tracer true blue (T1323, Section 14.3) for two-color neuronal mapping. In neuronal cells, nuclear yellow primarily stains the nucleus with yellow fluorescence,^{41–44} whereas true blue is a UV light-excitable, divalent cationic dye (Figure 12.5.24) that stains the cytoplasm with blue fluorescence.^{41,45–48} Both nuclear yellow and true blue are stable when subjected to immunohistochemical processing and can be used to photoconvert DAB into an insoluble, electron-dense reaction product^{49–52} (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2).

Orange-Fluorescent Counterstains

BOBO™-3 (B3586) and SYTOX® Orange (S11368, Figure 12.5.25) cyanine dyes have fluorescence emission that is similar to that of PI, but show greater fluorescence enhancement upon binding to DNA and so should provide brighter nuclear staining. BOBO™-3 dye has been used as a nuclear stain in whole-mount *Xenopus laevis* embryos.⁵³ YOYO®-3 (Y3606) and YO-PRO®-3 (Y3607) dyes show strong and specific staining of the nucleus in most cultured cells.³²

Red-Fluorescent Counterstains

Propidium iodide (PI; P1304MP, P3566, P21493) has long been a preferred dye for red-fluorescent counterstaining of nuclei and chromosomes (Figure 12.5.26). Under some fixation conditions, PI shows highly selective nuclear staining. Other preparations of cells and tissues require a simple treatment with a ribonuclease (RNase) to achieve specific nuclear staining. PI provides an excellent counterstain for cells stained with green-fluorescent probes or secondary antibodies conjugated to Alexa Fluor® 488, Oregon Green®, BODIPY® FL or fluorescein dyes.

SYTOX® Red dead cell stain (excitation/emission maxima ~640/658 nm, S34859) is a high-affinity nucleic acid stain that easily penetrates cells with compromised plasma membranes but will not cross uncompromised cell membranes. After brief incubation with SYTOX® Red stain, the nucleic acids of dead cells fluoresce bright red when excited at 633 nm or 635 nm (Figure 12.5.27). These properties, combined with its >500-fold fluorescence enhancement upon nucleic acid binding, make the SYTOX® Red stain a simple and quantitative single-step dead-cell indicator for use with red laser-equipped flow cytometers. Using 633 nm or 635 nm excitation, SYTOX® Red dead cell stain is distinct from other dead cell probes like 7-AAD and PI, which are excited using 488 nm. The emission of SYTOX® Red stain is limited to one channel with minimal spectral overlap, effectively freeing the channels of the 488 nm laser line.

The long-wavelength TOTO®-3 (T3604) and TO-PRO®-3 (T3605) dyes provide nuclear counterstains whose fluorescence is well separated from that of commonly used fluorophores, such as our popular Alexa Fluor® dyes, Oregon Green®, fluorescein (FITC), rhodamine (TRITC), Texas Red®, coumarin (AMCA), Marina Blue® and Pacific Blue™ dyes. Their long-wavelength spectra make these red-fluorescent nucleic acid stains particularly useful for three- or even four-color labeling using confocal laser-scanning or standard epifluorescence microscopes (Figure 12.5.28, Figure 12.5.29). The absorbance peaks of the TOTO®-3 (Figure 12.5.30) and TO-PRO®-3 (Figure 12.5.31) dyes closely match the 633 nm and 635 nm laser lines of many confocal laser-scanning microscopes and the spectra match filter sets typically used for the Alexa Fluor® 647 and Cy5 dyes.

Long-wavelength light-absorbing dyes have the advantage that their fluorescence is usually not obscured by the autofluorescence of tissues. For example, analysis of fluorescently stained whole-mount *Xenopus laevis* embryos has traditionally been difficult due to the large amount of autofluorescence from the yolk. Two reports have shown that the TO-PRO®-3 dye can be used as a fluorescent nuclear stain in these embryos, allowing them to be analyzed by confocal laser-scanning microscopy. When either the 633 nm or 635 nm spectral lines of a confocal laser-scanning microscope is used with long-wavelength filter sets, the autofluorescence from the yolk is almost completely eliminated.^{53,54}

The TOTO®-3 and TO-PRO®-3 dyes were tested as counterstains for aldehyde-fixed frozen rat tissue sections. The TO-PRO®-3 dye showed less cytoplasmic staining and little overlap with signals from fluorescein- or tetramethylrhodamine-labeled secondary antibodies in the same section.⁵⁵ The TO-PRO®-3 dye gives strong and selective staining of the nucleus in cultured cells.³² A high selectivity for nuclear staining over cytoplasmic staining made TO-PRO®-3 the preferred dye for detecting amplification of the *Her-2/neu* gene by dual-color FISH in paraffin sections.⁵⁶ Although its nucleic acid complex reportedly bleaches relatively rapidly,³² photobleaching can be slowed with antifade reagents such as are provided in our *SlowFade®*, *SlowFade®* Gold, *ProLong®* and *ProLong®* Gold antifade reagents (Section 23.1). Nuclear staining by TO-PRO®-3 dye has been used to study the structure of the nucleus in interphase cells⁵⁷ and to demonstrate segregation of chromosomes during meiosis in mouse oocytes.⁵⁸ TO-PRO®-3 dye was also used to counterstain the chromatin in nuclei of developing *Drosophila* embryos that were immunostained with Cy3 dye- or fluorescein-labeled antibodies.³¹ TOTO®-3 dye has been used as a counterstain for TUNEL assays⁵⁹ and for annexin V-based apoptosis assays⁶⁰ (Section 15.5). TOTO®-3 dye has also been used in combination with Cy3 dye-labeled anti-BrdU antibody staining to show that replicons labeled with BrdU form clusters in the nucleus that are stable through several cell cycles.⁶¹

Figure 12.5.30 Absorption and fluorescence emission spectra of TOTO®-3 bound to DNA.

Figure 12.5.31 Absorption and fluorescence emission spectra of TO-PRO®-3 bound to DNA.

Figure 12.5.28 Immunohistochemical detection using tyramide signal amplification. A transverse section of fixed zebrafish retina was probed with mouse monoclonal FRet 34 antibody and subsequently developed for visualization using HRP-conjugated goat anti-mouse IgG antibody and Alexa Fluor® 488 tyramide, which are supplied in the TSA™ Kit #2 (T20912). The section was counterstained with the blue-fluorescent Alexa Fluor® 350 wheat germ agglutinin (W11263) and the far red-fluorescent TOTO®-3 nuclear stain (T3604).

Figure 12.5.29 Rat brain cryosections were labeled with the red-fluorescent Alexa Fluor® 594 conjugate of anti-glial fibrillary acidic protein antibody (A21295). Nuclei were counterstained with TOTO®-3 iodide (T3604, pseudocolored blue).

Figure 12.5.32 Fluorescence excitation and emission spectra of SYTOX® AADvanced™ dead cell stain bound to DNA.

Figure 12.5.33 A mixture of heat-killed and untreated Jurkat cells were stained with 1 μ M SYTOX® AADvanced™ dead cell stain for 5 minutes. Cells were analyzed on a flow cytometer equipped with a 488 nm laser and a 695/40 nm bandpass filter. Live cells are easily distinguished from the dead cell population.

Figure 12.5.35 Absorption and fluorescence emission spectra for Qnuclear™ Deep Red stain (Q10363).

SYTOX® AADvanced™ Dead Cell Stain

Especially formulated for flow cytometry applications, SYTOX® AADvanced™ dead cell stain (excitation/emission maxima ~546/647 nm; S10274, S10349) labels the nucleic acids of dead cells with a bright red fluorescence when excited with the 488 nm spectral line of the argon-ion laser, with minimal compensation in the green, orange and near-infrared channels (Figure 12.5.32). This high-affinity red-fluorescent nucleic acid stain easily penetrates cells with compromised plasma membranes, but will not cross healthy cell membranes. These properties, combined with its >500-fold fluorescence enhancement upon nucleic acid binding, make the SYTOX® AADvanced™ dead cell stain a simple and quantitative single-step dead-cell indicator (Figure 12.5.33). Labeling of dead cells is achieved very rapidly, typically within 5 minutes. SYTOX® AADvanced™ dead cell stain may also be useful for DNA content cell-cycle analysis with the addition of RNase A in fixed cells.

Qnuclear™ Deep Red Stain

Qnuclear™ Deep Red stain (Q10363) is a bright and photostable nuclear counterstain designed for use with fixed and permeabilized cells that have been labeled with Qdot® nanocrystals (Section 6.6) and mounted in Qmount® Qdot® mounting media (Q10336, Section 23.1) (Figure 12.5.34). With excitation and emission maxima of 640 and 663 nm, respectively (Figure 12.5.35), this counterstain can be visualized with standard fluorescence microscopy filter sets. Qnuclear™ Deep Red stain is compatible with Qdot® 525, 565, 585, 605 and 625 nanocrystals; it can also be used with Qdot® 655 nanocrystals and its conjugates, though care must be taken to use appropriate excitation wavelengths and filter sets given the fluorescence emission overlap.

Qnuclear™ Deep Red stain is provided as a convenient, concentrated dimethylsulfoxide (DMSO) solution with a labeling protocol optimized for cells that have been formaldehyde fixed and permeabilized with Triton X-100; other fixation techniques may result in nonspecific staining or abnormal cellular morphology. Nuclear labeling with Qnuclear™ Deep Red stain should be the last step of the cell-staining protocol.

SelectFX® Nuclear Labeling Kit

The SelectFX® Nuclear Labeling Kit (S33025) provides four spectrally distinct fluorescent dyes—blue-fluorescent DAPI, green-fluorescent SYTOX® Green stain, red-fluorescent 7-amino-actinomycin D (7-AAD) and far-red-fluorescent TO-PRO®-3 dye—for staining nuclei in fixed and permeabilized cells and tissues with essentially no cytoplasmic background staining. When used according to the protocol provided, the dyes in the SelectFX® Nuclear Labeling Kit provide highly selective nuclear staining with little or no cytoplasmic labeling; they are ideal for use as counterstains in multicolor applications. The stained nuclei stand out in vivid contrast to other fluorescently labeled cell structures when observed by fluorescence microscopy. These dyes have excitation wavelengths that match the common laser lines for confocal microscopy and flow cytometry and can be used with standard filter sets on fluorescence microscopes and microplate readers. The staining protocol provided is compatible with a wide range of cytological

Figure 12.5.34 Human carcinoma (HeLa) cell labeled with Qdot® nanocrystals and mounted with Qmount® Qdot® mounting media. Mitochondria were detected with anti-OxPhos complex V inhibitor protein IgG (A21355) and labeled with Qdot® 625 goat F(ab)₂ anti-mouse IgG antibody (A10195, red fluorescence); the Golgi apparatus was detected with rabbit anti-giantin antibody and labeled with Qdot® 585 goat F(ab)₂ anti-rabbit IgG antibody (Q11411MP, yellow fluorescence); tubulin was detected with rat anti-tubulin antibody and labeled with DSB-X™ biotin goat anti-rat IgG antibody (D20697) and Qdot® 525 streptavidin (Q10141MP, green fluorescence). The nucleus was labeled with Qnuclear™ Deep Red Stain (Q10363, purple fluorescence), and the slide was mounted with Qmount® Qdot® mounting media (Q10336).

labeling techniques, including direct or indirect antibody-based detection methods, mRNA *in situ* hybridization and staining methods that incorporate organelle- and cytoskeleton-selective fluorescent probes (including MitoTracker® mitochondrion-selective probes and Alexa Fluor® dye-conjugated phalloidins). The dyes can also be used to fluorescently stain cells for analysis in multicolor flow cytometry experiments. All dyes are provided as stock solutions, convenient for diluting and staining, and each dye is also available separately.

The SelectFX® Nuclear Labeling Kit contains:

- DAPI, a blue-fluorescent counterstain (excitation/emission maxima ~358/451 nm)
- SYTOX® Green, a green-fluorescent counterstain (excitation/emission maxima ~504/523 nm)
- 7-Aminoactinomycin D (7-AAD), a red-fluorescent counterstain (excitation/emission maxima ~546/647 nm)
- TO-PRO®-3 iodide, a far-red-fluorescent counterstain (excitation/emission maxima ~642/661 nm)
- Detailed staining protocols

The SelectFX® Nuclear Labeling Kit contains sufficient reagents to prepare ~100 assays with each stain at 300 µL per assay.

Chromosome Counterstaining

Blue-Fluorescent Chromosome Counterstains

DAPI (D1306, D3571, D21490) is the classic blue-fluorescent nuclear and chromosome counterstain. DAPI binds selectively to dsDNA and thus shows little to no cytoplasmic background staining.⁶²⁻⁶⁴ DAPI's relatively low-level fluorescence emission does not overwhelm signals from green- or red-fluorescent secondary antibodies or FISH probes (Figure 12.5.36, Figure 12.5.37). We also offer DAPI premixed with our *SlowFade*®, *SlowFade*® Gold and ProLong® Gold antifade reagents (S36938, S36939, P36931, P36935). Hoechst 33342 dye (H1399, H3570, H21492) is also commonly used for chromosome counterstaining; SYTOX® Blue nucleic acid stain (S11348, S34857), which is essentially nonfluorescent except when bound to nucleic acids, may be similarly useful.

Green-Fluorescent Chromosome Counterstains

SYTOX® Green (S7020) and YOYO®-1 (Y3601) nucleic acid stains are useful green-fluorescent nuclear counterstains because of their bright nuclear signal and low cytoplasmic background staining. Both dyes show intense green fluorescence upon binding to nucleic acids, and a wash step is not required because the dyes are essentially nonfluorescent in aqueous medium. We have found that both SYTOX® Green and YOYO®-1 dyes provide simple and reliable green-fluorescent counterstains for FISH analysis, though they differ somewhat in their properties and applications. Optimal staining by the YOYO®-1 dye requires RNase treatment for background reduction, whereas SYTOX® Green dye staining does not. In addition, counterstaining with the SYTOX® Green dye is more rapid than YOYO®-1 dye counterstaining. Although the spectral properties of the two green-fluorescent dyes differ slightly, nucleic acids counterstained with either of these green-fluorescent dyes can be efficiently excited with the mercury-arc lamp or argon-ion laser and can be visualized using standard fluorescein optical filter sets.

Red-Fluorescent Chromosome Counterstains

Propidium iodide (PI; P1304MP, P3566, P21493) is the traditional red-fluorescent chromosome counterstain and can be excited with the same excitation filters used for the green-fluorescent probes. Some of our longer-wavelength cyanine dyes, including the YO-PRO®-3, TO-PRO®-3, YOYO®-3 and TOTO®-3 dyes yield red-fluorescent nuclear staining that can be excited without also exciting the fluorescence of green-fluorescent dyes. TO-PRO®-3 (T3605) and TOTO®-3 (T3604) dyes exhibit long-wavelength fluorescence emissions (maxima at ~660 nm, Figure 12.5.30) that are well separated from the emissions of other commonly used fluorophores, such as Texas Red® dye, fluorescein or the Alexa Fluor® dyes that absorb maximally below 600 nm (Section 1.3), making three- or even four-color labeling possible. *Drosophila* polytene chromosomes and nuclei of cultured mammalian cells stained with the TO-PRO®-3 dye have also been detected with two-photon scanning near-field optical microscopy.⁶⁵

Figure 12.5.36 Fluorescence *in situ* hybridization (FISH) mapping of a BAC clone on human metaphase chromosomes. FISH was performed using a BAC clone labeled using the ARES™ Alexa Fluor® 488 DNA Labeling Kit (A21665). The chromosomes were counterstained with DAPI (D1306, D3571, D21490). Image contributed by Nallasivam Palanisamy, Cancer Genetics Inc.

Figure 12.5.37 Human metaphase chromosomes hybridized to fluorescent probes from two overlapping microdissection libraries. Probes specific to chromosome regions 1p34-35 and 1p36 were labeled using the ULYSIS® Oregon Green® 488 (U21659) and Alexa Fluor® 594 (U21654) Nucleic Acid Labeling Kits, respectively. The chromosomes were counterstained with DAPI (D1306, D3571, D21490). Image contributed by Jingwei Yu, Colorado Genetics Laboratory.

Figure 12.5.38 Human metaphase chromosomes stained with SYTOX® Green nucleic acid stain (S7020) and methyl green, and then mounted in Cytoseal 60 mounting medium.

Figure 12.5.39 Human metaphase chromosomes stained with DAPI (D1306, D3571, D21490).

Figure 12.5.40 Pyramidal cells of the hippocampus and dentate gyrus in a transverse cryosection of formaldehyde-fixed mouse brain. NeuroTrace® green fluorescent Nissl stain (N21480) is localized to neuronal somata, while non-neuronal cells can be identified by the presence of DAPI-stained nuclei. This image is a composite of images taken using a 10x objective and filters appropriate for fluorescein and DAPI.

Chromosome Banding Dyes

SYTOX® Green Nucleic Acid Stain

Chromosomes stained with SYTOX® Green dye (S7020) in combination with methyl green—a major-groove-binding dye that binds selectively to AT sequences along the chromosome—exhibit a banding pattern that indicates the location of AT-rich regions (Figure 12.5.38), representing an extremely simple, rapid, fluorescence-based banding method that may prove useful for general karyotype analysis. This observation has been exploited to examine metaphase chromatin structure.⁶⁶ The green-fluorescent SYTOX® Green dye is efficiently excited by the argon-ion laser, permitting analysis of chromosome structure by confocal laser-scanning microscopy. In addition, use of SYTOX® Green dye eliminates the need for RNase treatment of slides.

Acridine Homodimer

The water-soluble acridine homodimer (A666) has extremely high affinity for AT-rich regions of nucleic acids, making it particularly useful for chromosome banding.^{67,68} Acridine homodimer emits a blue-green fluorescence when bound to DNA, yielding fluorescence that is proportional to the fourth power of the AT base-pair content.⁶⁹ Acridine homodimer has been recommended as an alternative to quinacrine for Q banding because of its greater brightness and higher photostability.⁶⁷

Other Chromosome Banding Dyes

A wide variety of fluorescent nucleic acid stains have been used for chromosome banding:^{67,70–72}

- 7-Aminoactinomycin D (7-AAD, A1310) binds selectively to GC regions of DNA,⁷³ yielding a distinct banding pattern in polytene chromosomes and chromatin.^{74,75}
- 9-Amino-6-chloro-2-methoxyacridine (ACMA, A1324) fluoresces with greater intensity in AT-rich regions on chromosomes,⁷⁶ yielding a staining pattern similar to the Q-banding pattern produced with quinacrine.
- DAPI (Figure 12.5.39) or combinations of DAPI or Hoechst 33258 (H1398, H3569, H21491) with nonfluorescent DNA-binding drugs have been used for chromosome-banding studies.⁷⁷
- High-resolution flow karyotyping has also been carried out with DAPI^{78,79} (D1306, D3571, D21490).
- Hoechst 33342 dye (H1399, H3570, H21492) has been used in chromosome sorting, multivariate analysis and karyotyping.⁸⁰
- Hoechst dyes have been employed in combination with chromomycin and a high-resolution, dual-laser method to sort 21 unique human chromosome types onto nitrocellulose filters, followed by hybridization to gene-specific probes.⁸¹

Figure 12.5.41 A mouse brain cryosection stained with the neuron-selective NeuroTrace® 500/525 green-fluorescent Nissl stain (N21480). The nuclei of the non-neuronal cells appear blue after incubation with the cell-permeant DNA counterstain, DAPI (D1306, D3571, D21490). The image is a composite of two micrographs acquired using filter sets appropriate for fluorescein and DAPI.

Figure 12.5.42 Neural somata from a mouse brain section labeled with NeuroTrace® 500/525 green-fluorescent Nissl stain (N21480). Nuclei are labeled with DAPI (D1306, D3571, D21490). Myelin and other lipophilic areas are stained with the red-orange fluorescence from CellTracker™ CM-Dil (C7000, C7001). The image is a composite of three micrographs acquired using filters appropriate for fluorescein, tetramethylrhodamine and DAPI.

NeuroTrace® Fluorescent Nissl Stains

The Nissl substance, described by Franz Nissl more than 100 years ago, is unique to neuronal cells.⁸² Composed of an extraordinary amount of rough endoplasmic reticulum, the Nissl substance reflects the unusually high protein synthesis capacity of neurons. Various fluorescent or chromophoric “Nissl stains” have been used for this counterstaining, including acridine orange,⁸³ ethidium bromide,⁸³ neutral red (N3246, Section 15.2), cresyl violet,⁸⁴ methylene blue, safranin-O and toluidine blue-O.⁸⁵ We have developed five fluorescent Nissl stains (Table 14.2) that not only provide a wide spectrum of fluorescent colors for staining neurons, but also are far more sensitive than the conventional dyes:

- NeuroTrace® 435/455 blue-fluorescent Nissl stain (N21479, Figure 12.5.22)
- NeuroTrace® 500/525 green-fluorescent Nissl stain (N21480; Figure 12.5.40, Figure 12.5.41, Figure 12.5.42)
- NeuroTrace® 515/535 yellow-fluorescent Nissl stain (N21481, Figure 12.5.43)
- NeuroTrace® 530/615 red-fluorescent Nissl stain (N21482; Figure 12.5.44, Figure 12.5.45)
- NeuroTrace® 640/660 deep red-fluorescent Nissl stain (N21483)

In addition, the Nissl substance redistributes within the cell body in injured or regenerating neurons. Therefore, these Nissl stains can also act as markers for physically or chemically induced neurostructural damage.^{86,87} Staining by the Nissl stains is completely eliminated by pretreatment of tissue specimens with RNase; however, these dyes are not specific stains for RNA in solutions. The strong fluorescence (emission maximum ~515–520 nm) of NeuroTrace® 500/525 green-fluorescent Nissl stain (N21480) makes it a good choice for use as a counterstain in combination with orange- or red-fluorescent neuroanatomical tracers such as DiI⁸⁸ (D282, D3911, V22885; Section 14.4).

Figure 12.5.43 Mouse brain section stained with NeuroTrace® 515/535 yellow-fluorescent Nissl stain (N21481) and counterstained with nuclear yellow (N21485).

Figure 12.5.44 Neurons in a mouse cerebellum section labeled with NeuroTrace® 530/615 red-fluorescent Nissl stain (N21482). The Nissl substance, ribosomal RNA associated with the rough endoplasmic reticulum, is specific to neuronal cells. Other cells in the sample are identified with the contrasting nuclear counterstain nuclear yellow (N21485). Smaller neurons appear to be labeled primarily with the nuclear yellow stain. This image is a composite of two micrographs acquired using a DAPI longpass filter set and a filter set appropriate for tetramethylrhodamine.

Figure 12.5.45 Neural somata labeled with NeuroTrace® 530/615 red-fluorescent Nissl stain (N21482). Nuclei in this mouse cerebellum section were counterstained with DAPI (D1306, D3571, D21490). The image is a composite of two micrographs acquired using filters appropriate for tetramethylrhodamine and DAPI.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

- Notes**
1. Spectra represent aqueous solutions of nucleic acid-bound dye. EC values are derived by comparing the absorbance of the nucleic acid-bound dye with that of free dye in a reference solvent (H₂O or MeOH).
 2. Spectra of this compound are in methanol acidified with a trace of HCl.
 3. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
 4. Although this compound is soluble in water, preparation of stock solutions in water is not recommended because of possible adsorption onto glass or plastic.
 5. This product is essentially nonfluorescent except when bound to DNA or RNA.
 6. DAPI in H₂O: Abs = 342 nm (EC = 28,000 cm⁻¹M⁻¹), Em = 450 nm. The fluorescence quantum yield of DAPI bound to dsDNA is 0.34, representing an ~20-fold increase relative to the free dye in H₂O. (*Photochem Photobiol* (2001) 73:585)
 7. This product is specified to equal or exceed 98% analytical purity by HPLC.
 8. MW is for the hydrated form of this product.
 9. The fluorescence quantum yield of Hoechst 33258 bound to dsDNA is 0.42, representing an ~30-fold increase relative to the free dye in H₂O. (*Photochem Photobiol* (2001) 73:585)
 10. The fluorescence quantum yield of Hoechst 33342 bound to dsDNA is 0.38, representing an ~10-fold increase relative to the free dye in H₂O. (*Photochem Photobiol* (2001) 73:585)
 11. The active ingredient of this product is an organic dye with MW <1000. The exact MW and extinction coefficient values for this dye are proprietary.
 12. Propidium iodide in H₂O: Abs = 493 nm (EC = 5900 cm⁻¹M⁻¹), Em = 636 nm (weakly fluorescent). Fluorescence is enhanced >10-fold on binding to dsDNA.
 13. MW: The preceding ~ symbol indicates an approximate value, not including counterions.

PRODUCT LIST 12.5 PROBES FOR THE NUCLEUS

Cat. No.	Product	Quantity
A1310	7-aminoactinomycin D (7-AAD)	1 mg
A1324	9-amino-6-chloro-2-methoxyacridine (ACMA)	100 mg
B3582	BOBO™-1 iodide (462/481) *1 mM solution in DMSO*	200 µL
B3586	BOBO™-3 iodide (570/602) *1 mM solution in DMSO*	200 µL
C10594	CellLight® Histone 2B-GFP *BacMam 2.0*	1 mL
C10595	CellLight® Histone 2B-RFP *BacMam 2.0*	1 mL
C10602	CellLight® Nucleus-GFP *BacMam 2.0*	1 mL

13.1 Introduction to Membrane Probes

Fluorescent and Biotinylated Membrane Probes

The plasma membranes and intracellular membranes of live cells and the artificial membranes of liposomes represent a significant area of application for fluorescent probes. Membrane probes include fluorescent analogs of natural lipids, as well as lipophilic organic dyes that have little structural resemblance to natural biomolecules. We offer a wide range of both types of membrane probes. These probes are used for structural and biophysical analysis of membranes, for following lipid transport and metabolism in live cells (Figure 13.1.1) and for investigating synaptosome recycling (Section 16.1) and lipid-mediated signal transduction processes (Chapter 17). Due to their low toxicity and stable retention, some lipid probes are particularly useful for long-term cell tracing (Section 14.4). Other, slightly less lipophilic probes are used as membrane markers of endocytosis and exocytosis (Section 16.1).

Figure 13.1.1 The cytoplasm of a live zebrafish embryo labeled with the green-fluorescent lipophilic tracer BODIPY[®] 505/515 (D3921). The image was contributed by Arantza Barrios, University College, London.

Fluorescent Analogs of Natural Lipids

We offer fluorescent and, in a few cases, biotinylated analogs of five naturally occurring lipid classes—phospholipids, sphingolipids (including ceramides), fatty acids, triglycerides and steroids. Phospholipids are the principal building blocks of cell membranes. Most phospholipids are derivatives of glycerol comprising two fatty acyl residues (nonpolar tails) and a single phosphate ester substituent (polar head group). Despite their overall structural similarity (Figure 13.1.2), natural phospholipids exhibit subtle differences in their fatty acid compositions, degree of acyl

Figure 13.1.2 A) Phosphatidylcholines, phosphatidylinositols and phosphatidic acids are examples of glycerolipids derived from glycerol. B) Sphingomyelins, ceramides and cerebroside are examples of sphingolipids derived from sphingosine. In all the structures shown, R represents the hydrocarbon tail portion of a fatty acid residue.

chain unsaturation and type of polar head group.¹ These differences can produce significant variations in membrane physical properties, in the location of phospholipids in a lipid bilayer and in their biological activity. Fluorescent phospholipid analogs (Section 13.2) can be classified according to where the fluorophore is attached. The fluorophore can be attached to one (or both) of the fatty acyl chains or to the polar head group. The attachment position of the fluorophore determines whether it is located in the nonpolar interior or at the water/lipid interface when the phospholipid analog is incorporated into a lipid bilayer membrane.

Fatty acids are the building blocks for a diverse set of biomolecules. Some fatty acids (e.g., arachidonic acid) are important in cell signaling.² Fatty acids are liberated by the enzymatic action of phospholipase A on phospholipids (Section 17.4) and also by various other lipases. Fluorescent fatty acids can often be used interchangeably with the corresponding phospholipids as membrane probes; however, fatty acids transfer more readily between aqueous and lipid phases.³ Although fatty acids are ionized at neutral pH in water ($pK_a \sim 5$), their pK_a is typically ~ 7 in membranes, and thus a significant fraction of membrane-bound fatty acids are neutral species.³ Certain fluorescent fatty acids (Section 13.2) are readily metabolized by live cells to phospholipids, mono-, di- and triacylglycerols, cholesteryl esters and other lipid derivatives.⁴

Sphingolipids play critical roles in processes such as proliferation, apoptosis, signal transduction and molecular recognition at cell surfaces.^{1,5,6} Defects in the lysosomal breakdown of sphingolipids are the underlying cause of lipid storage disorders such as Niemann–Pick, Tay–Sachs, Krabbe and Gaucher diseases. The sphingolipids described in Section 13.3 include ceramides, sphingomyelins, glycosylceramides (cerebrosides) and gangliosides. The structural backbone of sphingolipids is the lipophilic amino–dialcohol sphingosine (2-amino-4-octadecen-1,3-diol, Figure 13.1.2) to which a single fatty acid residue is attached via an amide linkage. Our fluorescent analogs of sphingolipids are prepared by replacing the natural amide-linked fatty acid with a fluorescent analog. Sphingolipids with an unmodified hydroxyl group in the 1-position are classified as ceramides. As part of the lipid-sorting process in cells, ceramides are glycosylated to cerebrosides (Figure 13.1.2) or converted to sphingomyelins (Figure 13.1.2) in the Golgi complex. Glycosylated

Figure 13.1.3 The neuronal tracer DiI (D282, D3911) used as a diagnostic tool to evaluate patterns of innervation in newborn mouse cochlea. The larger image is of a mutant cochlea and the inset is of a wild-type cochlea. Image contributed by Bernd Fritzsche, Creighton University, and L. Reichardt and I. Farinas, Howard Hughes Medical Institute, San Francisco.

sphingolipids (cerebrosides and gangliosides) occur in the plasma membranes of all eukaryotic cells and are involved in cell recognition, signal transduction and modulation of receptor function.⁷ Gangliosides have complex oligosaccharide head groups containing at least one sialic acid residue in place of the single galactose or glucose residues of cerebrosides.

Fluorescent cholesteryl esters and triglycerides (Section 13.3) can be used as structural probes and transport markers for these important lipid constituents of membranes and lipoproteins.⁸ They may also serve as fluorescent substrates for lipases and lipid-transfer proteins and can be incorporated into low-density lipoproteins (LDL, Section 16.1).

Other Lipophilic and Amphiphilic Fluorescent Probes

The probes described in Section 13.4 and Section 13.5 are not analogs of any particular biological lipid class, but they have a general structural resemblance that facilitates labeling of membranes, lipoproteins and other lipid-based molecular assemblies. Particularly notable members of this group are the lipophilic carbocyanines DiI (Figure 13.1.3), DiO, DiD and DiR, the lipid fluidity probes DPH and TMA-DPH and the membrane-surface probes ANS and laurdan. These probes generally have limited water solubility and exhibit substantially enhanced fluorescence upon partition into lipid environments. They can be classified as either amphiphilic (having both polar and nonpolar structural elements) or neutral (lacking charges and most soluble in very nonpolar environments). We use similar neutral lipophilic dyes for internal staining of our fluorescent polystyrene microspheres (Section 6.5).

Other Probes for Studying Cell Membranes

In addition to the lipophilic probes described in this chapter, we have available the following products for studying the properties and functions of cell membranes:

- Moderately lipophilic stains for the endoplasmic reticulum and Golgi apparatus (Section 12.4)
- FM[®] dyes—amphiphilic probes for cell membrane labeling (Section 14.4, Section 16.1)
- CellLight[®] Plasma Membrane-CFP, CellLight[®] Plasma Membrane-GFP and CellLight[®] Plasma Membrane-RFP, which are BacMam 2.0 vectors encoding fluorescent proteins targeted to the plasma membrane (C10606, C10607, C10608; Section 14.4)
- Alexa Fluor[®] dye-labeled cholera toxin subunit B conjugates for labeling lipid rafts (Section 14.7)
- Annexin V conjugates for detection of phosphatidylserine exposure in apoptotic cell membranes (Section 15.5)
- Fluorescent and fluorogenic phospholipase A substrates (Section 17.4)
- Amplex[®] Red Phosphatidylcholine-Specific Phospholipase C Assay Kit and Amplex[®] Red Phospholipase D Assay Kit (A12218, A12219; Section 17.4)
- Antibodies to phosphatidylinositol phosphates (Section 17.4)
- Lipophilic pH indicators (Section 20.4)
- Membrane potential-sensitive probes (Section 22.2, Section 22.3)

13.2 Fatty Acid Analogs and Phospholipids

The probes in this section and in Section 13.3 bear some structural resemblance to natural lipids. Included in this section are fluorescent fatty acid analogs, as well as phospholipids wherein one or both fatty acid esters are replaced by fluorescent fatty acid esters. The fluorophores in these probes tend to remain buried in the hydrophobic interior of lipid bilayer membranes.^{1,2} In this location, they are sensitive to membrane properties such as lipid fluidity, lateral domain formation and structural perturbation by proteins, drugs and other additives. Also included in this section are several head group–modified phospholipid analogs incorporating a fluorophore or biotin (Table 13.1).

Sphingolipids, steroids and lipopolysaccharides are discussed in Section 13.3. Important applications of the fluorescent phosphatidylinositol derivatives as probes for signal transduction and various fluorescent phospholipids as phospholipase substrates are further described in Section 17.4. A review of fluorescent lipid probes and their use in biological and biophysical research has been published.³

Fluorescent Fatty Acid Analogs

Our fluorescent fatty acid analogs have a fluorophore linked within the fatty acid chain or, more commonly, at the terminal (omega) carbon atom that is furthest from the carboxylate moiety. Although fluorescent fatty acid analogs are sometimes used as direct probes for membranes

Figure 13.2.2 BHK cells incubated in medium containing the fluorescent fatty acid analog BODIPY® 500/510 C₁₇C₁₂ (D3823). This photomicrograph, obtained through a standard fluorescein longpass filter set, reveals reticular green-fluorescent staining as well as yellow-orange fluorescent spherical structures. These fluorescent structures are indicative of the metabolic accumulation of BODIPY® dye–labeled neutral lipids in cytoplasmic droplets. Image contributed by Juha Kasurinen, University of Helsinki, Finland.

Lissamine rhodamine (560/581)	L1392
Texas Red® (582/601)	T1395MP
Biotin (<250/none)	B1550, B1616

* Fluorescence excitation (Ex) and emission (Em) spectral maxima, in nm, are in methanol. The spectra may be different in membranes.

and liposomes, their most common applications have been for synthesis of fluorescent phospholipids and for metabolic incorporation by live cells. Our fluorescent fatty acids currently include derivatives based on the BODIPY®, nitrobenzoxadiazole (NBD), pyrene and dansyl fluorophores, as well as the naturally fluorescent polyunsaturated fatty acid, *cis*-parinaric acid.

BODIPY® Fatty Acids

BODIPY® fatty acids are, by far, the most fluorescent fatty acid analogs that we have available.⁴ The lack of ionic charge on the BODIPY® fluorophore is unusual for long-wavelength fluorescent dyes and results in exclusive localization of the fluorophore within the membrane (Figure 13.2.1). BODIPY® derivatives typically have extinction coefficients greater than 90,000 cm⁻¹M⁻¹ with absorption maxima beyond 500 nm. A useful spectroscopic property of BODIPY® dyes is the concentration-dependent formation of excited-state dimers ("excimers") with red-shifted emission. We have observed this phenomenon particularly with our green-fluorescent BODIPY® fatty acid derivatives, which undergo a considerable red shift in their emission when metabolically incorporated into lipophilic products⁵ (Figure 13.2.2). Pyrene

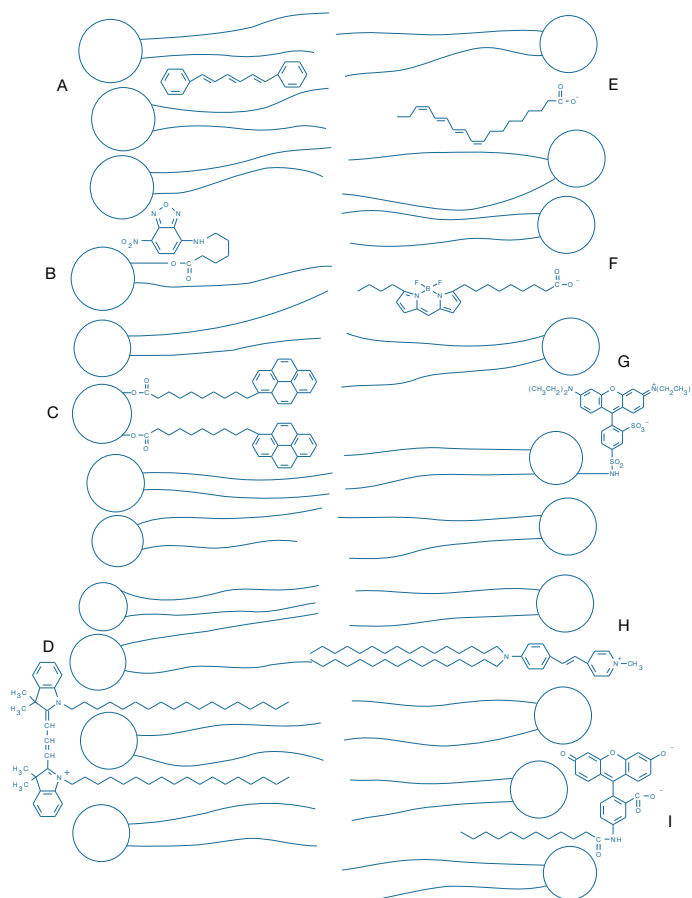

Figure 13.2.1 Location and orientation of representative fluorescent membrane probes in a phospholipid bilayer: A) DPH (D202), B) NBD-C₆-HPC (N3786), C) bis-pyrene-PC (B3782), D) DiI (D282), E) *cis*-parinaric acid (P36005), F) BODIPY® 500/510 C₄, C₉ (B3824), G) N-Rh-PE (L1392), H) DiA (D3883) and I) C₁₂-fluorescein (D109).

Figure 13.2.3 4,4-Difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-hexadecanoic acid (BODIPY[®] FL C₁₆, D3821).

Figure 13.2.4 Structural representations showing the positional shift of the fluorophore with respect to the terminal carboxyl group in a homologous series of BODIPY[®] 500/510 fatty acids (D3823, B3824, D3825).

Figure 13.2.5 4,4-Difluoro-5,7-diphenyl-4-bora-3a,4a-diaza-s-indacene-3-dodecanoic acid (BODIPY[®] 530/550 C₁₂, D3832).

Figure 13.2.6 4,4-Difluoro-5-(2-thienyl)-4-bora-3a,4a-diaza-s-indacene-3-dodecanoic acid (BODIPY[®] 558/568 C₁₂, D3835).

Figure 13.2.7 4,4-Difluoro-5-(4-phenyl-1,3-butadienyl)-4-bora-3a,4a-diaza-s-indacene-3-undecanoic acid (BODIPY[®] 581/591 C₁₁, D3861).

fatty acids also exhibit excimer formation but their emission is at much shorter wavelengths than that of the BODIPY[®] dyes and they are therefore less suitable for the study of live cells.

The fluorophores in our current selection of BODIPY[®] fatty acids and their approximate absorption/emission maxima (in nm) are:

- BODIPY[®] 503/512 (BODIPY[®] FL; D3821, Figure 13.2.3; D3822; D3834; D3862)
- BODIPY[®] 500/510 (D3823, B3824, D3825; Figure 13.2.4)
- BODIPY[®] 530/550 (D3832, Figure 13.2.5)
- BODIPY[®] 558/568 (D3835, Figure 13.2.6)
- BODIPY[®] 581/591 (D3861)

BODIPY[®] fatty acids are synthetic precursors to a wide variety of fluorescent phospholipids (described below), as well as several important sphingolipid probes described in Section 13.3. Some BODIPY[®] fatty acids are readily metabolized by live cells to phospholipids, di- and triacylglycerols, cholesteryl esters and other natural lipids.^{6–9} Analysis of cellular lipid extracts by HPLC has shown that glycerophosphocholines constitute more than 90% of the products of biosynthetic incorporation of BODIPY[®] 500/510 dodecanoic acid (D3823) by BHK cells.⁵

The three BODIPY[®] 500/510 probes form a unique series in which the green-fluorescent fluorophore is located within the fatty acid chain at different distances from the terminal carboxylate group.⁴ The overall length of the probe is constant and, including the fluorophore, is about equivalent to that of an 18-carbon fatty acid (Figure 13.2.4).

BODIPY[®] 581/591 undecanoic acid (D3861) is particularly useful for detecting reactive oxygen species in cells and membranes.^{10–13} Oxidation of the polyunsaturated butadienyl portion of the BODIPY[®] 581/591 dye (Figure 13.2.7) truncates the conjugated π -electron system, resulting in a shift of the fluorescence emission peak from \sim 590 nm to \sim 510 nm.^{10,13,14} This oxidation response mechanism is similar to that of the naturally occurring polyunsaturated fatty acid *cis*-parinaric acid. In comparison to *cis*-parinaric acid, advantages of BODIPY[®] 581/591 undecanoic acid include:

- Long-wavelength excitation, compatible with confocal laser-scanning microscopes and flow cytometers
- Avoidance of photooxidation effects induced by ultraviolet excitation
- Less interference by colored oxidant and antioxidant additives when detecting probe fluorescence¹²
- Greater resistance to spontaneous oxidation
- Red-to-green fluorescence shift, allowing the use of fluorescence ratio detection methods^{10,13}

An alternative technique for detecting lipid peroxidation utilizes the oxidation-induced decrease of concentration-dependent excimer formation by BODIPY® FL dye–labeled fatty acids.¹⁵

NBD Fatty Acids

Fluorescence of the nitrobenzoxadiazole (NBD) fluorophore is highly sensitive to its environment. Although it is moderately fluorescent in aprotic solvents, in aqueous solvents it is almost nonfluorescent.¹⁶ The NBD fluorophore is moderately polar and both its homologous 6-carbon and 12-carbon fatty acid analogs (N316, Figure 13.2.8; N678) and the phospholipids derived from these probes (N3786, N3787) tend to sense the lipid–water interface region of membranes instead of the hydrophobic interior¹⁷ (see part B of Figure 13.2.1). The environmental sensitivity of NBD fatty acids can be usefully exploited to probe the ligand-binding sites of fatty acid and sterol carrier proteins.¹⁸ NBD fatty acids are not well metabolized by live cells.^{9,19}

Pyrene Fatty Acids

The hydrophobic pyrene fluorophore is readily accommodated within the membrane.²⁰ ω -Pyrene derivatives of longer-chain fatty acids (Figure 13.2.9) were first described by Galla and Sackmann in 1975.²¹ We offer pyrene derivatives of the 4-, 10-, 12- and 16-carbon fatty acids (P1903MP, P31, P96, P243, respectively). Pyrenebutanoic acid—frequently called pyrenebutyric acid (P1903MP)—has rarely been used as a membrane probe; however, its conjugates have exceptionally long excited-state lifetimes ($\tau > 100$ nanoseconds) and are consequently useful for time-resolved fluorescence immunoassays and nucleic acid detection.^{22,23} The long excited-state lifetime of pyrenebutyric acid also makes it useful as a probe for oxygen in cells^{24–27} and lipid vesicles.²⁸

Pyrene derivatives form excited-state dimers (excimers) with red-shifted fluorescence emission^{29–31} (Figure 13.2.10). Pyrene excimers can even form when two pyrenes are tethered by a short trimethine spacer, as in 1,3-bis-(1-pyrenyl)propane (B311, Section 13.5). Pyrene excimer formation is commonly exploited for assaying membrane fusion^{32,33} (Lipid-Mixing Assays of Membrane Fusion—Note 13.1) and for detecting lipid domain formation.^{34–36} Pyrene fatty acids are metabolically incorporated into phospholipids, di- and tri-acylglycerols and cholesterol esters by live cells.^{19,37,38}

Other uses of pyrene fatty acids include:

- Detecting lipid–protein interactions^{9,40}
- Inducing photodynamic damage^{41,42}
- Investigating phospholipase A₂ action on lipid assemblies^{43–45}
- Studying lipid transport mechanisms and transfer proteins^{46–48}
- Synthesizing fluorescent sphingolipid probes^{49–52}

Dansyl Undecanoic Acid

Dansyl undecanoic acid (DAUDA, D94; Figure 13.2.11) incorporates a polar, environment-sensitive dansyl fluorophore that preferentially locates in the polar headgroup region of lipid bilayer membranes.⁵³ DAUDA exhibits a 60-fold fluorescence enhancement and a large emission spectral shift to shorter wavelengths on binding to certain proteins.⁵⁴ This property has been exploited to analyze fatty acid–binding proteins^{54–57} and also to develop a fluorometric phospholipase A₂ assay (Section 17.4) based on competitive fatty acid displacement.^{58–61}

cis-Parinaric Acid

The naturally occurring polyunsaturated fatty acid *cis*-parinaric acid (P36005, Figure 13.2.12) was initially developed as a membrane probe by Hudson and co-workers and published in 1975.⁶² *cis*-Parinaric acid is the closest structural analog of intrinsic membrane lipids among currently available fluorescent probes (Figure 13.2.1). The chemical and physical properties of *cis*-parinaric acid have been well characterized. The lowest absorption band of *cis*-parinaric acid has two main peaks around 300 nm and 320 nm, with a high extinction coefficient. *cis*-Parinaric acid offers several experimentally advantageous optical properties, including a very large fluorescence Stokes shift (~100 nm) and an almost complete lack of fluorescence in water. In addition, the fluorescence decay lifetime of *cis*-parinaric acid varies from 1 to ~40 nanoseconds, depending on the molecular packing density in phospholipid bilayers. Consequently, minutely detailed information on lipid-bilayer dynamics can be obtained.

Figure 13.2.8 NBD-X (6-(N-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoic acid; N316).

Figure 13.2.9 1-Pyrenedodecanoic acid (P96).

Figure 13.2.10 Excimer formation by pyrene in ethanol. Spectra are normalized to the 371.5 nm peak of the monomer. All spectra are essentially identical below 400 nm after normalization. Spectra are as follows: 1) 2 mM pyrene, purged with argon to remove oxygen; 2) 2 mM pyrene, air-equilibrated; 3) 0.5 mM pyrene (argon-purged); and 4) 2 μ M pyrene (argon-purged). The monomer-to-excimer ratio (371.5 nm/470 nm) is dependent on both pyrene concentration and the excited-state lifetime, which is variable because of quenching by oxygen.

Figure 13.2.11 11-(5-Dimethylaminonaphthalene-1-sulfonyl)amino)undecanoic acid (DAUDA, D94).

Figure 13.2.12 *cis*-Parinaric acid (P36005).

NOTE 13.1**Lipid-Mixing Assays of Membrane Fusion**

Fluorometric methods for assaying membrane fusion exploit processes, such as nonradiative energy transfer, fluorescence quenching and pyrene excimer formation, that are dependent on probe concentration.^{1–8} Assays of membrane fusion report either the mixing of membrane lipids (described here) or the mixing of the aqueous contents of the fused entities (Assays of Volume Change, Membrane Fusion and Membrane Permeability—Note 14.3). Chapter 13 describes additional methods for detecting membrane fusion based on image analysis.

NBD–Rhodamine Energy Transfer

Principle: Struck, Hoekstra and Pagano introduced lipid-mixing assays based on NBD–rhodamine energy transfer.⁹ In this method (Figure 1), membranes labeled with a combination of fluorescence energy transfer donor and acceptor lipid probes—typically NBD-PE and *N*-Rh-PE (N360, L1392; Section 13.2), respectively—are mixed with unlabeled membranes. Fluorescence resonance energy transfer (FRET), detected as rhodamine emission at ~585 nm resulting from NBD excitation at ~470 nm, decreases when the average spatial separation of the probes is increased upon fusion of labeled membranes with unlabeled membranes. The reverse detection scheme, in which FRET increases upon fusion of membranes that have been separately labeled with donor and acceptor probes, has also proven to be a useful lipid-mixing assay.¹⁰

Applications: Applications of the NBD–rhodamine assay are described in footnoted references.^{11–20}

Octadecyl Rhodamine B Self-Quenching

Principle: Lipid-mixing assays based on self-quenching of octadecyl rhodamine B (R18, O246; Section 13.5) were originally described by Hoekstra and co-workers.²¹ Octadecyl rhodamine B self-quenching occurs when the probe is incorporated into membrane lipids at concentrations of 1–10 mole percent.²² Unlike phospholipid analogs, octadecyl rhodamine B can readily be introduced into existing membranes in large amounts. Fusion with unlabeled membranes results in dilution of the probe, which is accompanied by increasing fluorescence^{23,24} (excitation/emission maxima 560/590 nm) (Figure 2). The assay may be compromised by effects such as spontaneous transfer of the probe to unlabeled membranes, quenching of fluorescence by proteins and probe-related inactivation of viruses; the prevalence of these effects is currently debated.^{25–27}

Applications: The octadecyl rhodamine B self-quenching assay is extensively used for detecting virus–cell fusion.^{28–39}

Pyrene Excimer Formation

Principle: Pyrene-labeled fatty acids (e.g., P31, P96, P243; Section 13.2) can be biosynthetically incorporated into viruses and cells in sufficient quantities to produce the degree of labeling required for long-wavelength pyrene excimer fluorescence (Figure 3). This excimer fluorescence is diminished upon fusion of labeled membranes with unlabeled membranes (Figure 4). Fusion can be monitored by following the increase in the ratio of monomer (~400 nm) to excimer (~470 nm) emission, with excitation at about 340 nm. This method appears to circumvent some of the potential artifacts of the octadecyl rhodamine B self-quenching technique²⁶ and, therefore, provides a useful alternative for virus–cell fusion applications.

Applications: Applications of pyrene excimer assays for membrane fusion are described in the footnoted references.^{26,28,40–43}

Figure 1 Pictorial representation of a lipid-mixing assay based on fluorescence resonance energy transfer (FRET). The average spatial separation of the donor (D) and acceptor (A) lipid probes increases upon fusion of labeled membranes with unlabeled membranes, resulting in decreased efficiency of proximity-dependent FRET (represented by yellow arrows). Decreased FRET efficiency is registered by increased donor fluorescence intensity and decreased acceptor fluorescence intensity.

Figure 2 Pictorial representation of a lipid-mixing assay based on fluorescence self-quenching. Fluorescence of octadecyl rhodamine B (O246), incorporated at >1:100 with respect to host membrane lipids, is quenched due to dye–dye interactions. Fusion with unlabeled membranes causes dispersion of the probe, resulting in a fluorescence increase that is represented here by a color change from black to green.

Figure 4 Pictorial representation of a lipid-mixing assay based on pyrene excimer formation. Locally concentrated pyrene-labeled lipid probes emit red-shifted fluorescence due to formation of excimers (excited-state dimers). Probe dilution by unlabeled lipids as a result of membrane fusion is registered by the replacement of excimer emission by blue-shifted monomer fluorescence.

Figure 3 Excimer formation by pyrene in ethanol. Spectra are normalized to the 371.5 nm peak of the monomer. All spectra are essentially identical below 400 nm after normalization. Spectra are as follows: 1) 2 mM pyrene, purged with argon to remove oxygen; 2) 2 mM pyrene, air-equilibrated; 3) 0.5 mM pyrene (argon-purged); and 4) 2 μ M pyrene (argon-purged). The monomer-to-excimer ratio (371.5 nm/470 nm) is dependent on both pyrene concentration and the excited-state lifetime, which is variable because of quenching by oxygen.

Selected applications of *cis*-parinaric acid include:

- Measurement of peroxidation in lipoproteins^{63–65} and the relationship of peroxidation to cytotoxicity^{66,67} and apoptosis^{68–71}
- Evaluation of antioxidants^{72–75}
- Detection of lipoproteins following chromatographic separation⁷⁶ and structural characterization of lipoproteins⁷⁷
- Detection of lipid–protein interactions^{78–80} and lipid clustering⁸¹
- High-affinity binding to a hydrophobic pocket between the heavy chain of myosin subfragment-1 and its essential light chain⁸²
- Investigation of the mechanism of fatty acid–binding proteins^{83–85} and phospholipid-transfer proteins^{86,87}

The extensive unsaturation of *cis*-parinaric acid makes it quite susceptible to oxidation. Consequently, we offer *cis*-parinaric acid in a 10 mL unit size of a 3 mM solution in deoxygenated ethanol (P36005); if stored protected from light under an inert argon atmosphere at -20°C , this stock solution should be stable for at least six months. During experiments, we strongly advise handling *cis*-parinaric acid samples under inert gas and preparing solutions using degassed buffers and solvents. *cis*-Parinaric acid is also somewhat photolabile, undergoing photodimerization under intense illumination, resulting in loss of fluorescence.⁸⁸

ADIFAB Fatty Acid Indicator

Fatty acid–binding proteins are small cytosolic proteins found in a variety of mammalian tissues, and studies of their physiological function frequently involve fluorescent fatty acid probes.⁸⁹ To facilitate these studies, we offer ADIFAB reagent (A3880), a dual-wavelength fluorescent indicator of free fatty acids^{90–92} (Figure 13.2.13, Figure 13.2.14). ADIFAB reagent is a conjugate of I-FABP, a rat intestinal fatty acid–binding protein with a low molecular weight (15,000 daltons) and a high binding affinity for free fatty acids,⁹³ and the polarity-sensitive acrylodan fluorophore (A433, Section 2.3). It is designed to provide quantitative monitoring of free fatty acids without resorting to separative biochemical methods.^{44,94,95} With appropriate precautions, which are described in the product information sheet accompanying this product, ADIFAB can be used to determine free fatty acid concentrations between 1 nM and $>20 \mu\text{M}$.

Figure 13.2.13 Ribbon representation of the ADIFAB free fatty acid indicator (A3880). In the left-hand image, the fatty acid binding site of intestinal fatty acid–binding protein (yellow) is occupied by a covalently attached acrylodan fluorophore (blue). In the right-hand image, a fatty acid molecule (gray) binds to the protein, displacing the fluorophore (green) and producing a shift of its fluorescence emission spectrum. Image contributed by Alan Kleinfeld, FFA Sciences LLC, San Diego.

Figure 13.2.14 The free fatty acid–dependent spectral shift of ADIFAB (A3880). Spectra shown represent 0.2 μM ADIFAB in pH 8.0 buffer with (+OA) and without (–OA) addition of 4.7 μM *cis*-9-octadecenoic (oleic) acid (OA). The ratio of fluorescence emission intensities at 505 nm and 432 nm can be quantitatively related to free fatty acid concentrations.

Phospholipids with BODIPY[®] Dye-Labeled Acyl Chains

BODIPY[®] Glycerophospholipids

We offer several glycerophospholipid analogs labeled with a single green-fluorescent BODIPY[®] 500/510 or a BODIPY[®] FL fluorophore or red-orange-fluorescent BODIPY[®] 530/550 fluorophore on the *sn*-2 acyl chain, including:

- BODIPY[®] 500/510 dye-labeled glycerophosphocholine (D3793, Figure 13.2.15)
- BODIPY[®] FL dye-labeled glycerophosphocholine (D3792, Figure 13.2.16; D3803, Figure 13.2.17)
- BODIPY[®] 530/550 dye-labeled glycerophosphocholine (D3815, Figure 13.2.18)
- BODIPY[®] FL dye-labeled phosphatidic acid (D3805, Figure 13.2.19)

In addition, we prepare a glycerophosphocholine analog with a single nonhydrolyzable ether-linked BODIPY[®] FL fluorophore on the *sn*-1 position (D3771, Figure 13.2.20), as well as several doubly labeled glycerophospholipids. These doubly labeled glycerophospholipids, which are discussed in greater detail in Section 17.4, are designed primarily for detection of phospholipase A₁ and phospholipase A₂ and include:

- Glycerophosphoethanolamine with a BODIPY[®] FL dye-labeled *sn*-1 acyl chain and a dinitrophenyl quencher-modified headgroup (PED-A1, A10070; Figure 13.2.21)
- Glycerophosphoethanolamine with a BODIPY[®] FL dye-labeled *sn*-2 acyl chain and a dinitrophenyl quencher-modified headgroup⁹⁶ (PED6, D23739; Figure 13.2.22)
- Glycerophosphocholine with two BODIPY[®] FL dye-labeled acyl chains (bis-BODIPY[®] FL C₁₁-PC, B7701; Figure 13.2.22)
- Glycerophosphocholine with a BODIPY[®] 558/568 dye-labeled *sn*-1 alkyl chain and a BODIPY[®] FL dye-labeled *sn*-2 acyl chain (Red/Green BODIPY[®] PC-A2, A10072; Figure 13.2.23)

The spectral properties of BODIPY[®] FL dye-labeled phospholipids are summarized in Table 13.2. Unlike the nitrobenzoxadiazole (NBD) fluorophore, the BODIPY[®] FL and BODIPY[®] 500/510 fluorophores are intrinsically lipophilic and readily localize in the membrane's interior.¹ The fluorophore is completely inaccessible to the membrane-impermeant anti-BODIPY[®] FL antibody (A5770, Section 7.4), which also recognizes the BODIPY[®] 500/510 derivative. As shown in Figure 13.2.24, the emission spectrum of the BODIPY[®] 500/510 fluorophore is much narrower than that of the NBD fluorophore. Because both the extinction coefficient of the BODIPY[®] 500/510 fluorophore and its quantum yield in a lipophilic environment (EC ~90,000 cm⁻¹M⁻¹ and QY ~0.9) are much higher than those of the NBD fluorophore (EC ~20,000 cm⁻¹M⁻¹ and QY ~0.3), much less BODIPY[®] 500/510 dye-labeled phospholipid is required for labeling membranes.⁴

Figure 13.2.21 PED-A1 (*N*-((6-(2,4-DNP)amino)hexanoyl)-1-(BODIPY[®] FL C₅)-2-hexyl-*sn*-glycero-3-phosphoethanolamine; A10070).

Figure 13.2.22 Mechanism of phospholipase activity-linked fluorescence enhancement responses of bis-BODIPY[®] FL C₁₁-PC (B7701) and PED6 (D23739). Note that enzymatic cleavage of bis-BODIPY[®] FL C₁₁-PC yields two fluorescent products, whereas cleavage of PED6 yields only one.

Figure 13.2.23 Red/Green BODIPY[®] PC-A2 (1-O-(6-BODIPY[®] 558/568-aminohexyl)-2-BODIPY[®] FL C₅-sn-glycero-3-phosphocholine; A10072).

Figure 13.2.24 Fluorescence spectra (excitation at 475 nm) of β -BODIPY[®] 500/510 C₁₂-HPC (blue line peak at 516 nm, D3793) and NBD C₁₂-HPC (red line peak at 545 nm, N3787) incorporated in DOPC (dioctadecenylglycerophosphocholine) liposomes at molar ratios of 1:400 mole:mole (labeled:unlabeled PC). The integrated intensities of the spectra are proportional to the relative fluorescence quantum yields of the two probes.

Table 13.2 Spectral properties of some lipid probes.

Spectral Property	Pyrene	DPH	NBD	BODIPY [®] FL
Ex/Em (nm) *	340/376	360/430	470/530	507/513
QY (†)	0.6 (>100 nanoseconds)	0.8 (4–8 nanoseconds)	0.32 (5–10 nanoseconds)	0.9 (6 nanoseconds)
Concentration dependence	Excimer emission (~470 nm) at high concentrations.	Self-quenched at high concentrations.	Self-quenched at high concentrations.	Excimer emission (~620 nm) at high concentrations.
Environmental sensitivity	Very sensitive to quenching by oxygen. Essentially nonfluorescent in water.	Essentially nonfluorescent in water.	Essentially nonfluorescent in water.	Relatively insensitive. Strongly fluorescent in both aqueous and lipid environments.

* Typical fluorescence excitation and emission maxima for membrane-intercalated probes. † QY = fluorescence quantum yield; † = fluorescence decay lifetime. Typical values for membrane-intercalated probes are listed. These values may show significant environment-dependent variations.

Figure 13.2.25 A) Fluorescence spectrum of β -C₈-BODIPY* 500/510 C₅-HPC (D3795) incorporated in DOPC (dioctadecenylphosphocholine) liposomes at 1:100 mole:mole (labeled:unlabeled PC). B) Fluorescence spectra at high molar incorporation levels: 1:10 mole:mole and 1:5 mole:mole.

Figure 13.2.26 Fluorescence resonance energy transfer from β -BODIPY* 500/510 C₁₂-HPC (peak at 516 nm, D3793) to BODIPY* 558/568 C₁₂ (peak at 572 nm, D3835) in DOPC (dioctadecenylglycerophosphocholine) lipid bilayers using 475 nm excitation. Ratio of acceptors to donors is: 1) 0; 2) 0.2; 3) 0.4; 4) 0.8; and 5) 2.0.

Figure 13.2.27 Confocal laser-scanning microscopy images of a giant unilamellar phospholipid vesicle (GUV). The lipid composition of this GUV was DPPC/DLPC = 1/1, with DiI_{C₂₀}(3) and β -BODIPY* FL C₅-HPC (D3803) dyes at mole fraction \sim 0.001. Excitation was at 488 nm. The upper left image is the fluorescence emission through a 585 nm longpass filter, thus almost exclusively from DiI_{C₂₀}(3). The lower left image is the emission through a 522 \pm 35 nm bandpass filter, thus almost exclusively from β -BODIPY* FL C₅-HPC. The right image is color-merged, using the public domain NIH Image program. Image contributed by Gerald W. Feigenson, Cornell University, and reprinted with permission from *Biophys J* (2001) 80:2775.

Incorporation of high molar ratios (>10 mole %) of the BODIPY* 500/510 dye-labeled phospholipids into membranes results in a dramatic spectral shift of the fluorescence emission spectrum to longer wavelengths (Figure 13.2.25). We have also observed this spectral shift in the Golgi of live cells that have been labeled with our BODIPY* dye-labeled ceramides (Section 12.4) and with BODIPY* fatty acids that have been metabolically incorporated by cells (Figure 13.2.2). In fluorescence resonance energy transfer (FRET) measurements, the green-fluorescent BODIPY* 500/510 dye is an excellent donor to longer-wavelength BODIPY* probes^{97,98} (Figure 13.2.26) and acceptor from dansyl-, DPH- or pyrene-labeled phospholipids.⁹⁹ These probe combinations offer several alternatives to the widely used NBD-rhodamine fluorophore pair for researchers using FRET techniques to study lipid transfer and membrane fusion.⁹⁷

Applications

Once cells are labeled with a BODIPY* phospholipid, the probe shows little tendency to spontaneously transfer between cells.¹⁰⁰ Consequently, BODIPY* dye-labeled phospholipids have been used in a number of studies of cell membrane structure and properties:

- Despite their good photostability, BODIPY* lipids are useful for fluorescence recovery after photobleaching (FRAP) measurements of lipid diffusion.^{101,102}
- Researchers have used BODIPY* fatty acids and phospholipids to visualize compartmentalization of specific lipid classes in *Schistosoma mansoni*¹⁰³ and fungi.^{104,105}
- β -BODIPY* FL C₁₂-HPC (D3792) has been used to examine lipid-protein interactions involved in bacterial protein secretion via fluorescence resonance energy transfer (FRET) measurements¹⁰⁶ (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2).
- β -BODIPY* FL C₅-HPC¹⁰⁷ (D3803) has been used to characterize lipid domains by fluorescence correlation spectroscopy¹⁰⁸ (Fluorescence Correlation Spectroscopy (FCS)—Note 1.3), confocal laser-scanning microscopy¹⁰⁹ (Figure 13.2.27) and near-field scanning optical microscopy.^{101,110}
- bis-BODIPY* FL C₁₁-PC (B7701) has BODIPY* FL dye-labeled *sn*-1 and *sn*-2 acyl groups (Figure 13.2.28), resulting in partially quenched fluorescence that increases when one of the acyl groups is hydrolyzed by phospholipase A₁ or A₂. The hydrolysis products are BODIPY* FL undecanoic acid (D3862) and BODIPY* FL dye-labeled lysophosphatidylcholine (Figure 13.2.22). The probe has been used successfully in human neutrophils, plants and zebrafish to detect phospholipase A activity^{111–116} (Section 17.4).
- β -BODIPY* FL C₅-HPC (D3803) has been used to investigate the cellular uptake of antineoplastic ether lipids.¹¹⁷

Figure 13.2.28 1,2-bis-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-undecanoyl)-*sn*-glycero-3-phosphocholine (bis-BODIPY* FL C₁₁-PC, B7701).

Phospholipid with DPH-Labeled Acyl Chain

Properties

The fluorescent phospholipid analog β -DPH HPC (D476) comprises diphenylhexatriene propionic acid coupled to glycerophosphocholine at the *sn*-2 position (Figure 13.2.29). It is therefore related to the neutral membrane probe DPH and the cationic derivative TMA-DPH (D202, T204; Section 13.5). DPH and its derivatives exhibit strong fluorescence enhancement when incorporated into membranes, as well as sensitive fluorescence polarization (anisotropy) responses to lipid ordering (Fluorescence Polarization (FP)—Note 1.4). β -DPH HPC was originally devised to improve the localization of DPH in membranes.^{118,119} Unlike underivatized DPH, it can be used to specifically label one leaflet of a lipid bilayer, facilitating analysis of membrane asymmetry.¹²⁰

Applications

DPH derivatives are predominantly used to investigate the structure and dynamics of the membrane interior either by fluorescence polarization or lifetime measurements. Researchers have used β -DPH HPC as a probe for lipid-protein interactions,^{121–123} alcohol-induced perturbations of membrane structure,^{124,125} molecular organization and dynamics of lipid bilayers^{11,126–128} and lipid peroxidation.¹²⁹ Fluorescence lifetime measurements of β -DPH HPC provide a sensitive indicator of membrane fusion.^{130–132} In addition to membrane fusion, β -DPH HPC has been used to monitor various other lipid-transfer processes.^{133–135}

Phospholipids with NBD-Labeled Acyl Chains

Properties

Our acyl-modified nitrobenzoxadiazole (NBD) phospholipid probes include both the NBD hexanoyl- and NBD dodecanoyl-glycerophosphocholines (NBD C₆-HPC, N3786; Figure 13.2.30 and NBD C₁₂-HPC, N3787). Table 13.2 compares the spectral properties of these probes with those of the BODIPY[®], DPH and pyrene lipid probes. Unlike the BODIPY[®] phospholipids, the location of the relatively polar NBD fluorophore of NBD C₆-HPC and NBD C₁₂-HPC in phospholipid bilayers does *not* appear to conform to expectations based on the probe structure. A variety of physical evidence indicates that the NBD moiety "loops back" to the head-group region^{136–139} (Figure 13.2.1). In fact, the fluorophore in this acyl-modified phospholipid appears to probe the same location as does the head group-labeled glycerophosphoethanolamine derivative NBD-PE¹⁷ (N360).

These NBD probes transfer spontaneously between membranes, with NBD C₆-HPC transferring more rapidly than its more lipophilic C₁₂ analog.^{140,141} NBD C₆-HPC can be readily removed (back-exchanged) from the plasma membrane by incubating the labeled cells either with unlabeled lipid vesicles¹⁴² or with bovine serum albumin.^{143–145} This property is useful for quantitating lipid transfer and for studying phospholipid distribution asymmetry and transmembrane "flip-flop" rates in lipid bilayers.^{17,146–151}

Applications

NBD acyl-modified probes are used for investigating lipid traffic, either by directly visualizing NBD fluorescence,^{152–155} by exploiting NBD self-quenching^{156–158} or by fluorescence resonance energy transfer methods.^{140,152,159–161} Lateral domains in model monolayers, bilayers and cell membranes have been characterized using NBD phospholipids in conjunction with fluorescence recovery after photobleaching^{162–164} (FRAP), fluorescence resonance energy transfer¹⁶⁵ (FRET) (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2) and direct microscopy techniques.^{166–169} Transmembrane lipid distribution (Lipid-Mixing Assays of Membrane Fusion—Note 13.1) has been assessed using fluorescence resonance energy transfer from NBD HPC to rhodamine DHPE^{149,151,170} (L1392) or alternatively by selective dithionite (S₂O₄²⁻) reduction of NBD phospholipids in the outer membrane monolayer¹⁷¹ (Figure 13.2.31).

Figure 13.2.29 β -DPH HPC (2-(3-(diphenylhexatrienyl)propanoic acid)-1-hexadecanoyl-*sn*-glycerol-3-phosphocholine; D476).

Figure 13.2.30 2-(6-(7-Nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoyl-1-hexadecanoyl-*sn*-glycerol-3-phosphocholine (NBD C₆-HPC, N3786).

Figure 13.2.31 Dithionite reduction of 6-(*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoic acid (NBD-X, N316). The elimination of fluorescence associated with this reaction, coupled with the fact that extraneously added dithionite is not membrane permeant, can be used to determine whether the NBD fluorophore is located in the external or internal monolayer of lipid bilayer membranes.

Phospholipids with Pyrene-Labeled Acyl Chains

Properties

Phospholipid analogs with pyrene-labeled *sn*-2 acyl chains (Figure 13.2.32) are among the most popular fluorescent membrane probes.^{29,172,173} We offer pyrenedecanoyl-labeled glycerophospholipids with phosphocholine (H361) and phosphoglycerol (H3809) head groups.

The spectral properties of the pyrene lipid probes are summarized in Table 13.2. Of primary importance in terms of practical applications is the concentration-dependent formation of excited-state pyrene dimers (excimers), which exhibit a distinctive red-shifted emission (peak ~470 nm) (Figure 13.2.10).

Applications

The excimer-forming properties of pyrene are well suited for monitoring membrane fusion (Lipid-Mixing Assays of Membrane Fusion—Note 13.1) and phospholipid transfer processes.^{37,173–178} The monomer/excimer emission ratio can also be used to characterize membrane structural domains and their dependence on temperature, lipid composition and other external factors.^{179–182} Pyrenedecanoyl glycerophosphocholine (β -py- C_{10} -HPC, H361) has been used to elucidate the effect of extrinsic species such as Ca^{2+} ,¹⁸³ platelet-activating factor,¹⁸⁴ drugs,¹⁸⁵ membrane-associated proteins^{186–188} and ethanol¹⁸⁹ on lipid bilayer structure and dynamics. The anionic phosphoglycerol analog (H3809, Figure 13.2.33) is preferred as a substrate for secretory phospholipases A_2 relative to other phospholipid classes.^{190,191} The long excited-state lifetime of pyrene (Table 13.2) renders the fluorescence of its conjugates very susceptible to oxygen quenching, and consequently these probes can be used to measure oxygen concentrations in solutions,¹⁹² lipid bilayers¹⁹³ and cells.^{194,195}

Glycerophospholipids in which both alcohols are esterified to pyrene fatty acids (Figure 13.2.1), as in our bis-(1-pyrenebutanoyl)- and bis-(1-pyrenedecanoyl)glycerophosphocholines (B3781, Figure 13.2.34; B3782) show strong excimer fluorescence, with maximum emission near 470 nm.²⁹ Hydrolysis of either fatty acid ester by a phospholipase results in liberation of a pyrene fatty acid and an emission shift to shorter wavelengths, making these probes useful as phospholipase substrates^{196–199} (Section 17.4).

NOTE 13.2

Antibodies for Detecting Membrane-Surface Labels

For detecting labels at the membrane surface, we offer antibodies that recognize the following labels:

- Alexa Fluor® 488 dye (A11094)
- BODIPY® FL dye (A5770)
- Alexa Fluor® 405 and Cascade Blue® dyes (A5760)
- Dansyl (A6398)
- Dinitrophenyl chromophore (A6423, A6430, A6435, A11097, Q17421MP)
- Fluorescein and Oregon Green® dyes (A889, A982, A6413, A6421, A11090, A11091, A11095, A11096, Q15421MP, Q15431MP)
- Green Fluorescent Protein (GFP, A6455, A10259, A10262, A10263, A11120, A11121, A11122, A21311, A21312, A31851, A31852, G10362)
- Lucifer yellow (A5750, A5751)
- Tetramethylrhodamine (A6397)
- Texas Red® dye (A6399)

Fluorescent conjugates of several of these anti-dye and anti-hapten antibodies are available; see Section 7.4 and Table 7.8 for complete product information. These antibodies can be used for direct detection of labeled phospholipids via fluorescence quenching^{1,2} (or fluorescence enhancement, in the case of the anti-dansyl antibody). When used in conjunction with phospholipids with dye-labeled head groups (Table 13.1), they are important tools for:

- Studies of molecular recognition mechanisms at membrane surfaces³
- Lipid diffusion measurements^{4,5}
- Quantitation of lipid internalization by endocytosis^{6,7}

In addition to anti-fluorophore antibodies, we offer a selection of streptavidin conjugates (Section 7.6, Table 7.9) for detecting biotinylated phospholipids.

Phospholipids with a Fluorescent or Biotinylated Head Group

Phospholipid with a Dansyl-Labeled Head Group

The phospholipid analog incorporating the environment-sensitive²⁰⁰ dansyl fluorophore (dansyl DHPE, D57; Figure 13.2.35) is a useful probe of lipid–water interfaces.^{53,201} It is sensitive to the interactions of a number of proteins, including protein kinase C,^{202,203} annexins^{204,205} and phospholipase A₂,^{206–208} with membrane surfaces. Dansyl DHPE has also been used to examine the effects of cholesterol on the accessibility of the dansyl hapten to antibodies²⁰⁹ (Antibodies for Detecting Membrane-Surface Labels—Note 13.2).

Phospholipid with a Marina Blue® Dye-Labeled Head Group

Marina Blue® DHPE (M12652, Figure 13.2.36) is optimally excited by the intense 365 nm spectral line of the mercury-arc lamp and exhibits bright blue fluorescence emission near 460 nm. Significantly, the pK_a value of this 6,8-difluoro-7-hydroxycoumarin derivative is 2–3 log units lower than that of nonfluorinated 7-hydroxycoumarin analogs; consequently, Marina Blue® DHPE is expected to be strongly fluorescent in membranes, even at neutral pH.

Phospholipid with a Pacific Blue™ Dye-Labeled Head Group

The Pacific Blue™ dye-labeled phospholipid (Pacific Blue™ DMPE, P22652; Figure 13.2.37) is our only head group–labeled phospholipid with tetradecanoyl (myristoyl) esters rather than hexadecanoyl (palmitoyl) esters. This blue-fluorescent phospholipid is structurally similar to a phospholipid described by Gonzalez and Tsien for use in a FRET-based measurement of membrane potential.²¹⁰

Figure 13.2.35 *N*-(5-dimethylaminonaphthalene-1-sulfonyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt (dansyl DHPE, D57).

Figure 13.2.36 Marina Blue® 1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine (Marina Blue® DHPE, M12652).

Figure 13.2.37 Pacific Blue™ DMPE (Pacific Blue™ 1,2-ditetradecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt; P22652).

Phospholipid with an NBD-Labeled Head Group

The widely used membrane probe nitrobenzoxadiazolyldihexadecanoylglycerophosphoethanolamine¹⁷ (NBD-PE, N360; Figure 13.2.38) has three important optical properties: photolability, which makes it suitable for photobleaching recovery measurements; concentration-dependent self-quenching; and fluorescence resonance energy transfer to rhodamine acceptors (usually rhodamine DHPE, L1392). Spectroscopic characteristics of NBD-PE are generally similar to those described for our phospholipids with NBD-labeled acyl chains (N3786, N3787). NBD-PE is frequently used in NBD–rhodamine fluorescence energy transfer experiments to monitor membrane fusion (Lipid-Mixing Assays of Membrane Fusion—Note 13.1). In addition, this method can be used to detect lipid domain formation¹⁶⁵ and intermembrane lipid transfer^{211–214} and to determine the transbilayer distribution of phospholipids.¹⁵¹ Attachment of the NBD fluorophore to the head group makes NBD-PE resistant to transfer between vesicles.¹⁴² NBD-PE has been used in combination with either rhodamine DHPE (L1392) or Texas Red® DHPE (T1395MP) for visualizing the spatial relationships of lipid populations by fluorescence resonance energy transfer microscopy.²¹⁵ The nitro group of NBD can be reduced with sodium dithionite, irreversibly eliminating the dye's fluorescence (Figure 13.2.31). This technique can be employed to determine whether the probe is localized on the outer or inner leaflet of the cell membrane.^{171,216–218} The argon-ion laser–excitable NBD-PE is also a frequent choice for fluorescence recovery after photobleaching (FRAP) measurements of lateral diffusion in membranes.^{219–222} In addition, NBD-PE is of particular value for monitoring bilayer-to-hexagonal phase transitions, because these transitions cause an increase in NBD-PE's fluorescence intensity.^{223–225}

Phospholipid with a Fluorescein-Labeled Head Group

Fluorescein-derivatized dihexadecanoylglycerophosphoethanolamine (fluorescein DHPE, F362; Figure 13.2.39) is a membrane-surface probe that is sensitive to both the local electrostatic potential and pH.^{226–228} An anti-fluorescein/Oregon Green® antibody (A889, Section 7.4) has been employed in combination with fluorescein DHPE

Figure 13.2.38 NBD-PE (*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt; N360).

Figure 13.2.39 Fluorescein DHPE (*N*-(fluorescein-5-thiocarbamoyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt; F362).

to investigate specific recognition interactions at membrane surfaces^{229,230} (Antibodies for Detecting Membrane-Surface Labels—Note 13.2).

Because of fluorescein's photolability, fluorescein DHPE is a useful reagent for measuring lateral diffusion in membranes using fluorescence photobleaching recovery methods.^{231,232} Another technique, single-particle tracking (SPT), provides direct measurements of diffusion rates by calculating the trajectories of fluorescent polystyrene beads or colloidal gold particles from time-sequential images.^{233,234} FluoSpheres® fluorescent microspheres (Section 6.5) were labeled with streptavidin and then coupled to fluorescein DHPE using a biotinylated conjugate of anti-fluorescein/Oregon Green® monoclonal 4-4-20 (A6421, Section 7.4). Diffusion rates measured with this bridged conjugate in glass-supported phospholipid bilayers were the same as those determined with streptavidin beads coupled directly to biotin-X DHPE (B1616). Fluorescein DHPE has also been used in conjunction with polyclonal anti-fluorescein/Oregon Green® antibody (A889, Section 7.4) to prepare colloidal gold probes for SPT diffusion measurements in supported phospholipid bilayers and in keratocyte plasma membranes.²³⁵

Phospholipid with an Oregon Green® 488 Dye-Labeled Head Group

With absorption and emission spectra that are virtually superimposable on those of fluorescein, our Oregon Green® 488 DHPE (O12650, Figure 13.2.40) provides an important alternative to fluorescein DHPE in its many applications. When compared with the fluorescein derivative, Oregon Green® 488 DHPE exhibits greater photostability and a lower pK_a (pK_a = 4.7 versus 6.4 for fluorescein); however, these pK_a values may differ when the probes are bound to membranes.

Phospholipid with a BODIPY® FL Dye-Labeled Head Group

Our phospholipid with the green-fluorescent BODIPY® FL dye attached to the head group (BODIPY® FL DHPE, D3800; Figure 13.2.41) has significant potential for studies of molecular recognition interactions at membrane surfaces (Antibodies for Detecting Membrane-Surface Labels—Note 13.2). Spectral properties of this BODIPY® probe is generally the same as those described above for phospholipids with BODIPY® FL dye-labeled acyl chains.

Figure 13.2.40 Oregon Green® 488 DHPE (Oregon Green® 488 1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine; O12650).

Figure 13.2.41 *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-propionyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt (BODIPY® FL DHPE, D3800).

Phospholipids with a Rhodamine or Texas Red® Dye-Labeled Head Group

The rhodamine-labeled phospholipids TRITC DHPE (T1391, Figure 13.2.42) and rhodamine DHPE (often referred to as *N*-Rh-PE, L1392; Figure 13.2.1) do not readily transfer between separated lipid bilayers.^{140,236} This property has led to the extensive use of rhodamine DHPE for membrane fusion assays based on fluorescence resonance energy transfer from NBD-PE (Lipid-Mixing Assays of Membrane Fusion—Note 13.1). In addition, these probes are good resonance energy transfer acceptors from fluorescent lipid analogs such as the BODIPY® and NBD phospholipids²³⁷ and from protein labels such as 5-iodoacetamidofluorescein 5-IAF, I30451; Section 2.2) and IAEDANS^{238,239} (I14, Section 2.3). Rhodamine-labeled phospholipids have also been used as tracers for membrane traffic during endocytosis²⁴⁰ and for lipid processing in hepatocytes.²⁴¹ Texas Red® DHPE (T1395MP) is principally employed as an energy transfer acceptor from NBD, BODIPY® and fluorescein lipid probes. The longer emission wavelength of the Texas Red® dye provides superior separation of the donor and acceptor emission signals in resonance energy transfer microscopy.^{216,242} This technique has enabled visualization of ATP-dependent fusion of liposomes with the Golgi apparatus.²⁴³ Membrane flux during hemagglutinin-mediated cell-cell fusion has been visualized using Texas Red® DHPE and the lipophilic carbocyanine DiI (D282, D3911; Section 13.4) as membrane labels.²⁴⁴

Phospholipids with a Biotinylated Head Group

We offer phospholipids labeled with a biotin at the head group to facilitate binding of labeled membranes to other biomolecules. The biotinylated phospholipids (biotin DHPE, B1550; biotin-X DHPE, B1616, Figure 13.2.43) can be used to couple avidin or streptavidin (Table 7.9) to cell membranes, liposomes and lipid monolayers.²⁴⁵⁻²⁴⁸ Avidin can then be employed as a bridge for antibody coupling or for assembling liposomes into multiplex structures.^{249,250} Liposomes incorporating biotinylated phospholipids can also be used to immobilize membrane-bound proteins for analysis by affinity chromatography.²⁵¹ Interactions of biotinylated lipids with streptavidin provide a model for molecular

Figure 13.2.42 TRITC DHPE (*N*-(6-tetramethylrhodaminethiocarbonyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt; T1391).

Figure 13.2.43 Biotin-X DHPE (*N*-((6-(biotinoyl)amino)hexanoyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt; B1616).

recognition processes at membrane surfaces.^{252–254} The phase structure of lipid assemblies incorporating biotinylated phospholipids has been studied by X-ray diffraction,²¹⁸ ³¹P NMR and differential scanning calorimetry.^{255,256}

LipidTOX™ Phospholipid and Neutral Lipid Stains for High-Content Screening

With the resolution inherent in an image-based methodology and the productivity of high-throughput assays, high-content screening (HCS) or automated imaging provides a powerful tool for studying biology in a spatial and temporal context. Using HCS technology, researchers can examine multiple cellular targets and parameters in a large number of individually imaged cells and quantitatively assess the data. While many Molecular Probes® products can be directly applied to HCS protocols, we have developed validated tools and assays specifically for HCS platforms. These HCS products are:

- Validated on multiple imaging platforms
- Packaged in automation-compatible formulations
- Compatible with multiplex applications

Although designed for HCS platforms, HCS products and kits can also be used with conventional fluorescence microscopes equipped with standard optical filter sets.

HCS LipidTOX™ Phospholipidosis Detection Reagents

Phospholipidosis is often triggered by cationic amphiphilic drugs, which become enriched in lysosomes to high concentrations and inhibit normal metabolism of phospholipids. The subsequent intracellular accumulation of phospholipids and formation of lamellar bodies—phospholipidosis—can be detected in cells incubated in the presence of phospholipids conjugated to fluorescent dyes.

HCS LipidTOX™ Green and HCS LipidTOX™ Red phospholipidosis detection reagents (H34350, H34351), also called LipidTOX™ phospholipid stains, were specifically developed to characterize the potentially toxic side effects of compounds on lipid metabolism in mammalian cell lines using image-based HCS assays.²⁵⁷ Key advantages of this series of phospholipidosis detection reagents over conventional stains such as NBD-PE (N360) include their ready-to-use aqueous formulation, their narrow emission profiles (excitation/emission maxima ~495/525 nm for HCS LipidTOX™ Green phospholipidosis detection reagent and ~595/615 nm for HCS LipidTOX™ Red phospholipidosis detection reagent) and their compatibility with HCS LipidTOX™ neutral lipid stains.

HCS LipidTOX™ phospholipidosis detection reagents have not been observed to affect the normal growth of cells, and their live-cell staining patterns are maintained after formaldehyde fixation. These reagents are designed for fixed-end point workflows in which formaldehyde-fixed cells in microplates are processed, imaged and analyzed. HCS LipidTOX™ phospholipidosis detection reagents can easily be detected with fluorescence microscopes or HCS readers equipped with standard filter sets.

HCS LipidTOX™ Neutral Lipid Stains

As with phospholipidosis, steatosis or the intracellular accumulation of neutral lipids as lipid droplets or globules is often triggered by drugs that affect the metabolism of fatty acids or neutral lipids. HCS

LipidTOX™ neutral lipid stains were developed to characterize the effects of drugs and other compounds on lipid metabolism in mammalian cell lines. HCS LipidTOX™ neutral lipid stains have an extremely high affinity for neutral lipid droplets. These reagents are added after cell fixation and do not require subsequent wash steps after incubation with the sample. Key advantages of this series of neutral lipid stains over conventional stains such as Nile red (N1142; Section 13.5) include their ready-to-use formulations, their flexibility for multiplexing protocols and their compatibility with HCS LipidTOX™ phospholipidosis detection reagents. HCS LipidTOX™ neutral lipid stains can also be used to monitor the formation and differentiation of adipocytes, a process called adipogenesis. Adipogenesis is of acute interest to the biomedical and drug discovery community as it plays an important role in diseases such as obesity, diabetes and atherosclerosis.

Described more thoroughly in Section 13.5, HCS LipidTOX™ neutral lipid stains are available with green, red and deep red fluorescence emission:

- HCS LipidTOX™ Green neutral lipid stain (H34475), with excitation/emission maxima ~495/505 nm (Figure 13.2.44)
- HCS LipidTOX™ Red neutral lipid stain (H34476), with excitation/emission maxima ~577/609 nm
- HCS LipidTOX™ Deep Red neutral lipid stain (H34477), with excitation/emission maxima ~637/655 nm

HCS LipidTOX™ neutral lipid stains are designed for fixed-end point workflows in which formaldehyde-fixed cells in microplates are processed, imaged and analyzed. These stains can easily be detected with fluorescence microscopes or HCS readers equipped with standard filter sets.

Figure 13.2.44 LipidTOX™ Green neutral lipid stain and fatty acid-binding protein (FABP4) antibody labeling in adipocytes. Adipocytes differentiated from 3T3-L1 mouse fibroblasts were fixed with formaldehyde and permeabilized with saponin before labeling with rabbit anti-fatty acid binding protein (FABP4) IgG (red). These cells were then stained with LipidTOX™ Green neutral lipid stain (H34475, green), counterstained with DAPI (D1306, D21490; blue) and mounted in ProLong® Gold antifade reagent (P36930).

HCS LipidTOX™ Phospholipidosis and Steatosis Detection Kit

The detection and analysis of prelethal mechanisms in toxicological profiling and compound screening are extremely important components of the drug discovery process. The cationic amphiphilic drugs are among the most prominent examples of compounds that impact lipid metabolism of cells. These drugs tend to become enriched in lysosomes to high concentrations and inhibit the normal metabolism of phospholipids, which in turn causes the intracellular accumulation of phospholipids and the formation of lamellar bodies. Other drug classes more adversely affect various aspects of fatty acid or neutral lipid metabolism, leading to the cytoplasmic accumulation of neutral lipid as lipid droplets or globules.

The HCS LipidTOX™ Phospholipidosis and Steatosis Detection Kit (H34157, H34158) provides a complete set of reagents for performing validated HCS assays to detect and distinguish these two facets of cytotoxicity—the intracellular accumulation of phospholipids (phospholipidosis) and of neutral lipids (steatosis)—in mammalian cell lines after exposure to test compounds.²⁵⁸ This kit includes an aqueous, red-fluorescent formulation of labeled phospholipids (LipidTOX™ Red phospholipid stain, excitation/emission ~595/615 nm) and a ready-to-use, highly selective green-fluorescent stain for neutral lipids (LipidTOX™ Green neutral lipid stain, excitation/emission ~495/505 nm), which can be used sequentially for the analysis of phospholipidosis and steatosis, respectively, or can be used separately for single-parameter analysis.

After incubation with LipidTOX™ Red phospholipid stain and a test compound, the cells are fixed with formaldehyde and labeled with LipidTOX™ Green neutral lipid stain (Figure 13.2.45). Neither LipidTOX™ Red phospholipid stain, nor LipidTOX™ Green phospholipid stain described above, requires sonication or organic solvents. Furthermore, LipidTOX™ Green neutral lipid stain (as well as the other LipidTOX™ neutral lipid stains described above) is more selective than Nile red, allowing you to easily distinguish neutral lipids (such as those in adipocytes and cells undergoing steatosis) from other types of lipids.

Figure 13.2.45 Multiplex detection of phospholipidosis and steatosis in HepG2 cells using the HCS LipidTOX™ Phospholipidosis and Steatosis Detection Kit (H34157, H34158). HepG2 cells were co-incubated with tamoxifen and LipidTOX™ Red phospholipid stain, followed by fixation with formaldehyde and labeling with HCS LipidTOX™ Green neutral lipid stain and Hoechst 33342 (H1399, H3570, H21492).

Each HCS LipidTOX™ Phospholipidosis and Steatosis Detection Kit provides:

- LipidTOX™ Red phospholipid stain
- LipidTOX™ Green neutral lipid stain
- Hoechst 33342 for nuclear labeling
- Propranolol, a positive-control compound for inducing phospholipidosis
- Cyclosporin A, a positive-control compound for inducing steatosis
- Dimethylsulfoxide (DMSO)
- Detailed protocols

Sufficient reagents are provided for 240 assays (H34157, 2-plate size) or 1200 assays (H34158, 10-plate size), based on assay volumes of 100 μ L per well. These kits are designed for fixed-end point workflows in which formaldehyde-fixed cells in microplates are processed, imaged and analyzed. The fluorescent stains used for the analysis of phospholipidosis and steatosis can easily be detected with fluorescence microscopes or HCS readers equipped with standard filter sets.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- ADIFAB fatty acid indicator is a protein conjugate with a molecular weight of approximately 15,350. Em shifts from about 432 nm to 505 nm upon binding of fatty acids. (Mol Cell Biochem (1999) 192:87)
- Chloroform is the most generally useful solvent for preparing stock solutions of phospholipids (including sphingomyelins). Glycerophosphocholines are usually freely soluble in ethanol. Most other glycerophospholipids (phosphoethanolamines, phosphatidic acids and phosphoglycerols) are less soluble in ethanol, but solutions up to 1–2 mg/mL should be obtainable, using sonication to aid dispersion if necessary. Labeling of cells with fluorescent phospholipids can be enhanced by addition of cyclodextrins during incubation. (J Biol Chem (1999) 274:35359)
- Phospholipase A cleavage generates a fluorescent fatty acid (P1903MP) and a fluorescent lysophospholipid.
- Phospholipase A cleavage generates a fluorescent fatty acid (P31) and a fluorescent lysophospholipid.
- The absorption and fluorescence spectra of BODIPY® derivatives are relatively insensitive to the solvent.
- Phospholipase A cleavage results in increased fluorescence with essentially no wavelength shift. The cleavage products are D3862 and a fluorescent lysophospholipid.
- Diphenylhexatriene (DPH) and its derivatives are essentially nonfluorescent in water. Absorption and emission spectra have multiple peaks. The wavelength, resolution and relative intensity of these peaks are environment dependent. Abs and Em values are for the most intense peak in the solvent specified.
- Oxidation of the polyunsaturated butadienyl portion of the BODIPY® 581/591 dye results in a shift of the fluorescence emission peak from ~590 nm to ~510 nm. (Methods Enzymol (2000) 319:603, FEBS Lett (1999) 453:278)
- Phospholipase A₂ cleavage results in increased fluorescence with essentially no wavelength shift. The cleavage products are D3834 and a dinitrophenylated lysophospholipid.
- Spectra of this compound are in methanol containing a trace of KOH.
- Alkylpyrene fluorescence lifetimes are up to 110 nanoseconds and are very sensitive to oxygen.
- Pyrene derivatives exhibit structured spectra. The absorption maximum is usually about 340 nm with a subsidiary peak at about 325 nm. There are also strong absorption peaks below 300 nm. The emission maximum is usually about 376 nm with a subsidiary peak at 396 nm. Excimer emission at about 470 nm may be observed at high concentrations.
- Fluorescence of NBD and its derivatives in water is relatively weak. QY and τ increase and Em decreases in aprotic solvents and other nonpolar environments relative to water. (Biochemistry (1977) 16:5150, Photochem Photobiol (1991) 54:361)
- Cis-parinaric acid is highly oxygen sensitive. Use under N₂ or Ar. Cis-parinaric acid is essentially nonfluorescent in water.
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- Phospholipase A₁ cleavage results in increased fluorescence with essentially no wavelength shift. The cleavage products are D3834 and a dinitrophenylated lysophospholipid.
- A10072 exhibits dual emission (Em = 510 nm and 567 nm in MeOH, 513 nm and 575 nm when incorporated in phospholipid bilayer membranes). Phospholipase A₂ cleavage results in increased 510–513 nm emission and reciprocally diminished 567–575 nm emission.
- A10072 is also soluble at 2 mM in 2-methoxyethanol.

PRODUCT LIST 13.2 FATTY ACID ANALOGS AND PHOSPHOLIPIDS

Cat. No.	Product	Quantity
A3880	ADIFAB fatty acid indicator	200 µg
B1550	biotin DHPE (<i>N</i> -(biotinoyl)-1,2-dihexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine, triethylammonium salt)	10 mg
B1616	biotin-X DHPE (<i>N</i> -((6-(biotinoyl)amino)hexanoyl)-1,2-dihexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine, triethylammonium salt)	5 mg
B7701	1,2-bis-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-undecanoyl)- <i>sn</i> -glycero-3-phosphocholine (bis-BODIPY® FL C ₁₁ -PC)	100 µg
B3781	1,2-bis-(1-pyrenebutanoyl)- <i>sn</i> -glycero-3-phosphocholine	1 mg
B3782	1,2-bis-(1-pyrenedecanoyl)- <i>sn</i> -glycero-3-phosphocholine	1 mg
B3824	BODIPY® 500/510 C ₄ , C ₉ (5-butyl-4,4-difluoro-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-nonanoic acid)	1 mg
D3771	2-decanoyl-1-(<i>O</i> -(11-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-propionyl)amino)undecyl)- <i>sn</i> -glycero-3-phosphocholine	1 mg
D3822	4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-dodecanoic acid (BODIPY® FL C ₁₂)	1 mg
D3792	2-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-dodecanoyl)-1-hexadecanoyl- <i>sn</i> -glycero-3-phosphocholine (β-BODIPY® FL C ₁₂ -HPC)	100 µg
D3821	4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-hexadecanoic acid (BODIPY® FL C ₁₆)	1 mg
D3834	4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-pentanoic acid (BODIPY® FL C ₅)	1 mg
D3805	2-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-pentanoyl)-1-hexadecanoyl- <i>sn</i> -glycero-3-phosphate, diammonium salt (β-BODIPY® FL C ₅ -HPA)	100 µg
D3803	2-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-pentanoyl)-1-hexadecanoyl- <i>sn</i> -glycero-3-phosphocholine (β-BODIPY® FL C ₅ -HPC)	100 µg
D3800	<i>N</i> -(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-propionyl)-1,2-dihexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine, triethylammonium salt (BODIPY® FL DHPE)	100 µg
D3862	4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-undecanoic acid (BODIPY® FL C ₁₁)	1 mg
D3832	4,4-difluoro-5,7-diphenyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-dodecanoic acid (BODIPY® 530/550 C ₁₂)	1 mg
D3815	2-(4,4-difluoro-5,7-diphenyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-pentanoyl)-1-hexadecanoyl- <i>sn</i> -glycero-3-phosphocholine (β-BODIPY® 530/550 C ₅ -HPC)	100 µg
D3823	4,4-difluoro-5-methyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-dodecanoic acid (BODIPY® 500/510 C ₁ , C ₁₂)	1 mg
D3793	2-(4,4-difluoro-5-methyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-dodecanoyl)-1-hexadecanoyl- <i>sn</i> -glycero-3-phosphocholine (β-BODIPY® 500/510 C ₁₂ -HPC)	100 µg
D3825	4,4-difluoro-5-octyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-pentanoic acid (BODIPY® 500/510 C ₈ , C ₅)	1 mg
D3861	4,4-difluoro-5-(4-phenyl-1,3-butadienyl)-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-undecanoic acid (BODIPY® 581/591 C ₁₁)	1 mg
D3835	4,4-difluoro-5-(2-thienyl)-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-dodecanoic acid (BODIPY® 558/568 C ₁₂)	1 mg
D94	11-((5-dimethylaminonaphthalene-1-sulfonyl)amino)undecanoic acid (DAUDA)	100 mg
D57	<i>N</i> -(5-dimethylaminonaphthalene-1-sulfonyl)-1,2-dihexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine, triethylammonium salt (dansyl DHPE)	25 mg
D23739	<i>N</i> -((6-(2,4-dinitrophenyl)amino)hexanoyl)-2-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-pentanoyl)-1-hexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine, triethylammonium salt (PED6)	1 mg
D476	β-DPH HPC (2-(3-(diphenylhexatrienyl)propanoyl)-1-hexadecanoyl- <i>sn</i> -glycero-3-phosphocholine)	1 mg
F362	fluorescein DHPE (<i>N</i> -(fluorescein-5-thiocarbamoyl)-1,2-dihexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine, triethylammonium salt)	5 mg
H34350	HCS LipidTOX™ Green phospholipidosis detection reagent *1000X aqueous solution* *for cellular imaging* *10-plate size*	each
H34157	HCS LipidTOX™ Phospholipidosis and Steatosis Detection Kit *for high-content screening* *for cellular imaging* *2-plate size*	1 kit
H34158	HCS LipidTOX™ Phospholipidosis and Steatosis Detection Kit *for high-content screening* *for cellular imaging* *10-plate size*	1 kit
H34351	HCS LipidTOX™ Red phospholipidosis detection reagent *1000X aqueous solution* *for cellular imaging* *10-plate size*	each
H361	1-hexadecanoyl-2-(1-pyrenedecanoyl)- <i>sn</i> -glycero-3-phosphocholine (β-py-C10-HPC)	1 mg
H3809	1-hexadecanoyl-2-(1-pyrenedecanoyl)- <i>sn</i> -glycero-3-phosphoglycerol, ammonium salt (β-py-C10-PG)	1 mg
L1392	Lissamine rhodamine B 1,2-dihexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine, triethylammonium salt (rhodamine DHPE)	5 mg
M12652	Marina Blue® 1,2-dihexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine (Marina Blue® DHPE)	1 mg
N360	NBD-PE (<i>N</i> -(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-1,2-dihexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine, triethylammonium salt)	10 mg
N316	NBD-X (6-(<i>N</i> -(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoic acid)	100 mg
N678	12-(<i>N</i> -(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)dodecanoic acid	100 mg
N3787	2-(12-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)dodecanoyl-1-hexadecanoyl- <i>sn</i> -glycero-3-phosphocholine (NBD C ₁₂ -HPC)	5 mg
N3786	2-(6-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoyl-1-hexadecanoyl- <i>sn</i> -glycero-3-phosphocholine (NBD C ₆ -HPC)	5 mg
O12650	Oregon Green® 488 DHPE (Oregon Green® 488 1,2-dihexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine)	1 mg
P22652	Pacific Blue™ DMPE (Pacific Blue™ 1,2-ditetradecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine, triethylammonium salt)	1 mg
P36005	<i>cis</i> -parinaric acid *3 mM in ethanol*	10 mL
A10070	PED-A1 (<i>N</i> -((6-(2,4-DNP)amino)hexanoyl)-1-(BODIPY® FL C ₅)-2-hexyl- <i>sn</i> -glycero-3-phosphoethanolamine) *phospholipase A ₁ selective substrate*	100 µg
P1903MP	1-pyrenebutanoic acid *high purity*	100 mg
P31	1-pyrenedecanoic acid	25 mg
P96	1-pyrenedodecanoic acid	25 mg
P243	1-pyrenehexadecanoic acid	5 mg
A10072	Red/Green BODIPY® PC-A2 (1-(<i>O</i> -(6-BODIPY® 558/568-aminohexyl)-2-BODIPY® FL C ₅ - <i>sn</i> -glycero-3-phosphocholine) *ratiometric phospholipase A ₂ substrate*	100 µg
T1395MP	Texas Red® DHPE (Texas Red® 1,2-dihexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine, triethylammonium salt)	1 mg
T1391	TRITC DHPE (<i>N</i> -(6-tetramethylrhodaminethiocarbamoyl)-1,2-dihexadecanoyl- <i>sn</i> -glycero-3-phosphoethanolamine, triethylammonium salt)	1 mg

13.3 Sphingolipids, Steroids, Lipopolysaccharides and Related Probes

Sphingolipids

Structure and Activity

Sphingolipids are essential components of the plasma membrane of eukaryotic cells, where they are typically found in the outer leaflet. Although particularly abundant in mammalian cells, sphingolipids are also present in *Saccharomyces cerevisiae*,¹ other fungi and plants. Sphingolipids differ from phospholipids in that they are based on a lipophilic amino alcohol (sphingosine, Figure 13.3.1) rather than glycerol. Sphingolipids play important roles in signal transduction processes^{2,3} (Chapter 17). Genetic defects in enzymes in the metabolic pathways of sphingolipid synthesis and degradation, including those involved in type I Gaucher (Ashkenazi) disease, type A Niemann-Pick disease, Krabbe disease,⁴⁻⁸ and other lysosomal storage diseases, can be detected at the cellular level using our fluorescent analogs of sphingolipids.

Ceramides are the biological building blocks of more complex sphingolipids. Metabolism of ceramides typically occurs in Golgi and endoplasmic reticulum membranes, and fluorescent ceramide analogs (Section 12.4) are important probes for measuring the intracellular distribution and transport of the labeled molecules in live cells.⁹

If the hydroxyl group of the ceramide is esterified to phosphocholine, the sphingolipid is a sphingomyelin (Figure 13.3.1). The main pathway of sphingomyelin biosynthesis in mammalian cells is based on the transfer of phosphocholine from glycerophosphocholine to ceramide, catalyzed by sphingomyelin synthase in the Golgi membrane. Synthesis is followed by exocytosis of the sphingomyelin to the plasma membrane, apparently via a vesicular pathway and flip-flop to the outer membrane.² Sphingomyelinases, which are functionally analogous to phospholipase C in their chemistry, hydrolyze sphingomyelins back to ceramides. Generation of ceramides by hydrolysis of sphingomyelins appears to play a role in mediating the effects of exposure to tumor necrosis factor- α (TNF- α), γ -interferon and several other agents, all of which induce an apoptosis-like cell death.¹¹⁻¹⁵ Section 15.5 describes our extensive selection of reagents for following the diverse morphological

and biochemical changes that occur during apoptosis. Sensitive fluorescence-based measurements of sphingomyelinase activity using natural, unlabeled sphingomyelin as the substrate can be carried out using our Amplex® Red Sphingomyelinase Assay Kit (A12220), described below.

In glycosylsphingolipids, the free hydroxyl group of the ceramide is glycosylated to give a sphingosyl glycoside (cerebroside, Figure 13.3.2) or a ganglioside (Figure 13.3.3). These glycosphingolipids form cell-type-specific patterns at the cell surface that change with cell growth, differentiation, viral transformation and oncogenesis.¹⁶

Figure 13.3.2 BODIPY® FL C₁₂-gluco-cerebroside.

Figure 13.3.3 BODIPY® FL C₅-ganglioside G_{M1} (B13950).

Figure 13.3.1 Sphingomyelins, ceramides and cerebroside are examples of sphingolipids derived from sphingosine. R represents the hydrocarbon tail portion of a fatty acid residue.

Glycosphingolipids interact at the cell surface with toxins, viruses and bacteria, as well as with receptors and enzymes¹⁷ and are involved in cell-type-specific adhesion processes.¹⁶ Gangliosides modulate the trophic factor-stimulated dimerization, tyrosine phosphorylation and subsequent signal transduction events of several tyrosine kinase receptors.¹⁷ Ganglioside G_{M1} has anti-neurotoxic, neuroprotective and neurorestorative effects on various central neurotransmitter systems.¹⁸ Gangliosides, including ganglioside G_{M1}, partition into lipid rafts—detergent-insoluble, sphingolipid- and cholesterol-rich membrane microdomains that form lateral assemblies in the plasma membrane.^{19–25} We offer Vybrant® Lipid Raft Labeling Kits (V34403, V34404, V34405), as well as Alexa Fluor® dye conjugates of subunit B of cholera toxin (Section 7.7), a protein that selectively binds to ganglioside G_{M1} in lipid rafts.

BODIPY® Sphingolipids

Ceramides (*N*-acylsphingosines), like diacylglycerols, are lipid second messengers that function in signal transduction processes.^{26–28} The concentration-dependent spectral properties of BODIPY® FL C₅-ceramide (D3521, B22650; Figure 13.3.4), BODIPY® FL C₅-sphingomyelin^{29–31} (D3522, Figure 13.3.5) and BODIPY® FL C₁₂-sphingomyelin³² (D7711) make them particularly suitable for investigating sphingolipid transport, metabolism and microdomains,^{31,33–37} in addition to their well-documented use as structural markers for the Golgi complex³⁸ (Section 12.4, Figure 13.3.6). BODIPY® FL C₅-ceramide can be visualized by fluorescence microscopy^{39,40} (Figure 13.3.7, Figure 13.3.8) or by electron microscopy following diaminobenzidine (DAB) photoconversion to an electron-dense product⁴¹ (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2).

Our range of BODIPY® sphingolipids also includes the long-wavelength light-excitable BODIPY® TR ceramide^{42,43} (D7540, Figure 13.3.9), as well as BODIPY® FL C₅-lactosylceramide^{44–49} (D13951), BODIPY® FL C₅-ganglioside G_{M1}⁵⁰ (B13950, Figure 13.3.3) and BODIPY® FL C₁₂-galactocerebroside⁵¹ (D7519). All Molecular Probes® sphingolipids are prepared from *D*-erythro-sphingosine and therefore have the same stereochemical conformation as natural biologically active sphingolipids.⁵²

Complexing fluorescent lipids with bovine serum albumin (BSA) facilitates cell labeling by eliminating the need for organic solvents to dissolve the lipophilic probe—the BSA-complexed probe can be directly dissolved in water. We offer four BODIPY® sphingolipid-BSA complexes for the study of lipid metabolism and trafficking, including BODIPY® FL C₅-ceramide, BODIPY® TR ceramide, BODIPY® FL C₅-ganglioside G_{M1} and BODIPY® FL C₅-lactosylceramide, each complexed with defatted BSA (B22650, B34400, B34401, B34402, respectively).

BODIPY® FL C₅-ceramide has been used to investigate the linkage of sphingolipid metabolism to protein secretory pathways^{53–56} and neuronal growth.^{47,57} Internalization of BODIPY® FL C₅-sphingomyelin from the plasma membrane of human skin fibroblasts results in a mixed population of labeled endosomes that can be distinguished based on the concentration-dependent green

Figure 13.3.4 *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-5-indacene-3-pentanoyl)sphingosine (BODIPY® FL C₅-ceramide, D3521).

Figure 13.3.5 *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-5-indacene-3-pentanoyl)sphingosyl phosphocholine (BODIPY® FL C₅-sphingomyelin, D3522).

Figure 13.3.6 Selective staining of the Golgi apparatus using the green-fluorescent BODIPY® FL C₅-ceramide (D3521) (top). At high concentrations, the BODIPY® FL fluorophore forms excimers that can be visualized using a red longpass optical filter (bottom). The BODIPY® FL C₅-ceramide accumulation in the trans-Golgi is sufficient for excimer formation (J Cell Biol (1991) 113:1267). Images contributed by Richard Pagano, Mayo Foundation.

Figure 13.3.7 Cells in the notochord rudiment of a zebrafish embryo undergoing mediolateral intercalation to lengthen the forming notochord. BODIPY® FL C₅-ceramide (D3521) localizes in the interstitial fluid of the zebrafish embryo and freely diffuses between cells, illuminating cell boundaries. This confocal image was obtained using a Bio-Rad® MRC-600 microscope. Image contributed by Mark Cooper, University of Washington.

Figure 13.3.8 Nucleus and Golgi apparatus of a bovine pulmonary artery endothelial cell (BPAEC) labeled with Hoechst 33342 (H1399, H3569, H21492) and the BSA complex of BODIPY® FL C₅-ceramide (D3521, B22650), respectively.

Figure 13.3.9 BODIPY® TR ceramide (*N*-((4-(4,4-difluoro-5-(2-thienyl)-4-bora-3a,4a-diaza-5-indacene-3-yl)phenoxy) acetyl)sphingosine; D7540).

Figure 13.3.10 A J774 mouse macrophage cell sequentially stained with BODIPY[®] FL ganglioside G_{M1} (B13950) and then with Alexa Fluor[®] 555 dye-labeled cholera toxin subunit B (C22843, C34776; also available as a component of V34404). The cell was then treated with an anti-CT-B antibody (a component of V34404) to induce crosslinking. Alexa Fluor[®] 555 dye fluorescence (top panel, red) and BODIPY[®] FL dye fluorescence (middle panel, green) were imaged separately and overlaid to emphasize the coincident staining (bottom panel, yellow). Nuclei were stained with blue-fluorescent Hoechst 33342 (H1399, H3570, H21492).

Figure 13.3.11 NBD C₆-ceramide (6-((N-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoyl)sphingosine, N1154).

(~515 nm) or red (~620 nm) emission of the probe³¹ (Figure 13.3.6). BODIPY[®] C₅-sphingomyelin has also been used to assess sphingomyelinase gene transfer and expression in hematopoietic stem and progenitor cells.⁴ Studies by Martin and Pagano have shown that the internalization routes for BODIPY[®] FL C₅-glucocerebroside follow both endocytic and nonendocytic pathways and are quite different from those for BODIPY[®] FL C₅-sphingomyelin.⁵⁸

BODIPY[®] FL C₅-lactosylceramide, BODIPY[®] FL C₅-ganglioside G_{M1} and BODIPY[®] FL cerebrosides are useful tools for the study of glycosphingolipid transport and signaling pathways in cells^{59,60} and for diagnosis of lipid-storage disorders such as Niemann–Pick disease,⁶¹ Gaucher disease, G_{M1} gangliosidosis, Morquio syndrome and type IV mucopolipidosis^{64,62–67} (ML-IV). Addition of BODIPY[®] FL C₅-lactosylceramide to the culture medium of cells from patients with sphingolipid-storage diseases (sphingolipidosis) results in fluorescent product accumulation in lysosomes, whereas this probe accumulates in the Golgi apparatus of normal cells and cells from patients with other storage diseases.^{46,48} BODIPY[®] FL C₅-ganglioside G_{M1} has been shown to form cholesterol-enhanced clusters in membrane complexes with amyloid β-protein in a model of Alzheimer disease amyloid fibrils.⁶⁸ As observed by fluorescence microscopy, the colocalization of BODIPY[®] FL C₅-ganglioside G_{M1} and fluorescent cholera toxin B conjugates (Section 7.7) provides a direct indication of the association of these molecules in lipid rafts⁵⁰ (Figure 13.3.10).

NBD Sphingolipids

NBD C₆-ceramide (N1154, Figure 13.3.11) and NBD C₆-sphingomyelin (N3524) analogs predate their BODIPY[®] counterparts and have been extensively used for following sphingolipid metabolism in cells^{9,59,69,70} and in multicellular organisms.⁷¹ As with BODIPY[®] FL C₅-ceramide, we also offer NBD C₆-ceramide complexed with defatted BSA (N22651) to facilitate cell loading without the use of organic solvents to dissolve the probe. Koval and Pagano have prepared NBD analogs of both the naturally occurring *D-erythro* and the nonnatural *L-threo* stereoisomers of sphingomyelin and have compared their intracellular transport behavior in Chinese hamster ovary (CHO) fibroblasts.⁷²

NBD C₆-ceramide lacks the useful concentration-dependent optical properties of the BODIPY[®] FL analog and is less photostable; however, the fluorescence of NBD C₆-ceramide is apparently sensitive to the cholesterol content of the Golgi apparatus, a phenomenon that is not observed with BODIPY[®] FL C₅-ceramide. If NBD C₆-ceramide-containing cells are starved for cholesterol, the NBD C₆-ceramide that accumulates within the Golgi apparatus appears to be severely photolabile but this NBD photobleaching can be reduced by stimulation of cholesterol synthesis. Thus, NBD C₆-ceramide may be useful in monitoring the cholesterol content of the Golgi apparatus in live cells.⁷³

Vybrant[®] Lipid Raft Labeling Kits

The Vybrant[®] Lipid Raft Labeling Kits (V34403, V34404, V34405) are designed to provide convenient, reliable and extremely bright fluorescent labeling of lipid rafts in live cells. Lipid rafts are detergent-insoluble, sphingolipid- and cholesterol-rich membrane microdomains that form lateral assemblies in the plasma membrane.^{19–25} Lipid rafts also sequester glycosphatidylinositol (GPI)-linked proteins and other signaling proteins and receptors, which may be regulated by their selective interactions with these membrane microdomains.^{50,74–78} Lipid rafts play a role in a variety of cellular processes—including the compartmentalization of cell-signaling events,^{79–86} the regulation of apoptosis^{87–89} and the intracellular trafficking of certain membrane proteins and lipids^{90–92}—as well as in the infectious cycles of several viruses and bacterial pathogens.^{93–98} Examining the formation and regulation of lipid rafts is a critical step in understanding these aspects of eukaryotic cell function.

The Vybrant[®] Lipid Raft Labeling Kits provide the key reagents for fluorescently labeling lipid rafts *in vivo* with our bright and extremely photostable Alexa Fluor[®] dyes (Figure 13.3.10). Live cells are first labeled with the green-fluorescent Alexa Fluor[®] 488, orange-fluorescent Alexa Fluor[®] 555 or red-fluorescent Alexa Fluor[®] 594 conjugate of cholera toxin subunit B (CT-B). This CT-B conjugate binds to the pentasaccharide chain of plasma membrane ganglioside G_{M1}, which selectively partitions into lipid rafts.^{50,99,100} All Molecular Probes[®] CT-B conjugates are prepared from recombinant CT-B and are completely free of the toxic subunit A, thus eliminating any concern for toxicity or ADP-ribosylating activity. An antibody that specifically recognizes CT-B is then

used to crosslink the CT-B-labeled lipid rafts into distinct patches on the plasma membrane, which are easily visualized by fluorescence microscopy.^{101,102}

Each Vybrant® Lipid Raft Labeling Kit contains sufficient reagents to label 50 live-cell samples in a 2 mL assay, including:

- Recombinant cholera toxin subunit B (CT-B) labeled with the Alexa Fluor® 488 (in Kit V34403), Alexa Fluor® 555 (in Kit V34404) or Alexa Fluor® 594 (in Kit V34405) dye
- Anti-cholera toxin subunit B antibody (anti-CT-B)
- Concentrated phosphate-buffered saline (PBS)
- Detailed labeling protocols

Because they are compatible with various multilabeling schemes, the Vybrant® Lipid Raft Labeling Kits can also serve as important tools for identifying physiologically significant membrane proteins that associate with lipid rafts. Cells can be labeled with other live-cell probes during the lipid raft labeling protocol or immediately following the antibody crosslinking step, depending on the specific labeling requirements of the other probes. Alternatively, once the lipid rafts have been labeled and crosslinked, the cells can be fixed for long-term storage or fixed and permeabilized for subsequent labeling with antibodies or other probes that are impermeant to live cells.

Amplex® Red Sphingomyelinase Assay Kit

The Amplex® Red Sphingomyelinase Assay Kit (A12220) is designed for measuring sphingomyelinase activity in solution using a fluorescence microplate reader or fluorometer¹⁰³ (Figure 13.3.12). This assay should be useful for screening sphingomyelinase activators or inhibitors or for detecting sphingomyelinase activity in cell and tissue extracts. The assay, which uses natural sphingomyelin as the principal substrate, employs an enzyme-coupled detection scheme in which phosphocholine liberated by the action of sphingomyelinase is cleaved by alkaline phosphatase to generate choline. Choline is, in turn, oxidized by choline oxidase, generating H₂O₂, which drives the conversion of the Amplex® Red reagent (A12222, A22177; Section 10.5) to red-fluorescent resorufin. This sensitive assay technique has been employed to detect activation of acid sphingomyelinase associated with ultraviolet

Figure 13.3.12 Measurement of sphingomyelinase activity using the Amplex® Red Sphingomyelinase Assay Kit (A12220). Each reaction contained 50 μ M Amplex® Red reagent, 1 U/mL horseradish peroxidase (HRP), 0.1 U/mL choline oxidase, 4 U/mL of alkaline phosphatase, 0.25 mM sphingomyelin and the indicated amount of *Staphylococcus aureus* sphingomyelinase in 1X reaction buffer. Reactions were incubated at 37°C for one hour. Fluorescence was measured with a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm.

radiation-induced apoptosis¹⁰⁴ and to characterize an insecticidal sphingomyelinase C produced by *Bacillus cereus*.¹⁰⁵

The Amplex® Red Sphingomyelinase Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- H₂O₂ for use as a positive control
- Concentrated reaction buffer
- Choline oxidase from *Alcaligenes* sp.
- Alkaline phosphatase from calf intestine
- Sphingomyelin
- Triton X-100
- Sphingomyelinase from *Bacillus* sp.
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using a fluorescence microplate reader and a reaction volume of 200 μ L per assay.

Steroids

Most steroids are neutral lipids and, as such, localize primarily within the cell's membranes, in lipid vacuoles and bound to certain lipoproteins. Fluorescent analogs of these biomolecules, most of which are derived from BODIPY® and NBD dyes, are highly lipophilic probes. One application of these probes is to detect enzymatic activity—either *in vitro* or *in vivo*—through hydrolysis of the fatty acid esters to fluorescent fatty acids.¹⁰⁶ Although the substrates and products in these enzyme assays typically have similar fluorescence properties, they are readily extracted by an organic solvent and separated by chromatography.

We have also developed sensitive fluorometric assays for cholesterol, cholesteryl esters and enzymes that metabolize natural cholesterol derivatives; the assay reagents and protocols are available in our Amplex® Red Cholesterol Assay Kit (A12216) described below. A review of the cellular organization, functions and transport of cholesterol has recently been published.¹⁰⁷

BODIPY® Cholesteryl Esters

Cholesteryl esters consist of a fatty acid esterified to the 3 β -hydroxyl group of cholesterol (Figure 13.3.13). These very nonpolar species are the predominant lipid components of atherosclerotic plaque and low- and high-density lipoprotein (LDL and HDL) cores. We offer cholesteryl esters of three of our BODIPY® fatty acids—BODIPY® FL C₁₂ (C3927MP), BODIPY® 542/563 C₁₁ (C12680) and BODIPY® 576/589 C₁₁ (C12681)—all of which have long-wavelength visible emission. BODIPY®

Figure 13.3.13 Cholesteryl BODIPY® FL C₁₂ (cholesteryl 4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-dodecanoate; C3927MP).

Figure 13.3.14 Selective uptake of cholesteryl esters (CE) in rat ovarian granulosa cells as monitored with cholesteryl BODIPY[®] FL C₁₂ (C3927MP). The hormone-stimulated cells internalized and stored CEs derived from reconstituted high-density lipoprotein (HDL)-BODIPY[®] CE complexes (*J Biol Chem* (1996) 271:16208). A low-light (<100 μW beam power) computerized imaging system minimized any photobleaching of the fluorophore. This pseudocolored image uses yellow-green to illustrate the low-level fluorescence of the cytoplasmic membranes, yellow to illustrate the medium-level fluorescence of the Golgi, and red to illustrate the high-level fluorescence of the lipid droplets. Image contributed by Eve Reaven, VA Medical Center, Palo Alto, California.

Figure 13.3.15 Detection of cholesterol using the Amplex[®] Red Cholesterol Assay Kit (A12220). Each reaction contained 150 μM Amplex[®] Red reagent, 1 U/mL horseradish peroxidase (HRP), 1 U/mL cholesterol oxidase, 1 U/mL cholesterol esterase and the indicated amount of cholesterol in 1X reaction buffer. Reactions were incubated at 37°C for 30 minutes. Fluorescence was measured with a fluorescence microplate reader using excitation at 560 ± 10 nm and fluorescence detection at 590 ± 10 nm. The insert above shows the high sensitivity and excellent linearity of the assay at low cholesterol levels (0–10 ng/mL).

Figure 13.3.16 Enzyme-coupled Amplex[®] Red assays. Enzyme reactions that produce H₂O₂ can be made into Amplex[®] Red assays. The Amplex[®] Red Cholesterol Assay Kit (A12216) uses cholesterol oxidase to produce H₂O₂, which is then detected by the Amplex[®] Red reagent in the presence of horseradish peroxidase (HRP). Similarly, the Amplex[®] Red Acetylcholine/Acetylcholinesterase Assay Kit (A12217) uses choline oxidase to produce H₂O₂.

FL cholesteryl ester can be used as a tracer of cholesterol transport and receptor-mediated endocytosis of lipoproteins by fluorescence microscopy^{108–110} (Figure 13.3.14) and as a general nonexchangeable membrane marker. Addition of methyl β-cyclodextrin to BODIPY[®] FL cholesteryl ester is reported to facilitate its uptake by cells and tissues.¹¹¹ Researchers have extensively used BODIPY[®] FL cholesteryl ester to measure cholesteryl ester-transfer protein (CETP) activity using fluorescence microplate readers.^{112–115} The longer-wavelength BODIPY[®] 542/563 and BODIPY[®] 576/589 cholesteryl esters likely have similar applications.

Side Chain-Modified Cholesterol Analog

We offer an NBD-labeled cholesterol analog in which the fluorophore replaces the terminal segment of cholesterol's flexible alkyl tail. The environment-sensitive NBD fluorophore of the NBD cholesterol analog (N1148) localizes in the membrane's interior, unlike the anomalous positioning of NBD-labeled phospholipid acyl chains.¹¹⁶ As with other NBD lipid analogs, this probe is useful for investigating lipid transport processes^{117,118} and lipid-protein interactions.^{119,120} NBD cholesterol is selectively taken up by high-density lipoproteins via the scavenger receptor B1.¹¹⁷ A lipid droplet-specific protein binds unesterified NBD cholesterol with extremely high affinity¹¹⁷ ($K_d = 2$ nM).

Amplex[®] Red Cholesterol Assay Kit

The Amplex[®] Red Cholesterol Assay Kit (A12216) provides an exceptionally sensitive assay for both cholesterol and cholesteryl esters in complex mixtures and is suitable for use with either fluorescence microplate readers or fluorimeters. The assay provided in this kit is designed to detect as little as 5 ng/mL (5×10^{-4} mg/dL) cholesterol (Figure 13.3.15) and to accurately measure the cholesterol or cholesteryl ester content in the equivalent of 0.01 μL of human serum.¹²¹ The assay uses an enzyme-coupled reaction scheme in which cholesteryl esters are hydrolyzed by cholesterol esterase into cholesterol, which is then oxidized by cholesterol oxidase to yield H₂O₂ and the corresponding ketone steroidal product (Figure 13.3.16). The H₂O₂ is then detected using the Amplex[®] Red reagent in combination with horseradish peroxidase (HRP).

The Amplex® Red cholesterol assay is continuous and requires no separation or wash steps. These characteristics make the assay particularly well suited for the rapid and direct analysis of cholesterol in blood and food samples using automated instruments. By performing two separate measurements in the presence and absence of cholesterol esterase, this assay is also potentially useful for determining the fraction of cholesterol that is in the form of cholesteryl esters within a sample. In addition, by adding an excess of cholesterol to the reaction, this assay can be used to sensitively detect the activity of cholesterol oxidase. The Amplex® Red Cholesterol Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- H₂O₂ for use as a positive control
- Concentrated reaction buffer
- Cholesterol oxidase from *Streptomyces*
- Cholesterol esterase from *Pseudomonas*
- Cholesterol for preparation of a standard curve
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using a fluorescence microplate reader and a reaction volume of 100 µL per assay.

Fluorescent Triacylglycerol

The fluorescent triacylglycerol 1,2-dioleoyl-3-(1-pyrenedodecanoyl)-*rac*-glycerol (D6562) has a pyrene fatty acid ester replacing one of the three fatty acyl residues of a natural triacylglycerol (Figure 13.3.17). Pyrene has the important spectral property of forming excimers (Figure 13.3.18) when two fluorophores are in close proximity during the excited state. Pyrene triacylglycerols are useful for measuring cholesteryl ester transfer protein-mediated triacylglycerol transport between plasma lipoproteins.¹²² They are also excellent substrates for lipoprotein lipase and hepatic triacylglycerol lipase.¹²³

Lipopolysaccharides

Fluorescent Lipopolysaccharides

We offer fluorescent conjugates of lipopolysaccharides (LPS) from *Escherichia coli* and *Salmonella minnesota* (Section 16.1, Table 16.1), including:

- Alexa Fluor® 488 LPS from *E. coli* serotype 055:B5 (L23351)
- Alexa Fluor® 488 LPS from *S. minnesota* (L23356)
- Alexa Fluor® 568 LPS from *E. coli* serotype 055:B5 (L23352)
- Alexa Fluor® 594 LPS from *E. coli* serotype 055:B5 (L23353)
- BODIPY® FL LPS from *E. coli* serotype 055:B5 (L23350)

LPS, also known as endotoxins, are a family of complex glycolipid molecules located on the surface of gram-negative bacteria. LPS play a large role in protecting the bacterium from host defense mechanisms and antibiotics. Binding of LPS to the CD14 cell-surface receptor of phagocytes (Figure 13.3.19) is the key initiation step in the mammalian immune response to infection by gram-negative bacteria. The structural

Figure 13.3.17 1,2-Dioleoyl-3-(1-pyrenedodecanoyl)-*rac*-glycerol (D6562).

Figure 13.3.18 Excimer formation by pyrene in ethanol. Spectra are normalized to the 371.5 nm peak of the monomer. All spectra are essentially identical below 400 nm after normalization. Spectra are as follows: 1) 2 mM pyrene, purged with argon to remove oxygen; 2) 2 mM pyrene, air-equilibrated; 3) 0.5 mM pyrene (argon-purged); and 4) 2 µM pyrene (argon-purged). The monomer-to-excimer ratio (371.5 nm/470 nm) is dependent on both pyrene concentration and the excited-state lifetime, which is variable because of quenching by oxygen.

Figure 13.3.19 Flow cytometry analysis of blood using an Alexa Fluor® 488 lipopolysaccharide (LPS). Human blood was incubated with Alexa Fluor® 488 LPS from *Escherichia coli* (L23351) and anti-CD14 antibody on ice for 20 minutes. The red blood cells were lysed and the sample was analyzed on a flow cytometer equipped with a 488 nm Ar-Kr excitation source and a 525 ± 12 nm bandpass emission filter. Monocytes were identified based on their light scatter and CD14 expression.

Figure 13.3.20 Structure of the lipid A component of *Salmonella minnesota* lipopolysaccharide.

Figure 13.3.21 Lipopolysaccharide staining with the Pro-Q® Emerald 300 Lipopolysaccharide Gel Stain Kit. Lipopolysaccharides (LPS) were electrophoresed through a 13% acrylamide gel and stained using the Pro-Q® Emerald 300 Lipopolysaccharide Gel Stain Kit (P20495). From left to right, the lanes contain: CandyCane™ glycoprotein molecular weight standards (~250 ng/band), blank, 4, 1 and 0.25 μg of LPS from *Escherichia coli* smooth serotype 055:B5 and 4, 1 and 0.25 μg of LPS from *E. coli* rough mutant EH100 (Ra mutant).

core of LPS, and the primary determinant of its biological activity, is an *N*-acetylglucosamine derivative, lipid A (Figure 13.3.20). Two plasma proteins, LPS-binding protein (LBP) and soluble CD14 (sCD14), play primary roles in transporting LPS and mediating cellular responses.^{124–129} If the fatty acid residues are removed from the lipid A component, the toxicity of the LPS can be reduced significantly; however, the mono- or diphosphoryl forms of lipid A are inherently toxic. In many gram-negative bacterial infections, LPS are responsible for clinically significant symptoms like fever, low blood pressure and tissue edema, which can lead to disseminated intravascular coagulation, organ failure and death. Studies also clearly indicate that LPS induce various signal transduction pathways, including those involving protein kinase C^{130,131} and protein myristylation,¹³² and stimulate a variety of immunochemical responses, including B lymphocyte¹³³ and G-protein activation.¹³⁴

The fluorescent BODIPY® FL and Alexa Fluor® LPS conjugates, which are labeled with succinimidyl esters of these dyes, allow researchers to follow LPS binding, transport and cell internalization processes. Lipopolysaccharide internalization activates endotoxin-dependent signal transduction in cardiomyocytes.¹³⁵ The Alexa Fluor® 488 LPS conjugates (L23351, L23356) selectively label microglia in a mixed culture containing oligodendrocyte precursors, astrocytes and microglia.¹³⁶ A biologically active conjugate of galactose oxidase-oxidized *S. minnesota* LPS and our Alexa Fluor® 488 hydrazide (A10436, Section 3.3; A10440) has been used to elucidate molecular mechanisms of septic shock.¹³⁷

The BODIPY® FL derivative of LPS from *E. coli* strain LCD25 (L23350) was used to measure the transfer rate of LPS from monocytes to high-density lipoprotein¹³⁸ (HDL). Another study utilized a BODIPY® FL derivative of LPS from *S. minnesota* to demonstrate transport to the Golgi apparatus in neutrophils,^{124,125} although this could have been due to probe metabolism. It has been reported that organelles other than the Golgi are labeled by some fluorescent or nonfluorescent LPS.^{139,140} Cationic lipids are reported to assist the translocation of fluorescent lipopolysaccharides into live cells;¹⁴¹ cell surface-bound LPS can be quenched by trypan blue.¹³⁸ Molecular Probes® fluorescent LPS can potentially be combined with other fluorescent indicators, such as Ca²⁺-, pH- or organelle-specific stains, for monitoring intracellular localization and real-time changes in cellular response to LPS.

Pro-Q® Emerald 300 Lipopolysaccharide Gel Stain Kit

The Pro-Q® Emerald 300 Lipopolysaccharide Gel Stain Kit (P20495) provides a simple, rapid and highly sensitive method for staining lipopolysaccharides (LPS) in gels (Figure 13.3.21, Figure 13.3.22, Figure 13.3.23). The structure of this important class of molecules can be analyzed by SDS-polyacrylamide gel electrophoresis, during which the heterogeneous mixture of polymers separates into a characteristic ladder pattern. This ladder has conventionally been detected using silver staining.^{142–144} However, despite the long and complex procedures required, silver staining provides poor sensitivity and cannot differentiate LPS from proteins in the sample. An alternative

Figure 13.3.22 Characterization of lipopolysaccharides. Lipopolysaccharides (LPS) from *Escherichia coli* smooth serotype 055:B5 were loaded onto a 13% polyacrylamide gel. Following electrophoresis, the gel was stained using the Pro-Q® Emerald 300 Lipopolysaccharide Gel Stain Kit (P20495), and the fluorescence was measured for the lane. A plot of fluorescence signal versus the relative distance from the dye front shows a characteristic ladder profile for smooth-type LPS.

Figure 13.3.23 Linearity of the Pro-Q® Emerald 300 stain for lipopolysaccharide (LPS) detection. A dilution series of lipopolysaccharides from *Escherichia coli* smooth serotype 055:B5 was loaded onto a 13% polyacrylamide gel. Following electrophoresis, the gel was stained using the Pro-Q® Emerald 300 Lipopolysaccharide Gel Stain Kit (P20495) and the same band from each lane was quantitated using a CCD camera. A plot of the fluorescence intensity versus the mass of LPS loaded shows a linear range over two orders of magnitude.

staining method that makes use of the reaction of the carbohydrates with detectable hydrazides obtains higher sensitivity, but requires blotting to a membrane and time- and labor-intensive procedures.^{145–149}

By comparison, the staining technology used in the Pro-Q® Emerald 300 Lipopolysaccharide Gel Stain Kit vastly simplifies detection of LPS in SDS-polyacrylamide gels. The key to this novel methodology is our bright green-fluorescent Pro-Q® Emerald 300 dye, which covalently binds to periodate-oxidized carbohydrates of LPS. This dye allows the detection of as little as 200 pg of LPS in just a few hours using a simple UV transilluminator. The sensitivity is at least 50–100 times that of silver staining and requires much less hands-on time. This dye is also used in our Pro-Q® Emerald 300 and Multiplexed Proteomics® Glycoprotein

Stain Kits (P21855, P21857, M33307; Section 9.4) and may be useful for detection of other molecules containing carbohydrates or aldehydes.

The Pro-Q® Emerald 300 Lipopolysaccharide Gel Stain Kit contains:

- Pro-Q® Emerald 300 reagent
- Pro-Q® Emerald 300 staining buffer
- Oxidizing reagent (periodic acid)
- Smooth LPS standard from *Escherichia coli* serotype 055-B5
- Detailed protocols

Sufficient materials are supplied to stain ten 8 cm × 10 cm gels, 0.5–0.75 mm thick.

- Notes**
- Em for BODIPY® FL sphingolipids shifts to ~620 nm when high concentrations of the probe (>5 mol %) are incorporated in lipid mixtures. (J Cell Biol (1991) 113:1267)
 - This product is a lipid complexed with bovine serum albumin (BSA). Spectroscopic data are for the free lipid in MeOH.
 - The absorption and fluorescence spectra of BODIPY® derivatives are relatively insensitive to the solvent.
 - Chloroform is the most generally useful solvent for preparing stock solutions of phospholipids (including sphingomyelins). Glycerophosphocholines are usually freely soluble in ethanol. Most other glycerophospholipids (phosphoethanolamines, phosphatidic acids and phosphoglycerols) are less soluble in ethanol, but solutions up to 1–2 mg/mL should be obtainable, using sonication to aid dispersion if necessary. Labeling of cells with fluorescent phospholipids can be enhanced by addition of cyclodextrins during incubation. (J Biol Chem (1999) 274:35359)
 - Alkylpyrene fluorescence lifetimes are up to 110 nanoseconds and are very sensitive to oxygen.
 - Pyrene derivatives exhibit structured spectra. The absorption maximum is usually about 340 nm with a subsidiary peak at about 325 nm. There are also strong absorption peaks below 300 nm. The emission maximum is usually about 376 nm with a subsidiary peak at 396 nm. Excimer emission at about 470 nm may be observed at high concentrations.
 - This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
 - Fluorescence of NBD and its derivatives in water is relatively weak. QY and τ increase and Em decreases in aprotic solvents and other nonpolar environments relative to water. (Biochemistry (1977) 16:5150, Photochem Photobiol (1991) 54:361)

13.4 Dialkylcarbocyanine and Dialkylaminostyryl Probes

The dyes in this section are all amphiphilic probes—molecules that comprise a charged fluorophore that localizes the probe at the membrane's surface and lipophilic aliphatic "tails" that insert into the membrane and thus anchor the probe to the membrane. In addition to labeling model membranes, most of these probes are very useful for cell tracing applications (Section 14.4). Table 14.3 lists all of our lipophilic carbocyanine and aminostyryl tracers and compares their properties and uses. Our FM[®] dyes, which are also amphiphilic styryl dyes but with less lipophilic character than the dyes in this section, are particularly useful for labeling membranes of live cells and for following synaptosome recycling (Section 16.1).

Dialkylcarbocyanine Probes

Carbocyanines are among the most strongly light-absorbing dyes known and have proven to be useful tools in several different areas of research. Carbocyanines with short alkyl tails attached to the imine nitrogens are employed both as membrane-potential sensors (Section 22.3) and as organelle stains for mitochondria and the endoplasmic reticulum (Section 12.2, Section 12.4). Those with longer alkyl tails (≥ 12 carbons) have an overall lipophilic character that makes them useful for neuronal tracing¹ and long-term labeling of cells in culture^{2,3} (Section 14.4), as well as for noncovalent labeling of lipoproteins (Section 16.1). This section describes the use and properties of dialkylcarbocyanines as general-purpose probes of membrane structure and dynamics.

DiI, DiO, DiD, DiR and Analogs

The most widely used carbocyanine membrane probes have been the octadecyl (C₁₈) indocarbocyanines (D282, D3911; Figure 13.4.1) and oxacarbocyanines (D275, Figure 13.4.2) often referred to by the generic acronyms DiI and DiO, or more specifically as DiIC₁₈(3) and DiOC₁₈(3), where the subscript is the number of carbon atoms in each alkyl tail and the bracketed numeral is the number of carbon atoms in the bridge between the indoline or benzoxazole ring systems. We also offer several variations on these basic structures (Section 14.4, Table 14.3):

- DiI and DiO analogs with unsaturated alkyl tails (Δ^9 -DiI, D3886; FAST DiO[™], D3898; FAST DiI[™], D3899, D7756)
- DiI and DiO analogs with shorter alkyl tails (DiIC₁₂(3), D383; Figure 13.4.3; DiIC₁₆(3), D384; DiOC₁₆(3), D1125)
- Long-wavelength light-excitable carbocyanines (DiD, D307, D7757; Figure 13.4.4)
- Infrared light-excitable carbocyanine (DiR, D12731; Figure 13.4.5)
- Chloromethylbenzamido DiI and sulfonated DiI and DiO derivatives

Spectral Properties of Dialkylcarbocyanines

The spectral properties of dialkylcarbocyanines are largely independent of the lengths of the alkyl chains, and are instead determined by the heteroatoms in the terminal ring systems and the length of the connecting bridge. The DiIC_n(3) probes have absorption and fluorescence spectra compatible with rhodamine (TRITC) optical filter sets (Figure 13.4.6), whereas DiOC_n(3) analogs can be used with fluorescein (FITC) optical filter sets (Figure 13.4.7). The emission maxima of

Figure 13.4.10 Fluorescence excitation and emission spectra of DiIC₁₈(7) ("DiR") bound to phospholipid bilayer membranes.

DiIC₁₈(3) and DiOC₁₈(3) incorporated in dioctadecenylphosphocholine (dioleoyl PC or DOPC) liposomes (Figure 13.4.8) are similar to those of the dyes in methanol.

The very large molar extinction coefficients of carbocyanine fluorophores are their most outstanding spectral property. Their fluorescence quantum yields are only modest—about 0.07 for DiI in methanol and about three-times greater in amphiphilic solvents such as octanol.^{4,5} Their fluorescence in water is quite weak.⁶ The excited-state lifetimes of carbocyanine fluorophores in lipid environments are short (~1 nanosecond), which is an advantage for flow cytometry applications because it allows more excitation/de-excitation cycles during flow transit; the overall decay is multi-exponential.⁷ Dialkylcarbocyanines are also exceptionally photostable.⁸

The red He-Ne laser-excitable indodicarbocyanines such as DiD (DiIC₁₈(5); D307, D7757) have long-wavelength absorption and red emission (Figure 13.4.8, Figure 13.4.9). Their extinction coefficients are somewhat larger and fluorescence quantum yields much larger than those of carbocyanines such as DiI.⁵ Moreover, photoexcitation of DiD seems to cause less collateral damage than photoexcitation of DiI in live cells.⁹ The DiIC₁₈(7) tricarbocyanine probe (DiR, D12731) has excitation and emission in the infrared (Figure 13.4.10), which may make the dye useful as an *in vivo* tracer for labeled cells and liposomes in live organisms.^{4,10}

Substituted DiI and DiO Derivatives

We have synthesized various derivatives of DiI, DiO and DiD. All of these derivatives have octadecyl (C₁₈) tails identical to those of DiI (D282, D3911) and DiO (D275), thereby preserving the excellent membrane retention characteristics of the parent molecules. A variety of substitutions have been made on the indoline or benzoxazole ring systems:

- Chloromethylbenzamido DiI derivatives (CellTracker™ CM-DiI; C7000, C7001; Figure 13.4.11)
- Anionic sulfophenyl derivatives¹¹ of DiI and DiO (SP-DiIC₁₈(3), D7777, Figure 13.4.12; SP-DiOC₁₈(3), D7778, Figure 13.4.13)
- Sulfonate derivatives of DiI and DiD (DiIC₁₈(3)-DS, D7776, Figure 13.4.14; DiIC₁₈(5)-DS, D12730, Figure 13.4.15)

Although these derivatives have primarily been developed to provide improved fixation and labeling in long-term cell tracing applications (Section 14.4), they also offer several features that can potentially be exploited for investigating membrane structure and dynamics. For researchers wishing to carry out comparative evaluations, our Lipophilic Tracer Sampler Kit (L7781) provides 1 mg samples of each of nine different carbocyanine derivatives, including several of the newer substituted derivatives:

- DiI (DiIC₁₈(3))
- DiD (DiIC₁₈(5))
- DiR (DiIC₁₈(7))
- DiO (DiOC₁₈(3))
- DiA (4-Di-16-ASP)
- DiIC₁₈(3)-DS
- SP-DiIC₁₈(3)
- SP-DiOC₁₈(3)
- 5,5'-Ph₂-DiIC₁₈(3)

The fluorescence quantum yields of the sulfophenyl and phenyl derivatives (measured in methanol) are generally 2- to 3-fold greater than those of DiI and DiO. In particular, we have found that the sulfophenyl derivatives (SP-DiIC₁₈(3), D7777; SP-DiOC₁₈(3), D7778) bound to phospholipid model membranes have approximately 5-fold higher quantum yields than DiI and DiO. DiIC₁₈(5)-DS (D12730) has been used in combination with an NBD-labeled glycerophosphoserine probe in a novel resonance energy transfer assay that detects inner monolayer membrane hemifusion, avoiding erroneous indications of membrane fusion due to lipid mixing and other environmental effects in the outer monolayer.¹² The negative charge and greater water solubility of the sulfonated carbocyanines results in modified lateral and transverse distributions of these probes in lipid bilayers relative to those of DiI and DiO. This characteristic has been exploited to identify plasma membrane lipid domains that are responsive to electrical stimulation of outer hair cells in the inner ear.¹³

Figure 13.4.11 CellTracker™ CM-DiI (C7000).

DiI and DiO as Probes of Membrane Structure

The orientation of DiIC₁₈(3) in membranes has been determined by fluorescence polarization microscopy.¹⁴ The long axis of the fluorophore is parallel to the membrane surface, and the two alkyl chains protrude perpendicularly into the lipid interior. There are conflicting reports in the literature regarding the ease of transbilayer migration ("flip-flop") of lipophilic indocarbocyanines.^{15–17} The lateral partitioning behavior of dialkylindocarbocyanines in membranes has been investigated by fluorescence recovery after photobleaching (FRAP),¹⁸ calorimetry,¹⁹ lifetime measurements⁸ and fluorescence resonance energy transfer techniques²⁰ (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). These studies demonstrate that the probe distribution between coexisting fluid and gel phases depends on the similarity of the alkyl chain lengths of the probe and the lipid. In general, the more dissimilar the lengths, the greater the preference for fluid-phase over gel-phase lipids. For example, the shorter-chain DiIC₁₂(3) has a substantial preference for the fluid phase (~6:1) in DOPC, whereas DiIC₁₈(3) is predominantly distributed in the gel phase²¹ (~1:10). Consequently, long-chain dialkylcarbocyanines are among the best probes for detecting particularly rigid gel phases.

Lipophilic carbocyanines have been used to visualize membrane fusion and cell permeabilization that occurs in response to electric fields,^{22–24} as well as fusion of liposomes with planar bilayers.²⁵ Membrane fusion can also be measured by fluorescence resonance energy transfer to DiIC₁₈(3) from dansyl- or NBD-labeled phospholipid donors²⁶ or by direct imaging.²⁷ In Langmuir–Blodgett films, excited-state energy transfer from DiIC₁₈(3) to DiIC₁₈(5) is exceptionally efficient because of the favorable orientations of the fluorophores.²⁸ Energy transfer from DiIC₁₈(5) to DiIC₁₈(7) should be similarly effective. Lipophilic carbocyanines have also been used to elicit photosensitized destabilization of liposomes,²⁹ to sensitize photoaffinity labeling of the viral glycoprotein hemagglutinin,³⁰ to image membrane domains in lipid monolayers³¹ and to develop a fiber-optic potassium sensor.³²

DiI and DiO as Probes of Membrane Dynamics

Despite their reasonably good photostability, dialkylcarbocyanines are widely employed to measure lateral diffusion processes using fluorescence recovery after photobleaching (FRAP) techniques.^{33–36} Their lateral diffusion coefficients in isolated fluid- and gel-phase bilayers are independent of the carbocyanine alkyl chain length.¹⁸ Phase-separated populations of lipophilic carbocyanine dyes can be distinguished by their diffusion rates and can therefore be used to define lateral domains in cell membranes.^{37,38} Combined lateral diffusion measurements of labeled proteins and lipids have demonstrated that transformed³⁹ and permeabilized⁴⁰ cells show marked changes in protein diffusion, whereas lipid diffusion rates remain unchanged. In other cases, coupling of lipid and protein mobility has been identified in the form of relatively immobilized lipid domains in yeast plasma membranes⁴¹ and around IgE receptor complexes.⁴² A different photobleaching technique, which depends on the *absence* of diffusional fluorescence recovery, was employed to determine lipid flow direction in locomoting cells by following the movement of a photobleached stripe of DiIC₁₆(3)⁴³ (D384).

Dialkylaminostyryl Probes

The lipophilic aminostyryl probes 4-Di-10-ASP (D291, Figure 13.4.16), DiA (4-Di-16-ASP, D3883; Figure 13.4.17) and FAST DiA™ (D7758, Figure 13.4.18) insert in membranes with their two alkyl

Figure 13.4.12 1,1'-Di-octadecyl-6,6'-di-(4-sulphophenyl)-3,3,3',3'-tetramethylindocarbocyanine (SP-DiIC₁₈(3), D7777).

tails and their fluorophore oriented parallel to the phospholipid acyl chains.⁴⁴ When these dialkylaminostyryl probes bind to membranes, they exhibit a strong fluorescence enhancement; their fluorescence in water is minimal. The interfacial solvation of the aminostyryl fluorophore causes a large blue shift of the absorption spectrum of the membrane-bound probe.⁴⁴ For example, the absorption maximum of DiA is 456 nm when incorporated into DOPC liposomes and 490 nm when in methanol. The fluorescence emission maximum of DiA in the membrane environment is 590 nm, which is quite close to that observed for probes with shorter alkyl tails such as 4-Di-10-ASP;⁴⁴ however, the fluorescence spectrum of DiA is very broad, with appreciable intensity from about 510 nm to 690 nm (Figure 13.4.19). Consequently, DiA can be detected as green, orange or even red fluorescence, depending on the optical filter employed. Like the lipophilic carbocyanines, DiA is commonly used for neuronal membrane tracing (Section 14.4). FAST DiA™ (D7758), the diunsaturated analog of DiA, is intended to facilitate these studies by accelerating dye diffusion within the membrane.

The FM* 1-43 (Figure 13.4.20), FM* 1-43FX, FM* 4-64 and FM* 5-95 dyes, which are discussed in detail in Section 16.1, are styryl dyes that also exhibit high Stokes shifts and broad fluorescence emission but have less lipophilic character than the 4-Di-10-ASP and DiA probes. The FM* dyes are commonly used to define the outer membranes of liposomes and live cells and to detect synaptosome recycling.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Abs and Em of styryl dyes are at shorter wavelengths in membrane environments than in reference solvents such as methanol. The difference is typically 20 nm for absorption and 80 nm for emission, but varies considerably from one dye to another. Styryl dyes are generally nonfluorescent in water.
- This product is intrinsically a liquid or an oil at room temperature.
- This product is intrinsically a sticky gum at room temperature.

PRODUCT LIST 13.4 DIALKYL CARBOCYANINE AND DIALKYL AMINOSTYRYL PROBES

Cat. No.	Product	Quantity
C7001	CellTracker™ CM-Dil	1 mg
C7000	CellTracker™ CM-Dil *special packaging*	20 x 50 µg
D291	4-(4-(didecylamino)styryl)-N-methylpyridinium iodide (4-Di-10-ASP)	25 mg
D383	1,1'-didodecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate (DiIC ₁₂ (3))	100 mg
D3883	4-(4-(dihexadecylamino)styryl)-N-methylpyridinium iodide (DiA; 4-Di-16-ASP)	25 mg
D1125	3,3'-dihexadecyloxycarbocyanine perchlorate (DiOC ₁₆ (3))	25 mg
D384	1,1'-dihexadecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate (DiIC ₁₆ (3))	100 mg
D7758	4-(4-(dilinoleylamino)styryl)-N-methylpyridinium 4-chlorobenzenesulfonate (FAST DiA™ solid; DiΔ ^{9,12} -C ₁₈ ASP, CBS)	5 mg
D3898	3,3'-dilinoleyloxycarbocyanine perchlorate (FAST DiO™ solid; DiOΔ ^{9,12} -C ₁₈ (3), ClO ₄)	5 mg
D7756	1,1'-dilinoleyl-3,3,3',3'-tetramethylindocarbocyanine, 4-chlorobenzenesulfonate (FAST DiI™ solid; DiIΔ ^{9,12} -C ₁₈ (3), CBS)	5 mg
D3899	1,1'-dilinoleyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate (FAST DiI™ oil; DiIΔ ^{9,12} -C ₁₈ (3), ClO ₄)	5 mg
D7778	3,3'-dioctadecyl-5,5'-di(4-sulfophenyl)oxycarbocyanine, sodium salt (SP-DiOC ₁₈ (3))	5 mg
D7777	1,1'-dioctadecyl-6,6'-di(4-sulfophenyl)-3,3,3',3'-tetramethylindocarbocyanine (SP-DiIC ₁₈ (3))	5 mg
D275	3,3'-dioctadecyloxycarbocyanine perchlorate ('DiO'; DiOC ₁₈ (3))	100 mg
D7776	1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine-5,5'-disulfonic acid (DiIC ₁₈ (3)-DS)	5 mg
D282	1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate ('DiI'; DiIC ₁₈ (3))	100 mg
D3911	1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate *crystalline* ('DiI'; DiIC ₁₈ (3))	25 mg
D7757	1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine, 4-chlorobenzenesulfonate salt ('DiD' solid; DiIC ₁₈ (5) solid)	10 mg
D12730	1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine-5,5'-disulfonic acid (DiIC ₁₈ (5)-DS)	5 mg
D307	1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate ('DiD' oil; DiIC ₁₈ (5) oil)	25 mg
D12731	1,1'-dioctadecyl-3,3,3',3'-tetramethylindotricarbocyanine iodide ('DiR'; DiIC ₁₈ (7))	10 mg
D3886	1,1'-dioleyl-3,3,3',3'-tetramethylindocarbocyanine methanesulfonate (Δ ⁹ -DiI)	25 mg
L7781	Lipophilic Tracer Sampler Kit	1 kit

13.5 Other Nonpolar and Amphiphilic Probes

Amphiphilic Rhodamine, Fluorescein and Coumarin Derivatives

Each of our amphiphilic probes comprises a moderately polar fluorescent dye with a lipophilic "tail." When used to stain membranes, including liposomes, the lipophilic portion of the probe tends to insert in the membrane and the polar fluorophore resides on the surface, where it senses the membrane's surface environment and the surrounding medium.¹ Our lipophilic carbocyanines and styryl dyes (Section 13.4) are also amphiphilic molecules with a similar binding mode.

This section includes the classic membrane probes DPH, TMA-DPH, ANS, bis-ANS, TNS, prodan, laurdan and nile red, and also some lipophilic BODIPY® and Dapoxyl® dyes developed in our laboratories. Although they bear little resemblance to natural products, these probes tend to localize within cell membranes or liposomes or at their aqueous interfaces, where they are often used to report on characteristics of their local environment, such as viscosity, polarity and lipid order.

Octadecyl Rhodamine B

The relief of the fluorescence self-quenching of octadecyl rhodamine B (O246, Figure 13.5.1) can be used to monitor membrane fusion²⁻⁷—one of several experimental approaches developed for this application (Lipid-Mixing Assays of Membrane Fusion—Note 13.1). Octadecyl rhodamine B has been reported to undergo a potential-dependent "flip-flop" from one monolayer of a fluid-state phospholipid bilayer membrane to the other, with partial relief of its fluorescence quenching.^{8,9} Investigators have used octadecyl rhodamine B in conjunction with video microscopy¹⁰⁻¹² or digital imaging techniques¹³ to monitor viral fusion processes. Membrane fusion can

also be followed by monitoring fluorescence resonance energy transfer to octadecyl rhodamine B from an acylaminofluorescein donor such as 5-hexadecanoylamino fluorescein^{5,7,14,15} (H110, Figure 13.5.2).

Fluorescence resonance energy transfer from fluorescein or dansyl labels to octadecyl rhodamine B has been used for structural studies of the blood coagulation factor IXa, EGF receptor and receptor-bound IgE.^{16–18} Octadecyl rhodamine B has also been used to stain kinesin-generated membrane tubules,¹⁹ to characterize detergent micelles,²⁰ to assay for lysosomal degradation of lipoproteins²¹ and to investigate the influence of proteins on lipid dynamics using time-resolved fluorescence anisotropy.²²

Amphiphilic Fluoresceins

The amphiphilic fluorescein probes bind to membranes with the fluorophore at the aqueous interface and the alkyl tail protruding into the lipid interior. 5-Dodecanoylamino fluorescein (D109) is the hydrolysis product of our ImaGene Green™ C₁₂-FDG β-galactosidase substrate (D2893, Section 10.2). We also offer the homologous membrane probe 5-hexadecanoylamino fluorescein^{1,15,23} (H110, Figure 13.5.2) and the octadecyl ester of fluorescein^{24,25} (F3857, Figure 13.5.3).

Amphiphilic fluorescein probes are commonly used for fluorescence recovery after photobleaching (FRAP) measurements of lipid lateral diffusion.²⁶ Some researchers have reported that 5-hexadecanoylamino fluorescein stays predominantly in the outer membrane leaflet of epithelia and does not pass through tight junctions, whereas the dodecanoyl derivative can “flip-flop” to the inner leaflet at 20°C (but not at <10°C) and may also pass through tight junctions.^{27,28} More recent studies have indicated that the lack of tight junction penetration of 5-hexadecanoylamino fluorescein is due to probe aggregation rather than a significant difference in its transport properties.²⁹

Amphiphilic Coumarin

4-Heptadecyl-7-hydroxycoumarin (H22730, Figure 13.5.4) is an alkyl derivative of the pH-sensitive blue-fluorescent 7-hydroxycoumarin (umbelliferone) fluorophore. As with other amphiphilic coumarins,³⁰ 4-heptadecyl-7-hydroxycoumarin is primarily useful as a probe of membrane surfaces. Deprotonation of the 7-hydroxyl group is expected to be strongly dependent on membrane-surface electrostatic potential. The pK_a of 4-heptadecyl-7-hydroxycoumarin varies from 6.35 in the cationic detergent CTAB to 11.15 in the anionic detergent sodium dodecyl sulfate (SDS), as measured by its fluorescence response.³¹ However, its pK_a in lipid assemblies is strongly dependent on the ionic composition of the membrane surface,^{31,32} making it a sensitive probe of membrane-surface electrostatic potential.³³ 4-Heptadecyl-7-hydroxycoumarin has been used to measure pH differences at membrane interfaces in isolated plasma membranes of normal and multidrug-resistant murine leukemia cells.^{34,35} 4-Heptadecyl-7-hydroxycoumarin has also been employed as a structural probe for the head-group region of phospholipid bilayers.³⁶

DPH and DPH Derivatives

Diphenylhexatriene (DPH)

1,6-Diphenyl-1,3,5-hexatriene (DPH, D202; Figure 13.5.5) continues to be a popular fluorescent probe of membrane interiors. We also offer the cationic DPH derivative TMA-DPH, as well as the phospholipid analog (D476, Section 13.2). The orientation of DPH within lipid bilayers is loosely constrained. It is generally assumed to be oriented parallel to the lipid acyl chain axis, but it can also reside in the center of the lipid bilayer parallel to the surface, as demonstrated by time-resolved fluorescence anisotropy and polarized fluorescence measurements of oriented samples.^{37–40} DPH shows no partition preference between coexisting gel- and fluid-phase phospholipids.⁴¹ Intercalation of DPH and its derivatives into membranes is accompanied by strong enhancement of their fluorescence; their fluorescence is practically negligible in water. The fluorescence decay of DPH in lipid bilayers is complex.^{42–44} Fluorescence decay data are often analyzed in terms of continuous lifetime distributions,^{45–48} which are in turn interpreted as being indicative of lipid environment heterogeneity.

DPH and its derivatives are cylindrically shaped molecules with absorption and fluorescence emission transition dipoles aligned approximately parallel to their long molecular

axis. Consequently, their fluorescence polarization is high in the absence of rotational motion and is very sensitive to reorientation of the long axis resulting from interactions with surrounding lipids. These properties have led to their extensive use for membrane fluidity measurements.⁴⁹ The exact physical interpretation of these measurements has some contentious aspects. For instance, the probes are largely sensitive to only the angular reorientation of lipid acyl chains—a motion that does not necessarily correlate with other dynamic processes such as lateral diffusion.⁵⁰ Reviews on this subject^{39,49,51,52} should be consulted for further discussion. Time-resolved fluorescence polarization measurements of lipid order are more physically rigorous because they allow the angular range of acyl chain reorientation ("lipid order") to be resolved from its rate, and considerable research has been devoted to the interpretation of these measurements.^{37,45,53,54}

TMA-DPH

Designed to improve the localization of DPH in the membrane, TMA-DPH (T204, Figure 13.5.6) contains a cationic trimethylammonium substituent that acts as a surface anchor.^{55–57} Like DPH, this derivative readily partitions from aqueous dispersions into membranes and other lipid assemblies, accompanied by strong fluorescence enhancement. The lipid–water partition coefficient (K_p) for TMA-DPH ($K_p = 2.4 \times 10^5$) is lower than for DPH ($K_p = 1.3 \times 10^6$), reflecting the increased water solubility caused by the polar substituents.⁵⁸ The fluorescence decay lifetime of TMA-DPH is more sensitive to changes in lipid composition and temperature than is the fluorescence decay lifetime of DPH.^{59–61}

Staining of cell membranes by TMA-DPH is much more rapid than staining by DPH; however, the duration of plasma membrane surface staining by TMA-DPH before internalization into the cytoplasm is quite prolonged.^{62,63} As a consequence, TMA-DPH introduced into Madin–Darby canine kidney (MDCK) cell plasma membranes does not diffuse through tight junctions and remains in the apical domain, whereas the anionic DPH propionic acid accumulates rapidly in intracellular membranes.⁶⁴ TMA-DPH residing in the plasma membrane can be extracted by washing with medium, thus providing a method for isolating internalized probe and monitoring endocytosis⁶⁵ (Section 16.1). Furthermore, because TMA-DPH is virtually nonfluorescent in water and binds in proportion to the available membrane surface,⁶⁶ its fluorescence intensity is sensitive to increases in plasma membrane surface area resulting from exocytosis.^{65,67,68}

TMA-DPH fluorescence polarization measurements can be combined with video microscopy to provide spatially resolved images of phospholipid order in large liposomes and single cells.^{69–72} Information regarding lipid order heterogeneity among cell populations can be obtained in a similar way using flow cytometry.^{73–75}

Nonpolar BODIPY® Probes

BODIPY® Fluorophores

BODIPY® fluorophore derivatives offer an unusual combination of nonpolar structure (Figure 13.5.7) and long-wavelength absorption and fluorescence.⁷⁶ BODIPY® dyes have small fluorescence Stokes shifts, extinction coefficients that are typically greater than $80,000 \text{ cm}^{-1} \text{ M}^{-1}$ and high fluorescence quantum yields that are not diminished in water.⁷⁷ These dyes have applications as stains for neutral lipids and as tracers

for oils and other nonpolar liquids. In addition, their photostability is generally high; this, together with other favorable characteristics (very low triplet–triplet absorption), make the BODIPY® 493/503 and BODIPY® 505/515 fluorophores excellent choices for flashlamp-pumped laser dyes.^{78,79}

Staining with the BODIPY® 493/503 dye (D3922, Figure 13.5.7) has been shown by flow cytometry to be more specific for cellular lipid droplets than staining with Nile red⁸⁰ (N1142). The low molecular weight of the BODIPY® 493/503 dye (262 daltons) results in the probe having a relatively fast diffusion rate in membranes.⁸¹ The BODIPY® 493/503 dye has also been used to detect neutral compounds in a microchip channel separation device.⁸²

BODIPY® 505/515 (D3921, Figure 13.5.8) rapidly permeates cell membranes of live zebrafish embryos,^{83,84} selectively staining cytoplasmic yolk platelets. This staining provides dramatic contrast enhancement of cytoplasm relative to nucleoplasm and interstitial spaces, allowing individual cell boundaries and cell nuclei to be imaged clearly with a confocal laser-scanning microscope (Figure 13.5.9).

The very long-wavelength BODIPY® 665/676 dye (B3932, Figure 13.5.10) has fluorescence that is not visible to the human eye; however, it has found use as a probe for reactive oxygen species⁸⁵ (Section 18.2).

Figure 13.5.8 4,4-Difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-s-indacene (BODIPY® 505/515, D3921).

Figure 13.5.13 Normalized absorption (—) and fluorescence emission (---) spectra of enhanced Green Fluorescent Protein (EGFP) and CellTrace™ BODIPY® TR methyl ester (C34556).

Figure 13.5.14 Live HeLa cells were transfected using pShooter™ vector pCMV/myc/mito/GFP and Lipofectamine® 2000 transfection reagent and stained with the reagents in the Image-iT™ LIVE Intracellular Membrane and Nuclear Labeling Kit (I34407). Intracellular membranes were stained with CellTrace™ BODIPY® TR methyl ester, and nuclei were stained with Hoechst 33342. Cells were visualized using epifluorescence microscopy.

BODIPY® FL C₅-Ceramide

BODIPY® FL C₅-ceramide (D3521, B22650; Section 13.3) stains the plasma membrane, Golgi apparatus and cytoplasmic particles within the superficial enveloping layer (EVL) of embryos. Once the fluorescent lipid percolates through the EVL epithelium, however, it remains localized within the interstitial fluid of the embryo and freely diffuses between cells (Figure 13.5.11). Vital staining with BODIPY® FL C₅-ceramide thus allows hundreds of cells to be imaged *en masse* during morphogenetic movements.^{83,86}

CellTrace™ BODIPY® TR Methyl Ester

Many research and biotechnological applications require detailed three- and four-dimensional visualization of embryonic cells labeled with Green Fluorescent Protein (GFP) within their native tissue environments. Fluorescent counterstains that label all the cells in a living embryo provide a histological context for the GFP-expressing cells in the specimen. The red-fluorescent CellTrace™ BODIPY® TR methyl ester (C34556, Figure 13.5.12) is an excellent counterstain for cells and tissues that are expressing GFP.⁸⁷ This dye readily permeates cell membranes and selectively stains mitochondria and endomembranous organelles such as endoplasmic reticulum and the Golgi apparatus, but does not appear to localize in the plasma membrane. These localization properties make the dye an ideal vital stain that can be used to reveal: (1) the location and shapes of cell nuclei, (2) the shapes of cells within embryonic tissues and (3) the boundaries of organ-forming tissues within the whole embryo.⁸⁷ Furthermore, CellTrace™ BODIPY® TR methyl ester staining is retained after formaldehyde fixation and permeabilization with Triton X-100, and the dye does not appear to produce any teratogenic effects on embryonic development. The emission spectra of enhanced GFP (EGFP) and CellTrace™ BODIPY® TR methyl ester are well separated, with peaks at 508 nm and 625 nm, respectively (Figure 13.5.13), allowing simultaneous dual-channel confocal imaging without significant overspill of GFP fluorescence into the CellTrace™ BODIPY® TR methyl ester detection channel.

The Image-iT™ LIVE Intracellular Membrane and Nuclear Labeling Kit (I34407, Section 14.4) provides the red-fluorescent CellTrace™ BODIPY® TR methyl ester along with the blue-fluorescent Hoechst 33342 dye for highly selective staining of the intracellular membranes and nuclei, respectively, of live or fixed cells or tissues (Figure 13.5.14). These two fluorescent stains were especially chosen for their compatibility with live GFP-expressing cells, and they can be combined into one staining solution to save labeling time and wash steps while still providing optimal staining.

Pyrene, Nile Red and Bimane Probes

Nonpolar Pyrene Probe

1,3-Bis-(1-pyrene)propane (B311, Figure 13.5.15) has two pyrene moieties linked by a three-carbon alkylene spacer. This probe is somewhat analogous to the bis-pyrenyl phospholipids (Section 13.2) in that excimer formation (and, consequently, the fluorescence emission wavelength) is controlled by intramolecular rather than bimolecular interactions. Thus, this probe is highly sensitive to constraints imposed by its environment, and can therefore be used as a viscosity sensor for interior regions of lipoproteins, membranes, micelles, liquid crystals and synthetic polymers.⁸⁸ Because excimer formation results in a spectral shift (Figure 13.5.16), the probe may be useful for ratio imaging of molecular mobility.⁸⁹ However, pyrene fatty acids (Section 13.2) appear to be preferable for this purpose because the uptake of 1,3-bis-(1-pyrene)propane by cells is limited.

Nile Red

The phenoxazine dye nile red (N1142, Figure 13.5.17) is used to localize and quantitate lipids, particularly neutral lipid droplets within cells.^{80,90–92} It is selective for neutral lipids such as cholesteryl esters^{93,94} (and also, therefore, for lipoproteins) and is suitable for staining lysosomal phospholipid inclusions.⁹⁵ Nile red is almost nonfluorescent in water and other polar solvents but undergoes fluorescence enhancement and large absorption and emission blue shifts in nonpolar environments.^{96,97} Its fluorescence enhancement upon binding to proteins is weaker than that produced by its association with lipids⁹⁷ (Figure 13.5.18). Ligand-binding studies on tubulin and tryptophan synthase⁹⁸ have exploited the environmental sensitivity of nile red's fluorescence. Nile red has also been used to detect sphingolipids on thin-layer chromatograms⁹⁹ and to stain proteins after SDS-polyacrylamide gel electrophoresis.¹⁰⁰

Bimane Azide

Bimane azide (B30600, Figure 13.5.19) is a small blue-fluorescent photoreactive alkyl azide (excitation/emission maxima ~375/458 nm) for photoaffinity labeling of proteins, potentially including membrane proteins from within the cell membrane. This reactive fluorophore's small size may reduce the likelihood that the label will interfere with the function of the biomolecule, an important advantage for site-selective probes.

Figure 13.5.15 1,3-Bis-(1-pyrenyl)propane (B311).

LipidTOX™ Neutral Lipid Stains

Steatosis, the intracellular accumulation of neutral lipids as lipid droplets or globules, is often triggered by drugs that affect the metabolism of fatty acids or neutral lipids. LipidTOX™ neutral lipid stains were developed to characterize the effects of drugs and other compounds on lipid metabolism in mammalian cell lines. LipidTOX™ neutral lipid stains have an extremely high affinity for neutral lipid droplets. These reagents are added after cell fixation and do not require subsequent wash steps after incubation with the sample. Key advantages of this series of neutral lipid stains over conventional stains such as Nile red include their ready-to-use formulations, their flexibility for multiplexing protocols and their compatibility with LipidTOX™ phospholipid stains (H34350, H34351; Section 13.2).

LipidTOX™ neutral lipid stains are available with green, red and deep red fluorescence emission:

- HCS LipidTOX™ Green neutral lipid stain (H34475), with excitation/emission maxima ~495/505 nm (Figure 13.5.20)
- HCS LipidTOX™ Red neutral lipid stain (H34476), with excitation/emission maxima ~577/609 nm
- HCS LipidTOX™ Deep Red neutral lipid stain (H34477), with excitation/emission maxima ~637/655 nm

Figure 13.5.16 Excimer formation by pyrene in ethanol. Spectra are normalized to the 371.5 nm peak of the monomer. All spectra are essentially identical below 400 nm after normalization. Spectra are as follows: 1) 2 mM pyrene, purged with argon to remove oxygen; 2) 2 mM pyrene, air-equilibrated; 3) 0.5 mM pyrene (argon-purged); and 4) 2 μM pyrene (argon-purged). The monomer-to-excimer ratio (371.5 nm/470 nm) is dependent on both pyrene concentration and the excited-state lifetime, which is variable because of quenching by oxygen.

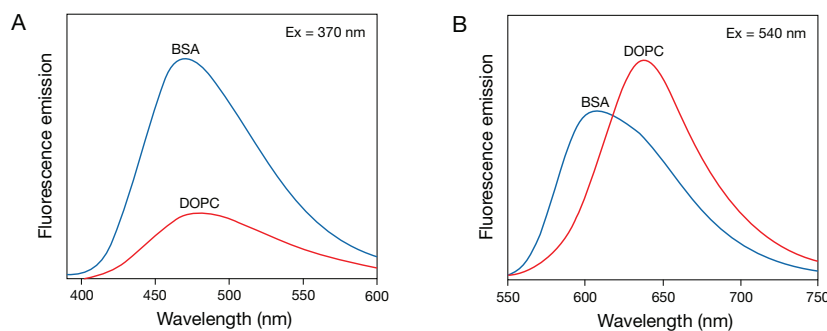

Figure 13.5.18 Fluorescence emission spectra of A) 1,8-ANS (A47) and B) Nile red (N1142) bound to protein and phospholipid vesicles. Samples comprised 1 μM dye added to 20 μM bovine serum albumin (BSA) or 100 μM dioctadecenyglycerophosphocholine (DOPC).

Figure 13.5.19 Bimane azide (B30600).

Figure 13.5.20 FABP4 antibody labeling in adipocytes. Adipocytes differentiated from 3T3-L1 mouse fibroblasts were fixed with formaldehyde and permeabilized with saponin before labeling with rabbit anti-fatty acid binding protein (FABP4) IgG (red). These cells were then stained with LipidTOX™ Green neutral lipid stain (H34475, green), counterstained with DAPI (D1306, D21490; blue) and mounted in ProLong® Gold antifade reagent (P36930).

Figure 13.5.25 Dapoxyl® sulfonic acid, sodium salt (D12800).

These HCS LipidTOX™ neutral lipid stains have been used to image intracellular lipid accumulation in rat cortical neurons, COS-7 cells and hepatitis C virus (HCV)-infected FT3-7 human hepatoma cells.^{101–103} HCS LipidTOX™ Red neutral lipid stain was used to detect RNAi knockdown of acyl-coenzyme A:cholesterol acyl transferase, isoform 1 (ACAT-1), an endoplasmic reticulum enzyme that regulates the equilibrium between free cholesterol and cholesteryl esters in cells.¹⁰⁴

LipidTOX™ Green neutral lipid stain is also a component of the HCS LipidTOX™ Phospholipidosis and Steatosis Detection Kit (H34157, H34158; Section 13.2), which provides a complete set of reagents for performing high-content screening (HCS) assays to detect and distinguish the intracellular accumulation of phospholipids (phospholipidosis) and of neutral lipids (steatosis) in mammalian cell lines after exposure to test compounds. In addition, HCS LipidTOX™ neutral lipid stains can be used to monitor the formation and differentiation of adipocytes, a process called adipogenesis. Adipogenesis is of acute interest to the biomedical and drug discovery community as it plays an important role in diseases such as obesity, diabetes and atherosclerosis.

HCS LipidTOX™ neutral lipid stains are designed for fixed-end point workflows in which formaldehyde-fixed cells in microplates are processed, imaged and analyzed. These stains can easily be detected with fluorescence microscopes or HCS readers equipped with standard filter sets.

Membrane Probes with Environment-Sensitive Spectral Shifts

Prodan and Laurdan

Prodan (P248, Figure 13.5.21), introduced by Weber and Farris in 1979, has both electron-donor and electron-acceptor substituent, resulting in a large excited-state dipole moment and extensive solvent polarity-dependent fluorescence shifts¹⁰⁵ (Figure 13.5.22). Several variants of the original probe have since been prepared, including the lipophilic derivative laurdan (D250, Figure 13.5.23) and thiol-reactive derivatives acrylodan and badan (A433, B6057; Section 2.3), which can be used to confer the environment-sensitive properties of this fluorophore on bioconjugates.

When Prodan or its derivatives are incorporated into membranes, their fluorescence spectra are sensitive to the physical state of the surrounding phospholipids.¹⁰⁶ In membranes, Prodan appears to localize at the surface,¹⁰⁷ although Fourier transform infrared (FTIR) measurements indicate some degree of penetration into the lipid interior.¹⁰⁸ Excited-state relaxation of Prodan is sensitive to the nature of the linkage (ester or ether) between phospholipid hydrocarbon tails and the glycerol backbone.¹⁰⁹ In contrast, laurdan's excited-state relaxation is independent of head-group type, and is instead determined by water penetration into the lipid bilayer.^{110,111} Two-photon infrared excitation techniques have been successfully applied to both Prodan and laurdan, although both probes nominally require ultraviolet excitation^{112–115} (~360 nm).

Much experimental work using these probes has sought to characterize coexisting lipid domains based on their distinctive fluorescence spectra,^{113,116–120} an approach that is intrinsically amenable to dual-wavelength ratio measurements.^{111,121} Other applications include detecting non-bilayer lipid phases,^{122,123} mapping changes in membrane structure induced by cholesterol and alcohols^{124–127} and assessing the polarity of lipid/water interfaces.^{128,129} Like ANS, Prodan is also useful as a noncovalently interacting probe for proteins.^{130–133}

Dapoxyl® Derivative

We have developed a variety of probes based on our Dapoxyl® fluorophore.¹³⁴ Dapoxyl® sulfonamide derivatives exhibit UV absorption with maxima near 370 nm, extinction coefficients >24,000 cm⁻¹M⁻¹ and Stokes shifts in excess of 200 nm (Figure 13.5.24). Dapoxyl® sulfonic acid (D12800, Figure 13.5.25) is an amphiphilic Dapoxyl® derivative with generally similar properties and applications to anilinnaphthalene sulfonate (ANS) (Monitoring Protein-Folding Processes with Environment-Sensitive Dyes—Note 9.1). Both ANS and Dapoxyl® sulfonic acid have been used in a drug-discovery assay based on the detection of protein thermal denaturation shifts.¹³⁵ Reactive versions of the Dapoxyl® fluorophore are described in Section 1.7 and Section 3.4.

Anilinnaphthalenesulfonate (ANS) and Related Derivatives

The use of anilinnaphthalene sulfonates (ANS) as fluorescent probes dates back to the pioneering work of Weber in the 1950s, and this class of probes remains valuable for studying both membrane

surfaces and proteins. Slavik's 1982 review of its properties is recommended reading, especially for the extensive compilation of spectral data.¹³⁶ The primary member of this class, 1,8-ANS (A47, Figure 13.5.26), and its analogs 2,6-ANS (A50) and 2,6-TNS (T53) are all essentially nonfluorescent in water, only becoming appreciably fluorescent when bound to membranes (quantum yields ~0.25) or proteins (quantum yields ~0.7)^{136–138} (Figure 13.5.18). This property makes them sensitive indicators of protein folding, conformational changes^{139–142} and other processes that modify the exposure of the probe to water (Monitoring Protein-Folding Processes with Environment-Sensitive Dyes—Note 9.1). Fluorescence of 2,6-ANS is also enhanced by cyclodextrins, permitting a sensitive method for separating and analyzing cyclodextrins with capillary electrophoresis.¹⁴³

Figure 13.5.26 1,8-ANS (1-anilinonaphthalene-8-sulfonic acid, A47).

Bis-ANS

Bis-ANS (B153, Figure 13.5.27) is superior to 1,8-ANS as a probe for nonpolar cavities in proteins, often binding with an affinity that is orders-of-magnitude higher.^{144–147} Bis-ANS has particularly high affinity for nucleotide-binding sites of some proteins.^{148–150} It is also useful as a structural probe for tubulin^{151,152} and as an inhibitor of microtubule assembly.^{153–155} Covalent photoincorporation of bis-ANS into proteins has been reported.¹⁵⁶

Figure 13.5.27 bis-ANS (4,4'-dianilino-1,1'-binaphthyl-5,5'-disulfonic acid, dipotassium salt; B153).

DCVJ

The styrene derivative DCVJ (D3923, Figure 13.5.28) is a sensitive indicator of tubulin assembly and actin polymerization.^{157,158} The fluorescence quantum yield of DCVJ is strongly dependent on environmental rigidity, resulting in large fluorescence increases when the dye binds to antibodies¹⁵⁹ and when it is compressed in synthetic polymers or phospholipid membrane interiors.^{160,161} DCVJ has been used for microviscosity measurements of phospholipid bilayers.¹⁶¹

Figure 13.5.28 DCVJ (4-(dicyanovinyl)julolidine, D3923).

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. Fluorescence quantum yields of ANS and its derivatives are environment dependent and are particularly sensitive to the presence of water. QY of A47 is about 0.4 in EtOH, 0.2 in MeOH and 0.004 in water. Em is also somewhat solvent dependent. (Biochim Biophys Acta (1982) 694:1)
2. B153 is soluble in water at 0.1–1.0 mM after heating.
3. Absorption spectra of bis-pyrenyl alkanes have additional peaks at ~325 nm and <300 nm. Emission spectra include both monomer (~380 nm and ~400 nm) and excimer (~470 nm) peaks.
4. The absorption and fluorescence spectra of BODIPY® derivatives are relatively insensitive to the solvent.
5. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
6. Spectra of this product are pH dependent. Data listed are for basic solutions prepared in methanol containing a trace of KOH.
7. Diphenylhexatriene (DPH) and its derivatives are essentially nonfluorescent in water. Absorption and emission spectra have multiple peaks. The wavelength, resolution and relative intensity of these peaks are environment dependent. Abs and Em values are for the most intense peak in the solvent specified.
8. Stock solutions of DPH (D202) are often prepared in tetrahydrofuran (THF). Long-term storage of THF solutions is not recommended because of possible peroxide formation in that solvent.
9. The emission spectrum of P248 is solvent dependent. Em = 401 nm in cyclohexane, 440 nm in CHCl₃, 462 nm in MeCN, 496 nm in EtOH and 531 nm in H₂O. (Biochemistry (1979) 18:3075) Abs is only slightly solvent dependent. The emission spectra of D250 in these solvents are similar to those of P248.
10. Em = 520 nm when bound to phospholipid bilayer membranes. Fluorescence in H₂O is weak (Em ~600 nm).
11. The absorption and fluorescence spectra and fluorescence quantum yield of N1142 are highly solvent dependent. (J Lipid Res (1985) 26:781, Anal Biochem (1987) 167:228)
12. This product is intrinsically a sticky gum at room temperature.
13. Abs/Em in trioctanoylglycerol = 498/507 nm, 582/616 nm and 635/652 nm for H34475, H34476 and H34477 respectively.

PRODUCT LIST 13.5 OTHER NONPOLAR AND AMPHIPHILIC PROBES

Cat. No.	Product	Quantity
A47	1,8-ANS (1-anilinonaphthalene-8-sulfonic acid) *high purity*	100 mg
A50	2,6-ANS (2-anilinonaphthalene-6-sulfonic acid)	100 mg
B30600	Bimane azide	5 mg
B153	bis-ANS (4,4'-dianilino-1,1'-binaphthyl-5,5'-disulfonic acid, dipotassium salt)	10 mg
B3932	(E,E)-3,5-bis-(4-phenyl-1,3-butadienyl)-4,4-difluoro-4-bora-3a,4a-diaza-s-indacene (BODIPY® 665/676)	5 mg
B311	1,3-bis-(1-pyrenyl)propane	25 mg
C34556	CellTrace™ BODIPY® TR methyl ester *lipophilic counterstain for GFP* *solution in DMSO*	1 mL
D12800	Dapoxyl® sulfonic acid, sodium salt	10 mg
D3923	DCVJ (4-(dicyanovinyl)julolidine)	25 mg
D3922	4,4-difluoro-1,3,5,7,8-pentamethyl-4-bora-3a,4a-diaza-s-indacene (BODIPY® 493/503)	10 mg
D3921	4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-s-indacene (BODIPY® 505/515)	10 mg
D109	5-dodecanoylamino fluorescein	100 mg
D250	6-dodecanoyl-2-dimethylaminonaphthalene (laurdan)	100 mg
D202	DPH (1,6-diphenyl-1,3,5-hexatriene)	100 mg
F3857	Fluorescein octadecyl ester	10 mg
H34477	HCS LipidTOX™ Deep Red neutral lipid stain *solution in DMSO* *for cellular imaging*	125 µL
H34475	HCS LipidTOX™ Green neutral lipid stain *solution in DMSO* *for cellular imaging*	125 µL
H34476	HCS LipidTOX™ Red neutral lipid stain *solution in DMSO* *for cellular imaging*	125 µL
H22730	4-heptadecyl-7-hydroxycoumarin	10 mg
H110	5-hexadecanoylamino fluorescein	100 mg
N1142	Nile red	25 mg
O246	Octadecyl rhodamine B chloride (R18)	10 mg
P248	Prodan (6-propionyl-2-dimethylaminonaphthalene)	100 mg
T204	TMA-DPH (1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene p-toluenesulfonate)	25 mg
T53	2,6-TNS (2-(p-toluidinyl)naphthalene-6-sulfonic acid, sodium salt)	100 mg

14.1 Choosing a Tracer

To serve as an effective tracer of cell morphology, a fluorescent probe or other detectable molecule must have the capacity for localized introduction into a cell or organelle, as well as for long-term retention within that structure. If used with live cells and tissues, then the tracer should also be biologically inert and nontoxic. When these conditions are satisfied, the fluorescence or other detectable properties of the tracer can be used to track the position of the tracer over time. Fluorescent tracers can be employed to investigate flow in capillaries, to define neuronal cell connectivity and to study dye translocation through gap junctions, as well as to follow cell division, cell lysis or liposome fusion. Furthermore, they can be used to track the movements of labeled cells in culture, tissues or intact organisms. The review of techniques for tracing neuronal pathways by Bohland and co-workers¹ is particularly recommended.

Although the predominant tracers have been fluorescent, not all of the useful tracers are intrinsically detectable. For example, biotin derivatives are widely used as polar tracers, especially in neurons. However, when a biotinylated or haptenylated tracer is used in live cells, detection requires cell fixation and permeabilization to allow access to fluorescent dye- or enzyme-labeled conjugates of avidin and streptavidin (Section 7.6) or of antibodies (Section 7.4).

In many of these tracing applications, the physical dimensions of the tracer molecule are an important consideration. We offer fluorescent tracers ranging in size from small molecules about 1 nm in diameter to polystyrene microspheres up to 15 μm in diameter. This chapter discusses our diverse selection of fluorescent tracers, as well as biotin derivatives and other tracers:

- **Cell-permeant cytoplasmic labels (Section 14.2).** We have developed several thiol-reactive CellTracker™ probes (Figure 14.1.1), which yield fluorescent products that are retained in many live

Figure 14.1.1 Collage of images of cyanobacteria stained with various blue- or green-fluorescent probes to complement the natural red autofluorescence from chlorophyll and phycobilisomes. The round cells are *Synechocystis* sp. (strain PCC 6803), and their membranes were labeled with green-fluorescent BODIPY™ FL propionic acid (D2183). The cylindrical cells are *Synechococcus* sp. (strain PCC 7942), stained with blue-fluorescent DAPI (D1306, D3571, D21490). The filamentous cyanobacteria, *Anabaena cylindrica*, were labeled with either the green-fluorescent cytosolic stain, CellTracker™ Green BODIPY* (C2102), or with the lipophilic membrane stain BODIPY™ FL (D2183). The image was contributed by Mary Sarcina, University College, London.

cells through several generations and are not transferred to adjacent cells in a population, except possibly by transport through gap junctions. These probes represent a significant breakthrough in the cellular retention of fluorescent dyes and are ideal long-term tracers for transplanted cells or tissues.

- **Microinjectable cytoplasmic labels (Section 14.3).** Polar tracers such as lucifer yellow CH, Cascade Blue® hydrazide, the Alexa Fluor® hydrazides and biocytin are membrane-impermeant probes that are usually introduced into cells by whole-cell patch clamping, iontophoresis, osmotic lysis of pinocytotic vesicles or comparable methods^{2,3} (Table 14.1). These tracers are commonly used to investigate cell-cell and cell-liposome fusion, as well as membrane permeability⁴ and transport through gap junctions⁵ or cell uptake during pinocytosis (Section 16.1).
- **Nissl stains for retrograde tracing in neurons (Section 14.3).** We have developed five fluorescent Nissl stains that not only provide a wide spectrum of fluorescent colors for staining neurons, but are also more sensitive than the conventional dyes.

Table 14.1 Techniques for loading molecules into the cytoplasm.

Method of Plasma Membrane Breach	Size of Molecules Loaded (MW) *
Chemical	
ATP ¹	1000
Cell-penetrating peptides ²⁻⁵ (CPP)	150,000; (DNA)
Influx™ pinocytotic cell-loading reagent ⁶⁻⁸ (I14402)	150,000
α -Toxin of <i>Staphylococcus aureus</i> ^{9,10}	1000
Vehicle	
Red blood cell fusion ^{11,12}	300,000
Cationic lipids ¹³⁻¹⁵ (Lipofectamine® reagents)	(DNA)
Mechanical	
Microinjection ^{16,17}	150,000
Whole-cell patch clamping ¹⁸	Very high
Carbon nanotubes and nanowires ¹⁹⁻²¹	150,000; (DNA)
Scrape loading ⁸	500,000; (DNA)
Ultrasonication ²²	70,000; (DNA)
Microprojectile bombardment ^{23,24}	10,000; (DNA)
Glass beads ²⁵	150,000
Electrical	
Electroporation ²⁶⁻²⁹ †	150,000; (DNA)

* Molecular weight (MW) of largest molecules reported loaded (DNA is listed separately if it has been successfully introduced by a technique). † We recommend the Neon™ Transfection System (www.invitrogen.com/handbook/neon) for efficient electroporation of cultured cell lines, primary cells and stem cells.

- **Membrane tracers—DiI, DiO, DiD, DiR, DiA, R18, FM® 1-43, FM® 4-64 and their analogs (Section 14.4).** Lipophilic carbocyanine, aminostyryl and rhodamine dyes can be introduced into membranes by direct application of a dye crystal onto a cell, by bulk loading from aqueous dispersions prepared from our Vybrant® DiI, DiO and DiD cell-labeling solutions or by application of the NeuroTrace® DiI, DiO and DiD tissue-labeling pastes. Lateral diffusion of the dye within the membrane eventually stains the entire cell. These probes are widely used for neuroanatomical tracing and long-term assays of cell–cell association. Some of our DiI and DiO analogs exhibit superior solubility and brightness and, in some cases, produce a cell-staining pattern that persists through fixation by aldehyde-based reagents and through acetone permeabilization (Figure 14.1.2).
- **Fluorescent and biotinylated dextran conjugates (Section 14.5).** Dextran conjugates are ideal cell-lineage tracers because they are relatively inert, exhibit low toxicity and are retained in cells for long periods. These membrane-impermeant probes are usually loaded into cells by invasive techniques such as microinjection, whole-cell patch clamping, scrape loading, microprojectile bombardment, electroporation or osmotic shock (Table 14.1). Availability of dextrans in a range of molecular weights makes them useful as size-exclusion probes for determining pore sizes in membranes.
- **Fluorescent microspheres (Section 14.6).** Molecular Probes® FluoSpheres® and TransFluoSpheres® fluorescent microspheres—which contain $\sim 10^2$ to $\sim 10^{10}$ fluorescent dyes per bead—are intensely fluorescent tracers (Figure 14.1.3). Although other multiply labeled particles such as our BioParticles® fluorescent bacteria (Section 16.1) may be used as tracers, they are often not biologically inert nor are they as physically durable as fluorescent microspheres. These properties make fluorescent beads particularly useful as long-term markers for transplantation studies. Submicron microspheres can be injected into cells or taken up by phagocytosis. Much larger (10–15 μm) beads provide an alternative to radioactive microspheres for determination of organ blood flow, and intermediate-sized (1–5 μm) microspheres are useful for studies that trace inhaled particles.
- **Qdot® nanocrystal tracers (Section 14.6).** Qtracker® Cell Labeling Kits provide spectrally distinct Qdot® nanocrystals that have been functionalized on their surface with polyarginine peptides to facilitate spontaneous uptake by live cells. Qtracker® non-targeted quantum dots are designed for small animal *in vivo* imaging, and especially for studying vascular structure after microinjection. These nanocrystals exhibit intense red or near-infrared fluorescence emission for maximum transmission through tissues and avoidance of background autofluorescence.
- **Proteins and protein conjugates (Section 14.7).** Our fluorescent protein tracers have molecular weights between $\sim 12,000$ (cholera toxin subunit B conjugates) and $\sim 240,000$ daltons (B- and R-phycoerythrin). Their applications are sometimes similar to those of the fluorescent dextrans; however, unlike the polydisperse dextrans, fluorescent protein tracers have molecular weights that are reasonably well defined.

Figure 14.1.2 The tracer DiI (D282, D3911) used as a diagnostic tool to evaluate retinal and tectal patterns in a chimeric 5-day-old zebrafish brain. *Acerebellar (Fgf8)* gene expression is required for development of midbrain polarity and correct retinotopic mapping of retinal ganglion cell axons. One eye of this brain was wild type, whereas the other was mutant for *fgf8* (derived from homozygous acerebellar donors). The chimera was obtained by transplanting eye primordia, and the eyes were subsequently removed for photography. Retinal ganglion cell axons in the dorsonasal retina were labeled with DiI and nuclei were counterstained with SYTOX® Green nucleic acid stain (S7020). Axons from the wild-type eye terminate correctly in the posterior tectum only, whereas axons from the mutant eye terminate inappropriately in the anterior and posterior tectum. This digital image, previously published on the cover of *Development* 125 (13) (1999), was created by Alexander Picker and Michael Brand, Neurobiology, University of Heidelberg. The image is used with the permission of The Company of Biologists, Ltd.

Figure 14.1.3 A photomicrograph of a multicolor mixture of Molecular Probes® FluoSpheres® fluorescent microspheres overlaid with a differential interference contrast (DIC) image of the same field. Molecular Probes® proprietary fluorescent dye technology is used to produce a range of intensely fluorescent FluoSpheres® microspheres labeled with biotin, streptavidin and NeutrAvidin™ biotin-binding protein, providing important tools for improving the sensitivity of flow cytometry applications and immunodiagnostic assays.

14.2 Membrane-Permeant Reactive Tracers

Thiol-Reactive CellTracker™ Probes

Molecular Probes® CellTracker™ reagents are fluorescent chloromethyl derivatives that freely diffuse through the membranes of live cells (Figure 14.2.1, Figure 14.2.2, Figure 14.2.3). Once inside the cell, these mildly thiol-reactive probes undergo what is believed to be a glutathione *S*-transferase-mediated reaction to produce membrane-impermeant glutathione–fluorescent dye adducts, although our experiments suggest that they may also react with other intracellular components (Figure 14.2.4). Regardless of the mechanism, many cell types loaded with the CellTracker™ probes are both fluorescent and viable for at least 24 hours after loading and often through several cell divisions. Most other cell-permeant fluorescent dyes, including the acetoxymethyl (AM) esters of calcein and BCECF (Section 15.2), are retained in viable cells for no more than a few hours at physiological temperatures (Figure 14.2.5). Furthermore, unlike the free dye, the peptide–fluorescent dye adducts contain amino groups and can therefore be covalently linked to surrounding biomolecules by fixation with formaldehyde or glutaraldehyde. This property permits long-term storage of the labeled cells or tissue and, in cases where the cognate anti-dye antibody is available (see below), amplification of the dye hapten by standard immunohistochemical techniques. Fixation without loss of the tracer also facilitates the safe handling and analysis of cells containing pathogens.

Figure 14.2.1 Detection of organisms in marine sediments by incubating an intact sediment core sample with the fixable, cell-permeant CellTracker™ Green CMFDA (C2925, C7025). The core sample was subsequently embedded, sectioned and examined for fluorescently labeled organisms. The micrograph reveals the microorganism *Leptohalysis scotti*, a marine benthic foraminifera. Image contributed by Joan M. Bernhard, Wadsworth Center, New York State Department of Health.

Figure 14.2.2 HL60 cells that have been stained with CellTracker™ Orange CMTMR (C2927) and then mixed with WEHI 7.1 cells stained with CellTracker™ Green CMFDA (C2925, C7025) (left). Several minutes after initiating cell–cell electrofusion, a CMTMR-stained HL60 cell is observed fusing with a CMFDA-stained WEHI 7.1 cell; cytoplasmic mixing is evident by the appearance of yellow fluorescence. After electrofusion is complete, dual-fluorescing (yellow) hybrids can be easily distinguished (right). Images contributed by Mark J. Jaroszeski, University of South Florida.

Figure 14.2.3 Individual populations of mouse myeloma (P3X) cells stained with our reactive tracers—CellTracker™ Orange CMTMR (C2927), CellTracker™ Green CMFDA (C2925) and CellTracker™ Blue CMAC (C2110). Each of three cell populations was stained with a different tracer and then the populations were mixed, demonstrating that these tracers allow simultaneous long-term monitoring of different groups of cells in transplantation and other assays.

Figure 14.2.4 Intracellular reactions of our fixable CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate; C2925, C7025). Once this membrane-permeant probe enters a cell, esterase hydrolysis converts nonfluorescent CMFDA to fluorescent 5-chloromethylfluorescein, which can then react with thiols on proteins and peptides to form aldehyde-fixable conjugates. This probe may also react with intracellular thiol-containing biomolecules first, but the conjugate is nonfluorescent until its acetates are removed.

Figure 14.2.5 Loading and retention characteristics of intracellular marker dyes. Cells of a human lymphoid line (GePa) were loaded with the following cell-permeant acetoxymethyl ester (AM) or acetate derivatives of fluorescein: 1) calcein AM (C1430, C3099, C3100MP), 2) BCECF AM (B1150), 3) fluorescein diacetate (FDA, F1303), 4) carboxyfluorescein diacetate (CFDA, C1354) and 5) CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate, C2925, C7025). Cells were incubated in 4 μM staining solutions in Dulbecco's modified eagle medium containing 10% fetal bovine serum (DMEM+) at 37°C. After incubation for 30 minutes, cell samples were immediately analyzed by flow cytometry to determine the average fluorescence per cell at time zero (0 hours). Retained cell samples were subsequently washed twice by centrifugation, resuspended in DMEM+, maintained at 37°C for 2 hours and then analyzed by flow cytometry. The decrease in the average fluorescence intensity per cell in these samples relative to the time zero samples indicates the extent of intracellular dye leakage during the 2-hour incubation period.

CellTracker™ Probes in a Variety of Fluorescent Colors

Molecular Probes® CellTracker™ product line includes reactive chloromethyl derivatives of:

- Blue-fluorescent 7-aminocoumarin (CellTracker™ Blue CMAC, C2110, Figure 14.2.6)
- Blue-fluorescent 7-hydroxycoumarin (CellTracker™ Blue CMHC, C2111, Figure 14.2.7)
- Blue-fluorescent 6,8-difluoro-7-hydroxycoumarin (CellTracker™ Blue CMF₂HC, C12881, Figure 14.2.8)
- Violet-fluorescent 2,3,6,7-tetrahydro-9-bromomethyl-1H,5H-quinolizino(9,1-gh)coumarin (CellTracker™ Violet BMQC, C10094, Figure 14.2.9)
- Green-fluorescent fluorescein diacetate (CellTracker™ Green CMFDA, C2925 and C7025, Figure 14.2.4)
- Green-fluorescent BODIPY® derivative (CellTracker™ Green BODIPY®, C2102, Figure 14.2.10)
- Orange-fluorescent tetramethylrhodamine (CellTracker™ Orange CMTMR, C2927, Figure 14.2.11)
- Orange-fluorescent CellTracker™ Orange CMRA (C34551, Figure 14.2.12)
- Red-fluorescent CellTracker™ Red CMTPX (C34552, Figure 14.2.13)

CellTracker™ Green CMFDA freely diffuses into the cell, where cytosolic esterases cleave the acetate groups, releasing the fluorescent product; CellTracker™ Orange CMRA also requires esterase cleavage to activate its fluorescence. The CellTracker™ Blue CMAC, CMHC and CMF₂HC, CellTracker™ Violet BMQC, CellTracker™ Green BODIPY®, CellTracker™ Orange CMTMR and CellTracker™ Red CMTPX probes do not require enzymatic cleavage to activate their fluorescence. CellTracker™ Orange CMRA is a rhodol-based fluorophore with an overall net charge at neutral pH that is expected to be negative, in contrast with the overall net positive charge of the tetramethylrhodamine-based CellTracker™ Orange CMTMR. Thus, unlike CellTracker™ Orange CMTMR, CellTracker™ Orange CMRA should remain primarily in the cytoplasm instead of being sequestered inside actively respiring mitochondria. The long-wavelength CellTracker™ Red CMTPX exhibits bright red fluorescence that is easily distinguished from that of blue-, green- and far-red-fluorescent probes, including CellTracker™ Green CMFDA and CFSE¹⁻³ (see below). We also offer the green-fluorescent BODIPY® 493/503 methyl bromide (B2103, Figure 14.2.14), which has slightly greater thiol-reactivity than do chloromethyl derivatives.

Applications for CellTracker™ Probes

The thiol-reactive CellTracker™ Green CMFDA is suitable for long-term cell labeling and has been frequently used for *in vitro* labeling of cells prior to adoptive transfer to animals and tissues.^{2,4,5} Other prominent applications include the analysis of cell-cell fusion,^{6,7} cell adhesion^{8,9} and multidrug resistance transporter function.^{10,11}

CellTracker™ Green CMFDA was used to track wild-type and myosin II mutant *Dictyostelium discoideum* cells within aggregation streams during early multicellular morphogenesis; differentiation and morphogenesis pathways were reportedly unaffected in labeled cells imaged over several days by confocal laser-scanning microscopy.^{12,13} CellTracker™ Green BODIPY® was used to label CD4⁺ T cells and follow their activation and proliferation in mice with the immunodeficiency syndrome MAIDS.¹⁴ CellTracker™ Green CMFDA and some other CellTracker™ dyes have been utilized to selectively label intracellular *Chlamydia psittaci* bacteria in infected cells.¹⁵

CellTracker™ Orange CMTMR has been used to stain the cytoplasm of *engrailed*-expressing *Drosophila* cells in an *in vitro* reconstruction experiment,¹⁶ to follow T-cell differentiation and maturation¹⁷ and to trace implanted tumor cells for at least two weeks.^{18,19} Chlamydia labeled

with CellTracker™ Orange CMTMR continued to grow and differentiate, and labeled chlamydia isolated from infected cells remained infectious.¹⁵

Metabolic activity and drug-induced cytotoxicity were measured with CellTracker™ Blue CMAC in a fluorescence-based microplate assay.²⁰ Peptidase substrates derived from CellTracker™ Blue CMAC yield blue-fluorescent products that are well retained in live cells²¹ (Section 10.4). Our CellTracker™ Blue CMF₂HC (C12881) has a low pK_a that helps ensure that the dye's conjugates will be ionized and have bright blue fluorescence in the cytoplasm.^{1,22} CellTracker™ Blue CMAC was used in combination with calcein AM (C1430, C3099, C3100MP; Section 15.6) and the lipophilic tracer DiI (D282, D3911, V22885; Section 14.4) to identify lipid mixing and cytoplasm mixing between labeled effector cells and labeled target cells.²³

The ability to fix the intracellular products of CellTracker™ Green CMFDA, CellTracker™ Green BODIPY* and CellTracker™ Orange CMTMR in permeabilized cells permits the stained cells to be probed with our anti-fluorescein/Oregon Green®, anti-BODIPY* FL and anti-tetramethylrhodamine antibodies, respectively (Section 7.4, Table 7.8).

Other Thiol-Reactive Tracers

Chloromethyl Derivatives of SNARF®-1 and H₂DCFDA

Although they were designed for other purposes, the chloromethyl derivatives of our SNARF®-1 pH indicator (C6826, Figure 14.2.15) and of 2',7'-dichlorodihydrofluorescein diacetate, acetate ester (CM-H₂DCFDA, C6827, Figure 14.2.16) possess some unique properties for tracking cells. As with the CellTracker™ probes, cytoplasmic enzymes hydrolytically remove the acetate groups from the membrane-permeant probes, and the chloromethyl moieties become conjugated to intracellular thiols.²⁴ With its long Stokes shift (Figure 14.2.17), the SNARF®-1 derivative has easily distinguished, red-orange fluorescence in the cytoplasm when excited at the same wavelengths used for the green-fluorescent CellTracker™ Green CMFDA (Figure 14.2.18).

As with other dihydrofluorescein derivatives (Section 18.2), CM-H₂DCFDA requires an additional oxidation step before becoming fluorescent. This probe is useful for following stimulation of oxidative activity by external agents or natural killer (NK) cells over extended periods, as well as for passively labeling cells that lack appropriate oxidative activity and then following their ingestion by scavengers such as neutrophils. CM-H₂DCFDA has been used to measure intracellular reactive oxygen species (ROS) in cardiac myocytes²⁵ and in human embryonic kidney 293 (HEK 293) cells stably transfected with the human vanilloid receptor 1 (VR1) cation channel.²⁶

Bimanes: Blue-Fluorescent Reactive Tracers

The bimeane derivatives, monobromobimane (mBBR; M1378, M20381) and monochlorobimane (mBCL, M1381MP), are important thiol-derivatization reagents (Section 2.3). The essentially nonfluorescent mBBR and mBCL dyes are known to passively diffuse across the plasma membrane into the cytoplasm, where they form blue-fluorescent adducts with intracellular glutathione and thiol-containing proteins²⁷ (Section 15.6).

Amine-Reactive Tracers

CFSE and Its Derivatives

Carboxyfluorescein diacetate succinimidyl ester (5(6)-CFDA, SE; C1157) is commonly referred to as CFSE. Among its many applications, the two most prominent are *ex vivo* labeling of cells for adoptive transfer and flow cytometric tracking of cell division by label partition analysis. CFSE is colorless and nonfluorescent until its acetate groups are cleaved by intracellular esterases to yield highly fluorescent, amine-reactive 5(6)-carboxyfluorescein succinimidyl ester (equivalent to C1311, Section 1.5). Upon reaction with amine-containing residues of intracellular proteins, the resulting dye-protein adducts are well retained in cells as they move and divide during embryonic development.^{28,29} In addition, these adducts survive subsequent fixation with formaldehyde or glutaraldehyde. Because it is intrinsically more reactive, the succinimidyl ester of CFDA is more likely to react at sites on the extracellular surface than is CMFDA.

Once incorporated into cells, CFSE remains there—even through cell division—thus preventing transfer to unlabeled cells.³⁰ Labeled cells can subsequently be immunohistochemically

Figure 14.2.15 5-(and-6)-Chloromethyl SNARF®-1, acetate (C6826).

Figure 14.2.16 5-(and-6)-Chloromethyl-2',7'-dichlorodihydrofluorescein diacetate, acetyl ester (CM-H₂DCFDA, C6827).

Figure 14.2.17 Absorption and fluorescence emission (excited at 488 nm) spectra of carboxy SNARF®-1 in pH 9.0 and pH 6.0 buffers.

Figure 14.2.18 Human neutrophils loaded with 5-(and-6)-chloromethyl SNARF®-1 acetate (C6826).

Figure 14.2.19 Tracking of asynchronous cell division using 5-(and 6)-carboxyfluorescein diacetate, succinimidyl ester (5(6)-CFDA SE or CFSE; C1157; V12883) labeling and flow cytometry. Cell division results in sequential halving of the initial fluorescence, resulting in a multipartite cellular fluorescence histogram. The peaks labeled 0, 1, 2, 3, 4 and 5 represent successive generations.

Figure 14.2.20 Following cell proliferation in human peripheral blood lymphocytes using the CellTrace™ CFSE Cell Proliferation Kit C34554). Human peripheral blood lymphocytes were harvested and stained with CellTrace™ CFSE (carboxyfluorescein diacetate, succinimidyl ester; 5(6)-CFDA, SE) on Day 0. A portion of the population was arrested at the parent generation using mitomycin C (red peak). The remainder of the sample was stimulated with phytohemagglutinin and allowed to proliferate for 5 days. Solid green peaks represent successive generations.

Figure 14.2.21 Human peripheral blood lymphocytes were harvested and stained with CellTrace™ Violet stain (C34557). The violet peaks represent successive generations of cells stimulated with mouse anti-human CD3 and Interleukin-2 and grown in culture for 7 days. The peak outlined in black represents cells that were grown in culture for 7 days with no stimulus.

detected post-mortem using our anti-fluorescein/Oregon Green® antibodies^{31–33} (Section 7.4). The feasibility of using cell-permeant fluorescent tracers to follow asynchronous cell division of natural killer (NK) cells, B cells, T cells, thymocytes, lymphocytes, fibroblasts and hematopoietic cells has been demonstrated with CFSE^{34–37} (Figure 14.2.19). Lymphocytes labeled with CFSE were detected up to eight weeks after injection into mice during lymphocyte migration studies,^{38–40} and similarly labeled hepatocytes were easily located by fluorescence microscopy even 20 days after intrahepatic transplantation.⁴¹ CFSE has also been successfully employed to quantitate adhesion of neutrophils⁴² and leukocytes,⁴³ to assay T-cadherin-mediated cell aggregation,⁴⁴ to follow neurite growth in an *in vitro* bioassay⁴⁵ and to trace fetal cells in culture.⁴⁶ Different loading concentrations of CFSE can be used to produce cells that can be distinguished by their relative brightness.⁴⁷ CFSE has been utilized for tracing the transport of viable bacterial cells in groundwater under no-growth conditions for periods of at least 28 days.⁴⁸ CFSE is also available conveniently packaged for cell-tracing applications in our Vybrant® CFDA SE Cell Tracer Kit (V12883) and for cell proliferation studies in our CellTrace™ CFSE Cell Proliferation Kit (C34554, Figure 14.2.20). The fluorescent CFSE product has excitation/emission maxima of ~492/517 nm and can be detected using a fluorescence microscope, flow cytometer or fluorescence microplate reader.

Carboxyeosin diacetate succinimidyl ester (C22803) has applications that are expected to be similar to CFSE; however, its fluorescence can be excited and detected at longer wavelengths, possibly permitting two-color tracing experiments of mixed-cell populations. Eosin derivatives are also effective reagents for photoablation of cells. Unlike CFSE, fluorescence of the intracellular hydrolysis products of the succinimidyl ester of 5-(and 6)-carboxy-2',7'-dichlorofluorescein diacetate (C1165) is relatively insensitive to fluctuations in pH. This amine-reactive tracer was reported to be more useful than the lipophilic marker DiI (D282, Section 14.4) in an investigation of palatal fusion in rodent embryos.⁴⁹

CellTrace™ Violet Cell Proliferation Kit

CellTrace™ Violet stain is an esterase-activated phenolic fluorophore with a succinimidyl ester substituent for coupling to cell surface and intracellular amines. It is functionally analogous to CFSE, equally partitioning between daughter cells during division resulting in successive 2-fold reductions in cell-associated fluorescence intensity. When analyzed by flow cytometry, this progressive label partitioning provides a direct indication of cell proliferation status (Figure 14.2.21). In contrast to CFSE, CellTrace™ Violet stain is optimally excited by 405 nm violet diode lasers and generates blue fluorescence (emission peak ~455 nm). Consequently, it can be used in combination with CFSE to track cells from different origins after mixing or to analyze proliferation of GFP-expressing cells. The CellTrace™ Violet Cell Proliferation Kit (C34557) includes the CellTrace™ Violet stain together with dimethylsulfoxide (DMSO) for preparation of a stock solution.

CellTrace™ Oregon Green® 488 Carboxylic Acid Diacetate Succinimidyl Ester

The succinimidyl ester of Oregon Green® 488 carboxylic acid diacetate (carboxy-DFFDA SE) offers several important advantages over CFSE as a fluorescent cell tracer. This Oregon Green® 488 probe passively diffuses into cells, where it is colorless and nonfluorescent until its acetate groups are removed by intracellular esterases to yield a highly green-fluorescent, amine-reactive dye. Upon reaction with intracellular amines, the probe forms Oregon Green® 488 conjugates that are well-retained by cells. Unlike fluorescein derivatives, however, Oregon Green® 488 derivatives exhibit bright green fluorescence that is not pH dependent at typical cellular pH values. Moreover, Oregon Green® 488 probes are usually brighter and more photostable than fluorescein probes. We offer carboxy-DFFDA SE in a 1 mg unit size (O34550) and specially packaged in a set of 20 vials, each containing 50 µg (CellTrace™ Oregon Green® 488 carboxylic acid diacetate succinimidyl ester, C34555).

CellTrace™ Far Red DDAO-SE

CellTrace™ Far Red DDAO-SE (C34553) is a fixable, far-red-fluorescent tracer for long-term cell labeling. The succinimidyl ester (SE) reactive group forms a strong covalent attachment to primary amines that occur in proteins and other biomolecules inside and outside of cells. With its far-red fluorescence, CellTrace™ Far Red DDAO-SE has minimal spectral overlap with most other fluorophores (Figure 14.2.22) and thus can be used simultaneously with almost any blue, green or orange fluorophores including Green Fluorescent Protein^{50–52} (GFP).

Amine-Reactive SNARF®-1 Carboxylic Acid Acetate

To permit simultaneous long-term tracing of mixed-cell populations using different fluorescent colors, we have developed an amine-reactive probe whose applications are similar to those of CFSE.⁵³ Cells labeled with our succinimidyl ester of SNARF®-1 carboxylic acid acetate (S22801, Figure 14.2.23) have a red-orange fluorescence that can easily be distinguished from that of cells loaded with green-fluorescent tracers such as CFSE. However, the fluorescence intensity of cells loaded with this SNARF®-1 derivative will not be as high as that of cells loaded with the same concentration of CFSE. Thus, it is necessary to adjust the reagent concentration and/or select optical filters to appropriately balance the fluorescence intensities when doing two-color experiments.

Figure 14.2.22 Normalized absorption and fluorescence emission spectra of DDAO.

Notes

- B2103 spectra are for the unreacted reagent. The thiol adduct has Abs = 493 nm, Em = 503 nm in MeOH.
- Acetate hydrolysis of this compound yields a fluorescent product with similar pH-dependent spectral characteristics to C1904.
- C1165 is converted to a fluorescent product with spectra similar to C368 after acetate hydrolysis.
- C2110 in MeOH: Abs = 364 nm (EC = 16,000 cm⁻¹M⁻¹), Em = 454 nm.
- Spectra of hydroxycoumarins are pH dependent. Below the pK_a (~7.8), Abs shifts to shorter wavelengths (325–340 nm) and fluorescence intensity decreases.
- C6826 and S22801 are converted to fluorescent products with spectra similar to C1270 after acetate hydrolysis.
- Acetate hydrolysis and subsequent oxidation of C6827 generate fluorescent 5-(and-6)-chloromethyl-2',7'-dichlorofluorescein with spectra similar to C368.
- Acetate hydrolysis of C22803 yields a fluorescent product with spectra similar to 5-carboxyeosin, Abs = 519 nm (EC = 100,000 cm⁻¹M⁻¹), Em = 542 nm in pH 9 buffer.
- The fluorescent phenolic dye generated by acetate hydrolysis of C34551 has Abs = 550 nm (EC = 72,000 cm⁻¹M⁻¹), Em = 572 nm in pH 7 buffer.
- Acetate hydrolysis of this compound yields a fluorescent product with similar spectral characteristics to O6146.
- Bimanes are almost nonfluorescent until reacted with thiols. For monobromobimane conjugated to glutathione, Abs = 394 nm, Em = 490 nm (QY ~0.1–0.3) in pH 8 buffer. (Methods Enzymol (1987) 143:76, Methods Enzymol (1995) 251:133)
- This product is specified to equal or exceed 98% analytical purity by HPLC.

PRODUCT LIST 14.2 MEMBRANE-PERMEANT REACTIVE TRACERS

Cat. No.	Product	Quantity
B2103	BODIPY® 493/503 methyl bromide (8-bromomethyl-4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-s-indacene)	5 mg
C1165	CDCFDA, SE (5-(and-6)-carboxy-2,7'-dichlorofluorescein diacetate, succinimidyl ester) *mixed isomers*	25 mg
C22803	CEDA, SE (5-(and-6)-carboxyeosin diacetate, succinimidyl ester) *mixed isomers*	5 mg
C34554	CellTrace™ CFSE Cell Proliferation Kit *for flow cytometry*	1 kit
C34553	CellTrace™ Far Red DDAO-SE *special packaging*	20 x 50 µg
C34555	CellTrace™ Oregon Green® 488 carboxylic acid diacetate, succinimidyl ester (carboxy-DFFDA, SE) *cell permeant* *mixed isomers*	20 x 50 µg
C34557	CellTrace™ Violet Cell Proliferation Kit *for flow cytometry*	1 kit
C2110	CellTracker™ Blue CMAC (7-amino-4-chloromethylcoumarin)	5 mg
C12881	CellTracker™ Blue CMF ₂ HC (4-chloromethyl-6,8-difluoro-7-hydroxycoumarin)	5 mg
C2111	CellTracker™ Blue CMHC (4-chloromethyl-7-hydroxycoumarin)	5 mg
C2102	CellTracker™ Green BODIPY® (8-chloromethyl-4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-s-indacene)	5 mg
C2925	CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate)	1 mg
C7025	CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate) *special packaging*	20 x 50 µg
C34551	CellTracker™ Orange CMRA *special packaging*	20 x 50 µg
C2927	CellTracker™ Orange CMTMR (5-(and-6)-(((4-chloromethyl)benzoyl)amino)tetramethylrhodamine) *mixed isomers*	1 mg
C34552	CellTracker™ Red CMTPX *special packaging*	20 x 50 µg
C10094	CellTracker™ Violet BMQC (2,3,6,7-tetrahydro-9-bromomethyl-1H,5H-quinolino(9,1-g)coumarin)	5 x 100 µg
C1157	5(6)-CFDA, SE; CFSE (5-(and-6)-carboxyfluorescein diacetate, succinimidyl ester) *mixed isomers*	25 mg
C6827	5-(and-6)-chloromethyl-2,7'-dichlorodihydrofluorescein diacetate, acetyl ester (CM-H ₂ DCFDA) *mixed isomers* *special packaging*	20 x 50 µg
C6826	5-(and-6)-chloromethyl SNARF®-1, acetate *mixed isomers* *special packaging*	20 x 50 µg
M1378	monobromobimane (mBBr)	25 mg
M20381	monobromobimane (mBBr) *FluoroPure™ grade*	25 mg
M1381MP	monochlorobimane (mBCl)	25 mg
O34550	Oregon Green® 488 carboxylic acid diacetate, succinimidyl ester (carboxy-DFFDA, SE) *mixed isomers*	1 mg
S22801	SNARF®-1 carboxylic acid, acetate, succinimidyl ester *special packaging*	10 x 50 µg
V12883	Vybrant® CFDA SE Cell Tracer Kit	1 kit

14.3 Polar Tracers

Fixable Polar Tracers

We prepare a wide variety of highly water-soluble dyes and other detectable probes that can be used as cell tracers. In most cases, the polarity of these water-soluble probes is too high to permit them to passively diffuse through cell membranes. Consequently, special methods for loading the dyes into cells must be employed, including microinjection, pinocytosis or techniques that temporarily permeabilize the cell's membrane^{1,2} (Table 14.1). Our Influx™ pinocytic cell-loading reagent (I14402, see below and Section 19.8) is particularly useful for loading many of the polar tracers in this section—as well as the dextrans and fluorescent proteins described in Section 14.5 and Section 14.7—into many types of cells. Permeabilization of cells with staphylococcal α -toxin³ or the saponin ester β -escin is reported to make the membrane of smooth muscle cells permeable to low molecular weight (<1000 daltons) molecules, while retaining high molecular weight compounds.^{4–6} Electroporation has been used to transport several of the polar tracers through the skin⁷ and into cells.^{8,9} Many of these tracers can also be loaded into cells noninvasively as their cell-permeant acetoxymethyl (AM) esters, which are discussed in more detail in Section 15.2.

Alexa Fluor® Hydrazides and Hydroxylamines

Our selection of fluorescent hydrazide and hydroxylamine derivatives continues to expand (Section 3.3, Table 3.2). The blue-fluorescent Alexa Fluor® 350 hydrazide and Alexa Fluor® 350 hydroxylamine (A10439, A30627), green-fluorescent Alexa Fluor® 488 hydrazide and Alexa Fluor® 488 hydroxylamine (A10436, A30629; Figure 14.3.1), orange-fluorescent Alexa Fluor® 555

Figure 14.3.1 The APR motor neuron of a larval moth, *Manduca sexta*, labeled by the intracellular injection of Alexa Fluor® 488 hydrazide, sodium salt (A10436). This pseudo-colored image was created by combining 21 optical sections obtained using a confocal laser-scanning microscope equipped with a bandpass filter appropriate for fluorescein. The image was contributed by Jack Gray and Walter Metcalfe, Institute of Neuroscience, University of Oregon.

and Alexa Fluor® 568 hydrazides (A20501MP, A10437, A10441; Figure 14.3.2), red-fluorescent Alexa Fluor® 594 hydrazide¹⁰ (A10438, A10442) and far-red-fluorescent Alexa Fluor® 633 hydrazide, Alexa Fluor® 647 hydrazide and Alexa Fluor® 647 hydroxylamine (A30634, A20502, A30632) are likely among the best overall polar tracers in each of their various spectral ranges.¹¹ These low molecular weight, cell membrane-impermeant molecules (Alexa Fluor® 350 hydrazide, 349 daltons; Alexa Fluor® 350 hydroxylamine, 585 daltons; ~570–760 daltons for the Alexa Fluor® 488, 568 and 594 hydrazides and hydroxylamine; and about 1200 daltons for the Alexa Fluor® 555 and 647 hydrazides and hydroxylamine) possess several properties that are superior to those of the widely used neuronal tracer lucifer yellow CH (L453, L682, L1177, L12926). Like lucifer yellow CH, the hydrazide moiety of the Alexa Fluor® derivatives makes these tracers fixable by common aldehyde-based fixatives. We have determined that Alexa Fluor® 594 hydrazide has a water solubility of ~84 mg/mL and the other Alexa Fluor® hydrazides are likely to have comparable or higher water solubility.

Our rabbit polyclonal antibody to the Alexa Fluor® 488 fluorophore (A11094, Section 7.4) quenches the fluorescence of the Alexa Fluor® 488 dye (Anti-Lucifer Yellow Dye, Anti-Alexa Fluor® 405/Cascade Blue® Dye and Anti-Alexa Fluor® 488 Dye Antibodies—Note 14.1) and, following cell fixation and permeabilization, can be used in conjunction with the reagents in our Tyramide Signal Amplification (TSA™) Kits (Section 6.2) to amplify the signal or with the anti-rabbit IgG conjugate of NANOGOLD® or Alexa Fluor® FluoroNanogold™ 1.4 nm gold clusters (N24916, A24926, A24927; Section 7.2) and the associated LI Silver Enhancement Kit (L24919, Section 7.2) for correlated fluorescence and light microscopy studies.

Although lucifer yellow CH can be used for confocal laser-scanning microscopy, its extinction coefficient at the 488 nm spectral line of the argon-ion laser (~700 cm⁻¹M⁻¹) is only about 1% of that of Alexa Fluor® 488 hydrazide and Alexa Fluor® 488 hydroxylamine (≥71,000 cm⁻¹M⁻¹) (Figure 14.3.3). Furthermore, the high photostability of the Alexa Fluor® dyes permits their detection in very fine structures that cannot be seen with lucifer yellow CH staining. All of these Alexa Fluor® dyes are remarkably bright and photostable. In addition, the Alexa Fluor® hydrazide salts have high water solubility (typically greater than 8%). We offer the Alexa Fluor® 568 and Alexa Fluor® 594 hydrazides either as solids (A10437, A10438) or as 10 mM solutions in 200 mM KCl (A10441, A10442). The 10 mM solutions have been filtered through a 0.2 μm filter to remove any insoluble material prior to packaging. Alexa Fluor® 488 hydrazide, Alexa Fluor® 555 hydrazide, Alexa Fluor® 633 hydrazide and Alexa Fluor® 647 hydrazide (A10436, A20501MP, A30634, A20502) and Alexa Fluor® 350, Alexa Fluor® 488 and Alexa Fluor® 647 hydroxylamines (A30627, A30629, A30632) are only available as solids. Our Alexa Fluor® 350 hydrazide and Alexa Fluor® 350 hydroxylamine, which

Figure 14.3.3 Absorption spectra showing that the molar extinction coefficient (EC) at 488 nm of Alexa Fluor® 488 hydrazide (A10436) in water (green line) is approximately 100-fold greater than that of lucifer yellow CH (L453, L682, L1177, L12926) in water (blue line).

NOTE 14.1

Anti-Lucifer Yellow Dye, Anti-Alexa Fluor® 405/Cascade Blue® Dye and Anti-Alexa Fluor® 488 Dye Antibodies

Molecular Probes® anti-lucifer yellow dye antibodies were specifically developed to overcome certain limitations of lucifer yellow CH (L453, L682, L12926, L1177). Lucifer yellow CH is an aldehyde-fixable fluorescent cell tracer that has long been used by neuroscientists to identify patterns of gap junctional communication,¹ to assay the outgrowth of developing neurons² and to characterize the morphology of neurons from which electrical recordings have been made.³ Even though the cell soma of a lucifer yellow CH-filled neuron may be brightly stained, its finer processes can sometimes be faint and may fade rapidly or be obscured by the more intensely stained portions of the neuron. Investigators have been able to overcome these limitations by using anti-lucifer yellow dye antibodies in conjunction with standard enzyme-mediated immunohistochemical methods to develop a more permanent, fade-free signal for light microscopy.⁴⁻⁷ Anti-lucifer yellow dye antibodies have also been used to develop tissue for electron microscopy⁸ and to distinguish neurons filled with lucifer yellow CH from those injected with the

lectin *Phaseolus vulgaris* leucoagglutinin⁹ (PHA-L). Molecular Probes® Cascade Blue® hydrazide (C3239), which can also be fixed in place with aldehyde-based fixatives, can potentially be used as a second label with lucifer yellow CH to characterize the morphology of interacting neurons.

For these applications, we offer unconjugated and biotinylated rabbit polyclonal anti-lucifer yellow dye (A5750, A5751) and anti-Alexa Fluor® 405/Cascade Blue® dye (A5760) antibodies. Similarly, our rabbit polyclonal anti-Alexa Fluor® 488 dye antibody (A11094) can be used to detect Alexa Fluor® 488 hydrazide (A10436), Alexa Fluor® 488 hydroxylamine (A30629), Alexa Fluor® 488 cadaverine (A30676) and Alexa Fluor® 488 biocytin (A12924) in fixed-cell preparations. See Section 7.4 (Table 7.8) for a complete description of these and other anti-fluorophore and anti-biotin antibodies.

1. Biotechniques (2008) 45:33; 2. Science (1988) 242:700; 3. J Neurosci (2003) 23:4700; 4. J Neurosci (1994) 14:5267; 5. J Neurosci Methods (1992) 41:45; 6. J Comp Neurol (1990) 296:598; 7. Dev Biol (1982) 94:391; 8. Circ Res (1992) 70:49; 9. J Neurosci Methods (1990) 33:207.

are sulfonated coumarin derivatives (Figure 14.3.4), are some of the few polar tracers that exhibit bright blue fluorescence.

Other Alexa Fluor® Derivatives

To allow amplification of signals, especially in the finer processes of dye-filled neurons, we also offer Alexa Fluor® 488 biocytin (A12924), Alexa Fluor® 546 biocytin (A12923) and Alexa Fluor® 594 biocytin (A12922). These unique probes combine our Alexa Fluor® 488, Alexa Fluor® 546 and Alexa Fluor® 594 fluorophores with biotin and an aldehyde-fixable primary amine (see “Fluorescent Biotin Derivatives,” below). In addition, we offer the bright blue-fluorescent Alexa Fluor® 405 cadaverine (A30675, see below) as well as several other Alexa Fluor® cadaverines (Section 3.3, Table 3.2), all of which should be useful as tracing molecules because they are exceptionally bright, small and water soluble, and they each contain an aldehyde-fixable functional group. Alexa Fluor® 546 biocytin has been used to label streptavidin-coated particles in order to quantitate fluorescence signals in an automated imaging system designed for analyzing immobilized particle arrays.¹²

Lucifer Yellow CH

Lucifer yellow CH (LY-CH or LY, Figure 14.3.5) has long been a favorite tool for studying neuronal morphology because it contains a carbonylhydrazone (CH) group that allows it to be covalently linked to surrounding biomolecules during aldehyde-based fixation.^{13,14} Loading of this polar tracer and other similar impermeant dyes is usually accomplished by microinjection,¹⁵ pinocytosis,¹⁶ scrape loading,¹⁷ ATP-induced permeabilization¹⁸ or osmotic shock¹⁹ (Table 14.1), but can also be accomplished in cell suspensions or with adherent cells by using our Influx™ pinocytic cell-loading reagent (I14402, see below). Lucifer yellow CH localizes in the plant vacuole when taken up either through what is thought to be anion-transport channels^{20–22} or by fluid-phase endocytosis.²³ Upon injection into the epidermal cells of *Egeria densa* leaves, lucifer yellow CH reportedly moved into the cytoplasm of adjacent cells, localized in the plant vacuole or moved in and out of the nucleus.²⁴ The lithium salt of lucifer yellow CH is widely used for microinjection because of its relatively high water solubility (~8%). In addition to the solid (L453), we offer the lithium salt of lucifer yellow CH as a filtered 100 mM solution (L12926), ready for microinjection. The potassium salt (L1177, solubility ~1%) or the ammonium salt of lucifer

yellow CH (L682, solubility ~6%) may be preferred in applications where lithium ions interfere with biological function.

Although its weak absorption at 488 nm ($\text{EC} \sim 700 \text{ cm}^{-1}\text{M}^{-1}$) (Figure 14.3.3) makes it inefficiently excited with the argon-ion laser, lucifer yellow CH has been used as a neuronal tracer in some confocal laser-scanning microscopy studies.^{25–27} For electron microscopy studies, lucifer yellow CH can be used to photoconvert diaminobenzidine (DAB) into an insoluble, electron-dense reaction product^{28–30} (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2). Alternatively, rabbit anti-lucifer yellow dye antibodies (Section 7.4) can be used in conjunction with our goat anti-rabbit IgG antibody conjugated to either NANOGOLD® or Alexa Fluor® FluoroNanogold™ 1.4 nm gold clusters (Section 7.2) and the LI Silver (LIS) Enhancement Kit (L24919, Section 7.2) to develop a more permanent, fade-free colorimetric or electron-dense signal from dye-filled neurons that is suitable for light or electron microscopy^{31–36} (Anti-Lucifer Yellow Dye, Anti-Alexa Fluor® 405/Cascade Blue® Dye and Anti-Alexa Fluor® 488 Dye Antibodies—Note 14.1).

Intracellular injection of lucifer yellow CH has been extensively employed to delineate neuronal morphology in live neurons^{37–39} (Figure 14.3.6) and in fixed brain slices,³¹ as well as to investigate intercellular communication through gap junctions.^{40–42} Lucifer yellow CH can also be used to label neurons by using dye-filled electrodes during electrophysiological recording in order to correlate neuronal function with structure and connectivity.

Other Lucifer Yellow Derivatives

Like lucifer yellow CH, lucifer yellow ethylenediamine (A1339) is fixable with standard aldehyde-based fixatives and can be used as a building block for new lucifer yellow derivatives.⁴³ The thiol-reactive lucifer yellow iodoacetamide (L1338) can also be used as a microinjectable polar tracer, as well as for preparing fluorescent liposomes⁴⁴ and for detecting the accessibility of thiols in membrane-bound proteins.^{45–47} In addition to these lucifer yellow derivatives, we offer a lucifer yellow-conjugated 10,000 MW dextran (D1825, Section 14.5).

Cascade Blue® Hydrazide

Molecular Probes® Cascade Blue® hydrazide is a fixable analog of the nonfixable, bright blue-fluorescent tracer methoxypyrenetrisulfonic acid⁴⁸ (MPTS). All of the Cascade Blue® hydrazide derivatives have

Figure 14.3.4 Alexa Fluor® 350 hydrazide, sodium salt (A10439).

Figure 14.3.5 Lucifer yellow CH, lithium salt (L453).

Figure 14.3.6 Cultured left-upper quadrant neurons from *Aplysia californica* that have been microinjected with either lucifer yellow CH (L453, L682, L1177, L12926) or sulforhodamine 101 (S359). These neurons display an extensive array of overlapping processes (J Neurophysiol (1991) 66:316). Image contributed by David Kleinfeld, AT&T Bell Laboratories, and Brian Salzberg, University of Pennsylvania School of Medicine.

Figure 14.3.7 Absorption spectra for equal concentrations of Cascade Blue® hydrazide (C687, C3221, C3239) and lucifer yellow CH (L453, L682, L1177, L12926) in water.

reasonable water solubility, ~1% for the sodium and potassium salts (C687, C3221) and ~8% for the lithium salt (C3239). They also exhibit a stronger absorption ($EC_{400} > 28,000 \text{ cm}^{-1}\text{M}^{-1}$) and quantum yield (~0.54 in water) than lucifer yellow CH. In addition, Cascade Blue® derivatives have good photostability and emissions that are well resolved from those of fluorescein and lucifer yellow CH.⁴⁹ Cascade Blue® hydrazide, which readily passes through gap junctions, and lucifer yellow derivatives can be simultaneously excited at 405 nm (Figure 14.3.7) for two-color detection at about 430 and 530 nm.⁵⁰ Cascade Blue® dyes, lucifer yellow CH and sulforhodamine 101 can be used in combination for three-color mapping of neuronal processes (Figure 14.3.8). We also offer anti-Alexa Fluor® 405/Cascade Blue® dye antibodies (Section 7.4) for localizing Cascade Blue® dye-filled cells following fixation (Anti-Lucifer Yellow Dye, Anti-Alexa Fluor® 405/Cascade Blue® Dye and Anti-Alexa Fluor® 488 Dye Antibodies—Note 14.1). Like lucifer yellow CH, Cascade Blue® hydrazide and some other polar tracers are taken up by plants and sequestered into their central vacuoles. In onion epidermal cells, this uptake of Cascade Blue® hydrazide is blocked by probenecid (P36400; Section 19.8), indicating that transfer may be through anion-transport channels.^{21,22}

Figure 14.3.8 Normalized fluorescence emission spectra for Cascade Blue® hydrazide (C687, C3221, C3239), lucifer yellow CH (L453, L682, L1177, L12926) and sulforhodamine 101 (S359) in water.

NOTE 14.2

Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents

Photoconversion of Diaminobenzidine

We offer a variety of fluorescent probes for photoconverting diaminobenzidine (DAB), enabling researchers to take advantage of an important development in correlated fluorescence, transmitted and electron microscopy. In 1982, Maranto first described the use of the fluorophore lucifer yellow for DAB photoconversion.¹ When a fluorophore is exposed to light of an appropriate wavelength, excitation from the electronic ground state to a higher singlet state occurs. Instead of emitting a photon, the excited state of the fluorophore may undergo intersystem crossing to the triplet state. Transfer of energy to ground state triplet oxygen ($^3\text{O}_2$) generates toxic and highly reactive singlet oxygen ($^1\text{O}_2$), which is capable of causing damage to lipids, proteins and nucleic acids.² However, the reactive potential of $^1\text{O}_2$ can also be harnessed to oxidize diaminobenzidine (DAB) into an electron-opaque osmiophilic precipitate within cells (Figure 1). The resulting DAB reaction product exhibits exceptionally uniform, nondiffusible staining properties, making it extremely useful for subsequent

Figure 1 Electron micrograph of an 80 nm-thick section of formaldehyde-fixed rat soleus muscle, which was first stained with eosin α -bungarotoxin and then used to photoconvert DAB into an insoluble osmiophilic polymer. Photo contributed by Thomas J. Deerinck, University of California, San Diego.

electron microscopy investigation of cellular ultrastructure.¹ Punctate background staining can reportedly be eliminated without affecting the DAB photoconversion signal by treating the sample with the peroxisomal catalase inhibitor aminotriazole.³

Eosin Probes

In 1994, Deerinck and colleagues reported a simple method for eosin-mediated photoconversion of DAB.^{4,5} Halogenated derivatives of fluorescein dyes are known to be effective photosensitizers and singlet oxygen generators.⁶ Eosin is a brominated analog of fluorescein that has a $^1\text{O}_2$ yield 19 times greater than fluorescein and is an excellent dye for photoconverting DAB.^{4,7} Furthermore, the small size of eosin promotes exceptional penetration into tissues resulting in increased resolution for electron microscopy.⁸ We offer amine- and thiol-reactive eosin derivatives for preparing eosin-labeled bioconjugates (Section 1.5, Section 2.2). Some other fluorescent tracers that have been used to photoconvert DAB include:⁹

- BODIPY® FL C₅-ceramide¹⁰ (D3521, B22650; Section 12.4)
- DiI^{11,12} (D282, Section 14.4)
- Fluorescent polystyrene microspheres¹³ (Section 6.5)
- Fluoro-ruby dextran¹⁴ (D1817, Section 14.5)
- Lucifer yellow¹⁵ (L453, L12926; Section 14.3)
- Propidium iodide¹⁶ (P1304MP, P3566, P21493; Section 8.1)
- ReAsH¹⁷ (T34562, Section 2.2)
- Texas Red®-X succinimidyl ester¹⁸ (T6134, Section 1.6)

Other Cascade Blue® and Alexa Fluor® 405 Derivatives

Cascade Blue® acetyl azide (C2284) and Alexa Fluor® 405 succinimidyl ester (A30000, A30100) are water-soluble, amine-reactive tracers that can be introduced either by microinjection or by fusion of dye-filled liposomes with cells. Once inside the cell, these derivatives will react with the amine groups of intracellular proteins. Cascade Blue® ethylenediamine (C621) and Alexa Fluor® 405 cadaverine (previously called Cascade Blue® cadaverine, A30675) are aldehyde-fixable fluorophores with reactive properties similar to those of the ethylenediamine derivative of lucifer yellow (A1339). A Cascade Blue® dye-labeled 10,000 MW dextran (D1976, Section 14.5) is also available.

Biocytin and Other Biotin Derivatives

Biocytin (ϵ -biotinoyl-L-lysine, B1592, Figure 14.3.9) and biotin ethylenediamine (A1593, Figure 14.3.10) are microinjectable anterograde and transneuronal tracers.^{51–54} Retrograde transport of biocytin and biotin ethylenediamine in neurons has also been reported.^{55,56} These water-soluble tracers are often used to label neurons during electrophysiological measurements in order to correlate neuronal function with structure and connectivity.^{57,58} Biotin cadaverine (A1594) and biotin-X cadaverine (B1596) have slightly longer spacers than their ethylenediamine counterparts, making the hapten more accessible to the deep biotin-binding site in avidins.^{59–61}

Biocytin, biotin ethylenediamine, biotin cadaverine and biotin-X cadaverine all contain primary amines and can therefore be fixed in cells with formaldehyde or glutaraldehyde and subsequently detected using fluorescent- or enzyme-labeled avidin or streptavidin second-step reagents or with NANOGOLD® and Alexa Fluor® FluoroNanogold™ streptavidin⁶² (Section 7.6). Biocytin hydrazide (B1603) and DSB-X™ biotin hydrazide (D20653) can serve as aldehyde-fixable tracers⁵⁷ and as reactive probes for labeling glycoproteins and nucleic acids (Section 4.2).

As with the reactive lucifer yellow, and Cascade Blue® and Alexa Fluor® 405 derivatives discussed above, amine- or thiol-reactive biotin derivatives are useful for intracellular labeling applications. The succinimidyl esters of biotin and biotin-X (B1513, B1582) have been used to trace retinal axons in avian embryos.⁶³ Because they are more water soluble, the *sulfosuccinimidyl* esters of biotin-X and biotin-XX (B6353, B6352) or the thiol-reactive biocytin maleimide (M1602) may be preferred for these applications.

Fluorescent Biotin Derivatives

Fluorescence of the finer processes of dye-filled neurons may fade rapidly or be obscured by the more intensely stained portions of the neuron, necessitating further amplification of the signal or other

ultrastructural detection methods. Lucifer yellow biocytin (L6950), Alexa Fluor® 488 biocytin (A12924), Alexa Fluor® 546 biocytin (A12923), Alexa Fluor® 594 biocytin (A12922), Oregon Green® 488 biocytin (O12920) and tetramethylrhodamine biocytin (T12921) each incorporate a fluorophore, biotin and an aldehyde-fixable primary amine into a single molecule, thus enabling researchers to amplify the signals of these tracers with fluorescent or enzyme-labeled avidin or streptavidin conjugates (Section 7.6). Although our lucifer yellow cadaverine biotin-X (L2601) lacks a primary amine, it was reported that this tracer was well retained in aldehyde-fixed tissues, even after sectioning, extraction with detergents and several washes.^{64,65} Because fluorescent biocytin derivatives contain free primary amines, they should be even more efficiently fixed by formaldehyde or glutaraldehyde.

Nonfixable Polar Tracers

Polar fluorescent dyes are commonly used to investigate fusion, lysis and gap-junctional communication and to detect changes in cell or liposome volume. These events are primarily monitored by following changes in the dye's fluorescence caused by interaction with nearby molecules. For example, because the fluorescence of many dyes at high concentrations is quenched, various processes that result in a dilution of the dyes, such as lysis or fusion of fluorescent dye-filled cells or liposomes, can produce an increase in fluorescence, thereby providing an easy method for monitoring these events. Cell-cell and cell-liposome fusion, as well as membrane permeability and transport through gap junctions, can all be monitored using these methods. Furthermore, a fluorogenic substrate such as fluorescein diphosphate (FDP, F2999; Section 10.3) can be incorporated within a cell or vesicle that lacks the enzymatic activity to generate a fluorescent product; subsequent fusion with a cell or vesicle that contains the appropriate enzyme will generate a fluorescent product.⁶⁶

An ultrasensitive fusion assay that can be used to follow fusion of single vesicles utilizes an almost nonfluorescent potassium salt of an ion-sensitive indicator such as fluo-3 (F1240, F3715; Section 19.3) in one vesicle and a polyvalent ion such as Ca^{2+} —or perhaps better La^{3+} , which causes greater enhancement of the fluorescence of fluo-3—in a second vesicle.⁶⁷

Fluorescein Derivatives

The self-quenching of fluorescein derivatives provides a means of determining their concentration in dynamic processes such as lysis or fusion of dye-filled cells or liposomes (Assays of Volume Change, Membrane Fusion and Membrane Permeability—Note 14.3). Calcein

Figure 14.3.9 ϵ -Biotinoyl-L-lysine (biocytin, B1592).

Figure 14.3.10 *N*-(2-aminoethyl)biotinamide, hydrobromide (biotin ethylenediamine, A1593).

NOTE 14.3**Assays of Volume Change, Membrane Fusion and Membrane Permeability Fusion**

Assays of membrane fusion report either the mixing or leakage of the aqueous contents of the fused entities (described here) or the mixing of membrane lipids (Lipid-Mixing Assays of Membrane Fusion—Note 13.1). Leakage of aqueous contents from cells or vesicles as a result of lysis, fusion or physiological permeability can be detected fluorometrically using low molecular weight soluble tracers. Assays designed to detect solution mixing often rely on a fluorophore and quencher pair, whereas assays that detect solution leakage into the external medium typically exploit the self-quenching properties of a fluorophore.

Fluorescence Quenching Assays with ANTS/DPX

Originally developed by Smolarsky and co-workers to follow complement-mediated immune lysis,¹ the ANTS/DPX fluorescence quenching assay has since been widely used to detect membrane fusion.² This assay is based on the collisional quenching of the polyanionic fluorophore ANTS by the cationic quencher DPX (Figure 1). Separate vesicle populations are loaded with 25 mM ANTS (A350) in 40 mM NaCl and 90 mM DPX (X1525).

Vesicle fusion results in quenching of ANTS fluorescence monitored at 530 nm, with excitation at 360 nm. External leakage of vesicle contents does not cause quenching due to the accompanying high dilution of ANTS and DPX. For assays of vesicle leakage, ANTS (12.5 mM) and DPX (45 mM) can be co-encapsulated into liposomes; upon dilution into surrounding medium, ANTS fluorescence will increase because quenching by DPX will be diminished.

Examples employing ANTS/DPX quenching include studies of the role of amino lipids³ and phospholipid asymmetry⁴ in membrane fusion; glycoprotein-mediated viral fusion with membranes;⁵ and the interactions of vesicle membranes with annexins,⁶ HIV fusion peptide⁷ and apolipoprotein.⁸

Additional Dye/Quencher Pairs

The fluorescence of HPTS and pyrenetetrasulfonic acid is also effectively quenched by DPX.^{9–11} Thallium (Tl⁺) and cesium (Cs⁺) ions quench the fluorescence of ANTS, pyranine (HPTS, H348), pyrenetetrasulfonic acid (P349) and some other polyanionic fluorophores. A review by Garcia¹² describes how fluorescence quenching with a variety of dye/quencher pairs can be used to determine transmembrane ion permeability.

Figure 1 Pictorial representation of the ANTS/DPX vesicle-fusion assay.

Fluorescence Enhancement Assays with Tb³⁺/DPA

In the Tb³⁺/dipicolinic acid (DPA) assay, which was originally described by Wilschut and Papahadjopoulos,^{13,14} separate vesicle populations are loaded with 2.5 mM TbCl₃ (T1247) in 50 mM sodium citrate, or 50 mM DPA in 20 mM NaCl.

Vesicle fusion results in formation of Tb³⁺/DPA chelates that are ~10,000 times more fluorescent than free Tb³⁺ (Figure 2). Fluorescence of the chelates is detected at 490 nm or 545 nm, with excitation at 276 nm. Including Ca²⁺ and EDTA in the external medium inhibits formation of the complex outside the fused vesicles. The Tb³⁺/DPA fluorescence enhancement assay has been used to investigate the role of phospholipid conformation in vesicle fusion¹⁵ and the interaction of cardiotoxin with phospholipid vesicles.¹⁶

Self-Quenching Assays with Fluorescein Derivatives

Fluorescence of carboxyfluorescein (C194, C1904) or calcein (C481) is >95% self-quenched at concentrations >100 mM. Concentrated solutions of these water-soluble dyes are encapsulated in liposomes, which are then separated from any remaining free dye by gel filtration. Upon addition of a fusogen or other permeabilizing agent, dye release is accompanied by an increase in fluorescence (excitation/emission maxima ~490 nm/520 nm). Complete lysis of the liposomes with 0.1% Triton® X-100 can be used to determine the assay endpoint. Calcein may be preferred over carboxyfluorescein because of higher net charge and lower pH sensitivity. Note that this assay will detect any process that causes leakage of aqueous contents, including fusion, lysis or permeabilization. In a modification of this assay designed to specifically detect vesicle fusion, a nonfluorescent Co²⁺ complex of calcein contained in a vesicle is disrupted upon fusion with a second vesicle that delivers EDTA, a chelator of Co²⁺.^{17,18} Studies employing carboxyfluorescein self-quenching include investigations of interactions of membranes with mycobacterial glycopeptidolipids¹⁹ and with HIV glycoprotein peptide fragments.²⁰

Figure 2 Pictorial representation of the terbium/dipicolinic acid (DPA) fluorescence enhancement assay for vesicle fusion.

Figure 14.3.11 Calcein (C481).

Figure 14.3.12 2,7'-Bis-(2-carboxyethyl)-5-(and-6)-carboxyfluorescein (BCECF acid, B1151).

Figure 14.3.13 Oregon Green® 488 carboxylic acid diacetate (carboxy-DFFDA, O6151).

Figure 14.3.14 Calcein, AM (C1430).

(C481)—a polyanionic fluorescein derivative that has about six negative and two positive charges at pH 7 (Figure 14.3.11)—as well as BCECF (B1151, Figure 14.3.12), carboxyfluorescein (C194, C1904), the 5-isomer of Oregon Green® 488 carboxylic acid (O6146) and fluorescein-5-(and 6-) sulfonic acid (F1130) are all soluble in water at >100 mM at pH 7. Unlike the other fluorescein derivatives, both calcein and Oregon Green® 488 carboxylic acid exhibit fluorescence that is essentially independent of pH between 6.5 and 12.

These green-fluorescent polar tracers are widely used for investigating:

- Cell volume changes in neurons and other cells^{68–71}
- Gap junctional communication^{72–74}
- Liposome formation, fusion and targeting^{75–78}
- Membrane integrity and permeability^{79–90}

Fluorescence of calcein (but not of carboxyfluorescein or fluorescein sulfonic acid) is strongly quenched by Fe^{3+} , Co^{2+} , Cu^{2+} and Mn^{2+} at physiological pH but not by Ca^{2+} or Mg^{2+} ions.⁹¹ Monitoring the fluorescence level of cells that have been loaded with calcein (or its AM ester, see below) may provide an easy means for following uptake of Fe^{3+} , Co^{2+} , Cu^{2+} , Mn^{2+} and certain other metals through ion channels.⁹² Increases in the internal volume of lipid vesicles and virus envelopes cause a decrease in Co^{2+} -induced quenching of calcein, a change that can be followed fluorometrically.⁹³ In addition, the Co^{2+} -quenched calcein complex is useful for both lysis and fusion assays⁹⁴ (Assays of Volume Change, Membrane Fusion and Membrane Permeability—Note 14.3). Calcein is a widely used reagent for following volume changes because its fluorescence is not particularly sensitive to either pH or physiological concentrations of other ions.⁶⁹

We prepare a high-purity grade of calcein (C481) that is generally >97% pure by HPLC. The chemical structure assigned to “calcein” in various literature references and by commercial sources has been inconsistent;^{95,96} our structure (Figure 14.3.11) has been confirmed by NMR spectroscopy, and we believe that several past assignments of other structures to calcein were incorrect. We also offer a high-purity grade of 5-(and 6-)carboxyfluorescein (C1904) that contains essentially no polar or nonpolar impurities that might alter transfer rates of the dye between vesicles and cells.⁹⁷

Cell-Permeant Fluorescein Derivatives

Cell-permeant versions of carboxyfluorescein, fluorescein sulfonic acid, calcein and the Oregon Green® dyes permit passive loading of cells (Section 15.2). Acid hydrolysis of nonfluorescent carboxyfluorescein diacetate (CFDA; C195, C1361, C1362; Section 15.2) to fluorescent carboxyfluorescein has been used to detect the fusion of dye-loaded clathrin-coated vesicles with lysosomes.⁹⁸ CFDA has also been used to investigate cell–cell communication in plant cells.^{99–101} A probenecid-inhibitable anion-transport mechanism permits loading of carboxyfluorescein diacetate and Oregon Green® 488 carboxylic acid diacetate (O6151, Figure 14.3.13; Section 15.2) into hyphal tip-cells of some fungi.¹⁰²

Calcein AM (Figure 14.3.14), but not the AM or acetate esters of BCECF or CFDA, is reported to differentially label lymphocytes, permitting their resolution into two populations based on fluorescence intensity, only one of which is taken up by lymphoid organs. This unique property makes calcein AM a useful probe for determining the lymph node homing potential of lymphocytes.¹⁰³

In an important technique for studying gap junctional communication, cells are simultaneously labeled with calcein AM (C1430, C3099, C3100MP) and DiI (D282, D3911, V22885; Section

Figure 14.3.15 A simple technique for the study of gap junctional communication. A population of cells is labeled simultaneously with DiI (D282, D3911) and calcein AM (C1430, C3099, C3100MP), and then mixed with an unlabeled cell population (A). The formation of gap junctions allows the cytosolic tracer calcein to cross into the unlabeled cell, while the membrane-bound DiI does not (B). Cells from the initial unlabeled population that have taken part in gap junctional communication will therefore display the green fluorescence of calcein while lacking the red-fluorescent signal of DiI.

14.4) and then mixed with unlabeled cells (Figure 14.3.15). When gap junctions are established, only the cytosolic calcein tracer (but not the DiI membrane probe) is transferred from the labeled cell to the unlabeled cell. Thus, after gap-junctional transfer, the initially unlabeled cells exhibit the green fluorescence of calcein but not the red fluorescence of DiI.^{73,104–107} This assay can be followed by either imaging or flow cytometry.¹⁰⁸ In addition, calcein AM and DiI have been combined for use in following cell fusion¹⁰⁹ and for analysis of cholesterol processing by macrophages following ingestion of apoptotic cells.¹¹⁰

Fluorescein Substitutes

Chapter 1 describes several of our proprietary green-fluorescent dyes that have exceptional optical properties, including our Alexa Fluor® 488 dye (Section 1.3), BODIPY® FL dye (Section 1.4) and Oregon Green® dyes (Section 1.5). Not only do these innovative fluorescein substitutes exhibit high quantum yields in aqueous solution, but the dyes are significantly more photostable than fluorescein (Figure 14.3.16) and their fluorescence is less sensitive to pH (Figure 14.3.17). Their greater photostability makes them the preferred green-fluorescent dyes for fluorescence microscopy. In addition to their membrane-permeant versions, which are described in Section 15.2, highly water-soluble derivatives of these fluorescein substitutes are available for use as polar tracers:

- Oregon Green® 514 carboxylic acid (O6138, Figure 14.3.18), which is highly photostable and has little pH sensitivity at near-neutral pH
- BODIPY® 492/515 disulfonic acid¹¹¹ (D3238), which has narrow spectral bandwidths and bright green, pH-independent fluorescence
- Carboxy-2',7'-dichlorofluorescein (C368), which has a lower pK_a than fluorescein

Sulforhodamines

Sulforhodamine 101 (S359, Figure 14.3.19) and sulforhodamine B (S1307, Figure 14.3.20) are orange- to red-fluorescent, very water-soluble sulfonic acid tracers with strong absorption and good photostability. Sulforhodamine 101—the precursor to reactive Texas Red® derivatives—has been the preferred red-fluorescent polar tracer for use in combination with lucifer yellow CH, carboxyfluorescein or calcein^{112–114} (Figure 14.3.6). Activity-dependent uptake of sulforhodamine 101 during nerve stimulation has been reported.^{115–119} Sulforhodamine 101 specifically labels astrocytes both *in vivo*¹²⁰ and in acute brain slice preparations.¹²¹ Labeling is accomplished by application of a sulforhodamine 101 solution (1–25 μM in artificial cerebrospinal fluid) to the tissue for 1–5 minutes and is stable for several hours.¹²⁰ This technique is particularly useful for cellular-context identification in conjunction with calcium imaging using Oregon Green® 488 BAPTA-1, fluo-4 and related fluorescent indicators^{122–125} (Section 19.3). Because it is chemically stable, can be prepared in high purity and has a fluorescence quantum yield of nearly 1.0, we have included sulforhodamine 101 in our Reference Dye Sampler Kit (R14782, Section 23.1), along with four other dyes whose spectra cover the visible wavelengths.

Sulforhodamine B is an alternative to sulforhodamine 101 for investigating neuronal morphology,^{126,127} preparing fluorescent liposomes,¹²⁸ studying cell–cell communications^{129,130} and labeling elastic and collagen fibers.¹³¹

Hydroxycoumarins

7-Hydroxycoumarin-3-carboxylic acid (H185) is a blue-fluorescent polar tracer (excitation/emission maxima of ~388/445 nm) with uses that complement those of calcein and the other green-fluorescent polar tracers.¹⁰⁶ The membrane-permeant AM ester of calcein blue (C1429, Section 15.2), another coumarin-based tracer, can be used for passive loading of cells.¹³²

Figure 14.3.20 Sulforhodamine B (S1307).

Figure 14.3.16 Comparison of photostability of green-fluorescent antibody conjugates. The following fluorescent goat anti-mouse IgG antibody conjugates were used to detect mouse anti-human IgG antibody labeling of human anti-nuclear antibodies in HEP-2 cells on prefixed test slides (INOVA Diagnostics Corp.): Oregon Green® 514 (O6383, ■), Alexa Fluor® 488 (A11001, ○), BODIPY® FL (B2752, △), Oregon Green® 488 (O6380, □) or fluorescein (F2761, ●). Samples were continuously illuminated and viewed on a fluorescence microscope using a fluorescein longpass filter set. Images were acquired every 5 seconds. For each conjugate, three data sets, representing different fields of view, were averaged and then normalized to the same initial fluorescence intensity value to facilitate comparison.

Figure 14.3.17 Comparison of pH-dependent fluorescence of the Oregon Green® 488 (●), carboxyfluorescein (○) and Alexa Fluor® 488 (□) fluorophores. Fluorescence intensities were measured for equal concentrations of the three dyes using excitation/emission at 490/520 nm.

Figure 14.3.21 8-Hydroxypyrene-1,3,6-trisulfonic acid, trisodium salt (HPTS; pyranine; H348).

Figure 14.3.22 Sternomastoid muscle fibers of a living mouse that have been transfected with YOYO[®]-1 dye-stained DNA (red) containing the *lacZ* reporter gene and then stained with β -galactosidase substrate fluorescein di- β -D-galactopyranoside (FDG, F1179). DNA stained with YOYO[®]-1 (Y3601) prior to implantation could still be localized 5 days after application. Fluorescence signals were visualized *in situ* by epifluorescence microscopy with a low-light level SIT camera and a computer imaging system. Image contributed by Peter van Mier, Washington University School of Medicine.

Figure 14.3.23 A zebrafish embryo that was injected with a 1% solution (in 0.2 M KCl) of DMNB-caged fluorescein 10,000 MW dextran at the two-cell stage and then allowed to grow for 19 hours. The posterior lateral line placode was then exposed to a 5-second pulse from an epifluorescence microscope fitted with a DAPI optical filter set. After 6 hours of further development, the labeled primordium has migrated caudally, away from the activation site. Image contributed by Walter K. Metcalfe, Institute of Neuroscience, University of Oregon.

Polysulfonated Pyrenes

HPTS (8-hydroxypyrene-1,3,6-trisulfonic acid, also known as pyranine, H348; Figure 14.3.21) is a unique pH-sensitive tracer. It fluoresces blue in acidic solutions and in acidic organelles,^{133–135} but fluoresces green in more basic organelles.¹³⁶ In addition to its use as a probe for proton translocation,^{137–140} HPTS has been employed for intracellular labeling of neurons¹⁴¹ and as a fluid-phase endocytic tracer in catecholamine-secreting PC12 rat pheochromocytoma cells.¹⁴² HPTS forms a nonfluorescent complex with the cationic quencher DPX (X1525), and several assays have been described that monitor the increase in HPTS fluorescence that occurs upon lysis or fusion of liposomes or cells containing this quenched complex^{135,143–145} (Assays of Volume Change, Membrane Fusion and Membrane Permeability—Note 14.3). HPTS has also been used as a viscosity probe in unilamellar phospholipid vesicles.¹⁴⁶

The pH-insensitive 8-aminopyrene-1,3,6-trisulfonic acid (APTS, A6257) and 1,3,6,8-pyrenetetrasulfonic acid (P349) are extremely soluble in water (>25%); they have been utilized as blue-fluorescent tracers.^{147–150} As with HPTS, the fluorescence of APTS and 1,3,6,8-pyrenetetrasulfonic acid is quenched by DPX^{135,144,151} (Assays of Volume Change, Membrane Fusion and Membrane Permeability—Note 14.3) and by the cationic spin label CAT 1¹⁵² (T506, see below). These quenched-fluorophore complexes are useful for following lysis of cells and liposomes.

ANTS-DPX

The polyanionic dye ANTS (A350) is often used in combination with the cationic quencher DPX (X1525) for membrane fusion or permeability assays, including complement-mediated immune lysis¹⁵³ (Assays of Volume Change, Membrane Fusion and Membrane Permeability—Note 14.3). Thallium (Tl⁺) and cesium (Cs⁺) ions quench the fluorescence of ANTS, pyrenetetrasulfonic acid and some other polyanionic fluorophores.^{154,155} A review by Garcia¹⁴⁸ describes how this quenching effect can be utilized to determine transmembrane ion permeability. The unusually high Stokes shift of ANTS in water (>150 nm) separates its emission from much of the autofluorescence of biological samples. An approximately 4-fold enhancement of the quantum yield of ANTS is induced by D₂O—a spectral characteristic that has been used to determine water permeability in red blood cell ghosts and kidney collecting tubules.^{156,157} ANTS has also been employed as a neuronal tracer.¹⁴¹

Lanthanide Chelates

Terbium ion (Tb³⁺ from TbCl₃, T1247) forms a chelate with dipicolinic acid (DPA) that is ~10,000 times more fluorescent than free Tb³⁺. Fusion of vesicles that have been separately loaded with DPA and Tb³⁺ results in enhanced fluorescence, providing the basis for liposome fusion assays (Assays of Volume Change, Membrane Fusion and Membrane Permeability—Note 14.3). The fluorescence emission spectrum of the Tb³⁺/DPA complex exhibits two sharp spectral peaks at 491 nm and 545 nm and a lifetime of several milliseconds. Because DPA is a major constituent of bacterial spores, Tb³⁺/DPA complex luminescence provides a straightforward yet sensitive method for their detection.^{158–160}

TOTO[®], YOYO[®] and SYTO[®] Nucleic Acid Stains

Our high-affinity nucleic acid stains, including TOTO[®]-1 and YOYO[®]-1 (T3600, Y3601; Chapter 8), form tight complexes with nucleic acids with slow off-rates for release of the dye. Consequently, nucleic acids that have been prelabeled with these dyes can be traced in cells following microinjection or during gene transfer^{161–163} (Figure 14.3.22). The cell-to-cell transport via plasmodesmata of TOTO[®]-1 dye-labeled RNA, single-stranded DNA and double-stranded DNA has been determined following microinjection of the labeled nucleic acids into plant cells.^{164–167}

Khoobehi and Peyman have demonstrated the use of our cell-permeant SYTO[®] nucleic acid stains as ophthalmological tracers of blood flow. White blood cells were passively loaded with the green-fluorescent SYTO[®] 16 dye (S7578, Section 8.1) or the red-fluorescent SYTO[®] 59 dye (S11341, Section 8.1). Red blood cell membranes were labeled with DiD (D307, Section 14.4). By using an argon-ion laser to excite SYTO[®] 16 and a red light-emitting He-Ne laser to excite both SYTO[®] 59 and DiD, they were able to follow the relative mobility of the two types of blood cells.¹⁶⁸

Caged Fluorescent Dye Tracers

UV photolysis of photoactivatable fluorescent dyes provides a means of controlling—both spatially and temporally—the release of fluorescent tracers (Section 5.3). Thus, caged dyes enable researchers to follow the movement of individual molecules and cellular structures,^{169–171} as well as to study cell lineage in live organisms (Figure 14.3.23). CMNB-caged fluorescein^{172,173} (F7103, Figure 14.3.24) is colorless and nonfluorescent until it is photolyzed at <365 nm to the intensely green-fluorescent free dye. Movement of the liberated fluorophore from the site of photolysis can then be followed. The succinimidyl ester of CMNB-caged carboxyfluorescein (C20050, Section 1.5), which is water soluble at pH 7, is useful for preparation of other caged dye tracers, including those of proteins.

Fluorescent Retrograde Tracers

Anterograde and retrograde tracing of neurons has utilized a wide variety of fluorescent and nonfluorescent probes¹⁷⁴ (Figure 14.3.25). Among the retrograde and anterograde tracers are biotin derivatives and polar fluorescent dyes (described in this section), lipophilic tracers such as DiI (D282, Section 14.4), dextran conjugates (Section 14.5), fluorescent microspheres (Section 14.6) and protein conjugates, including lectins (Section 14.7).

True Blue and Nuclear Yellow

The popular retrograde tracer true blue (T1323) is a UV light–excitable, divalent cationic dye that stains the cytoplasm with blue fluorescence.^{175–179} For two-color neuronal mapping, true blue has been combined with longer-wavelength tracers such as nuclear yellow^{175,180–182} (Hoechst S769121, N21485) or diamidino yellow,^{183–186} which primarily stain the neuronal nucleus with yellow fluorescence (Figure 14.3.26, Figure 14.3.27, Figure 14.3.28). Fluorescent microspheres have also been used as a counterstain with true blue.¹⁸⁷ True blue is reported to be a less cytotoxic retrograde tracer than Fluoro-Gold[™] and to be a more efficient retrograde tracer than diamidino yellow.¹⁷⁷ Both true blue and nuclear yellow are stable when subjected to immunohistochemical processing and can be used to photoconvert DAB into an insoluble, electron-dense reaction product.^{28,188,189}

Figure 14.3.24 Fluorescein bis-(5-carboxymethoxy-2-nitrobenzyl) ether, dipotassium salt (CMNB-caged fluorescein, F7103).

Figure 14.3.25 Structural schematic of a neuron indicating the directions of retrograde and anterograde transport.

Figure 14.3.26 Capillaries in the hippocampal region of a mouse brain cryosection were visualized with the green-fluorescent Alexa Fluor[®] 488 conjugate of lectin HPA from *Helix pomatia* (L11271), which specifically binds to type A erythrocytes and *N*-acetylgalactosaminyl residues. The nuclei were counterstained with nuclear yellow (N21485). The multiple-exposure image was acquired using a DAPI longpass filter set and a filter set appropriate for fluorescein.

Figure 14.3.27 A binucleate bovine pulmonary artery endothelial cell labeled with the biotin-XX conjugate of anti- α -tubulin antibody (A21371) and Alexa Fluor[®] 568 streptavidin (S11226), then counterstained with nuclear yellow (N21485).

Figure 14.3.28 Neurons in a mouse cerebellum section labeled with NeuroTrace[®] 530/615 red-fluorescent Nissl stain (N21482). The Nissl substance, ribosomal RNA associated with the rough endoplasmic reticulum, is specific to neuronal cells. Other cells in the sample are identified with the contrasting nuclear counterstain nuclear yellow (N21485). Smaller neurons appear to be labeled primarily with the nuclear yellow stain. This image is a composite of two micrographs acquired using a DAPI longpass filter set and a filter set appropriate for tetramethylrhodamine.

Figure 14.3.29 Hydroxystilbamidine, methanesulfonate (H22845).

Figure 14.3.30 Aminostilbamidine, methanesulfonate (A22850).

Hydroxystilbamidine and Aminostilbamidine

Hydroxystilbamidine methanesulfonate (H22845, Figure 14.3.29) was originally developed as a trypanocide and has been identified by Wessendorf¹⁹⁰ as the active component of a dye that was named Fluoro-Gold™ by Schmued and Fallon¹⁹¹ and later sold for retrograde tracing by Fluorochrome, Inc. The use of hydroxystilbamidine as a histochemical stain and as a retrograde tracer for neurons apparently goes back to the work of Snapper and collaborators in the early 1950s who, while studying the effects of hydroxystilbamidine on multiple myeloma, showed that therapeutically administered hydroxystilbamidine gives selective staining of ganglion cells.^{192,193} The comprehensive article by Wessendorf¹⁹⁰ also describes several other early applications of hydroxystilbamidine that do not include its therapeutic uses:

- As an AT-selective, nonintercalating nucleic acid stain for discriminating between DNA and RNA^{194–196} (Section 8.1)
- For histochemical staining of DNA, mucosubstances and elastic fibers, as well as mast cells¹⁹⁷
- As a ribonuclease inhibitor¹⁹⁸
- For lysosomal staining of live cells^{199–204} (Section 12.3)

The weakly basic properties of hydroxystilbamidine that result in its uptake by lysosomes are reportedly important for its mechanism of retrograde transport.^{190,199} We developed a product that we called hydroxystilbamidine (formerly catalog number H7599) in April 1995; however, we subsequently discovered that the chemical structure of our original “hydroxystilbamidine” corresponded to a novel dye that we now call aminostilbamidine (A22850, Figure 14.3.30). Apparently, aminostilbamidine functions at least as well as authentic hydroxystilbamidine as a tracer.²⁰⁵ Aminostilbamidine, however, does not show the spectral shifts with DNA and RNA that are observed with authentic hydroxystilbamidine.

Propidium Iodide and DAPI for Retrograde Tracing

A variety of other low molecular weight dyes have been used as fluorescent retrograde neuronal tracers.^{206,207} These include propidium iodide^{208,209} (P1304MP, P21493) and DAPI.^{210,211} Both propidium iodide and DAPI can be used to photoconvert DAB into an insoluble, electron-dense product.^{28,212} The lactate salt of DAPI (D3571) has much higher water solubility than the chloride salt (D1306, D21490), making it the preferred form for microinjection.

NeuroTrace® Fluorescent Nissl Stains

The Nissl substance, described by Franz Nissl more than 100 years ago, is unique to neuronal cells.²¹³ Composed of an extraordinary amount of rough endoplasmic reticulum, the Nissl substance reflects the unusually high protein synthesis capacity of neuronal cells. Various fluorescent or chromophoric “Nissl stains” have been used for this counterstaining, including acridine orange,²¹⁴ ethidium bromide,²¹⁴ neutral red (N3246, Section 15.2), cresyl violet,²¹⁵ methylene blue, safranin-O and toluidine blue-O.²¹⁶ We have developed five fluorescent Nissl stains

Table 14.2 Fluorescence characteristics of NeuroTrace® fluorescent Nissl stains.

Cat. No.	Fluorescent Color	Ex *	Em *	Signal Using Various Filter Sets †				
				405 ± 20	485 ± 11	510 ± 11.5	560 ± 20	640 ± 10
				445	505	540	590	660
				≥450	535 ± 17.5	≥550	610 ± 10	682 ± 11
N21479	Blue	435	455	+++	+	–	–	–
N21480	Green	500	525	–	+++	+++	–	–
N21481	Yellow	515	535	–	+++	+++	+++	–
N21482	Red	530	615	–	–	++	+++	–
N21483	Deep red	640	660	–	–	–‡	–	++

* Approximate fluorescence excitation (Ex) and emission (Em) maxima, in nm. † Spectral characteristics in nm of the excitation filter, dichroic mirror and emission filter are shown top to bottom for each filter set. Relative signal strength for each filter combination is indicated with pluses and minuses. ‡ High background fluorescence.

(Table 14.2) that not only provide a wide spectrum of fluorescent colors for staining neurons, but also are far more sensitive than the conventional dyes:

- NeuroTrace® 435/455 blue-fluorescent Nissl stain (N21479, Figure 14.3.31)
- NeuroTrace® 500/525 green-fluorescent Nissl stain (N21480; Figure 14.3.32, Figure 14.3.33, Figure 14.3.34)
- NeuroTrace® 515/535 yellow-fluorescent Nissl stain (N21481, Figure 14.3.35)
- NeuroTrace® 530/615 red-fluorescent Nissl stain (N21482; Figure 14.3.28, Figure 14.3.36)
- NeuroTrace® 640/660 deep red-fluorescent Nissl stain (N21483)

In addition, the Nissl substance redistributes within the cell body in injured or regenerating neurons. Therefore, these Nissl stains can also act as markers for the physiological state of the neuron. Staining by the Nissl stains is eliminated by pretreatment of tissue specimens

with RNase; however, these dyes are not specific stains for RNA in solutions. The strong fluorescence (emission maximum ~515–520 nm) of NeuroTrace® 500/525 green-fluorescent Nissl stain (N21480) makes it the preferred dye for use as a counterstain in combination with orange- or red-fluorescent neuroanatomical tracers such as Dil²¹⁷ (D282, D3911, V22885; Section 14.4; Figure 14.3.34).

Polar Spin Label

The highly water-soluble cationic spin label 4-trimethylammonium-2,2,6,6-tetramethylpiperidine-1-oxyl iodide (CAT 1, T506) has been used to:

- Quench fluorescent dyes in solutions, cells and cell membranes²¹⁸
- Detect oxygen gradients and oxidation–reduction properties of cells^{219–223}
- Study liposome permeability^{218,223}

Figure 14.3.31 Mouse brain section stained with NeuroTrace® 435/455 blue-fluorescent Nissl stain (N21479) and counterstained with nuclear yellow (N21485).

Figure 14.3.32 Pyramidal cells of the hippocampus and dentate gyrus in a transverse cryosection of formaldehyde-fixed mouse brain. NeuroTrace® green fluorescent Nissl stain (N21480) is localized to neuronal somata, while non-neuronal cells can be identified by the presence of DAPI-stained nuclei. This image is a composite of images taken using a 10x objective and filters appropriate for fluorescein and DAPI.

Figure 14.3.33 A mouse brain cryosection stained with the neuron-selective NeuroTrace® 500/525 green-fluorescent Nissl stain (N21480). The nuclei of the non-neuronal cells appear blue after incubation with the cell-permeant DNA counterstain, DAPI (D1306, D3571, D21490). The image is a composite of two micrographs acquired using filter sets appropriate for fluorescein and DAPI.

Figure 14.3.34 Neural somata from a mouse brain section labeled with NeuroTrace® 500/525 green-fluorescent Nissl stain (N21480). Nuclei are labeled with DAPI (D1306, D3571, D21490). Myelin and other lipophilic areas are illustrated with the aid of the red-orange fluorescence from CellTracker™ CM-Dil (C7000, C7001). The image is a composite of three micrographs acquired using filters appropriate for fluorescein, tetramethylrhodamine and DAPI.

Figure 14.3.35 Mouse brain section stained with NeuroTrace® 515/535 yellow-fluorescent Nissl stain (N21481) and counterstained with nuclear yellow (N21485).

Figure 14.3.36 Neural somata labeled with NeuroTrace® 530/615 red-fluorescent Nissl stain (N21482). Nuclei in this mouse cerebellum section were counterstained with DAPI (D1306, D3571, D21490). The image is a composite of two micrographs acquired using filters appropriate for tetramethylrhodamine and DAPI.

Figure 14.3.38 3T3 cells loaded with calcein (C481) using the Influx™ pinocytotic cell-loading reagent (I14402). The image was acquired using a fluorescence microscope equipped with a cooled CCD camera and a bandpass filter set appropriate for fluorescein.

Figure 14.3.39 Adherent CRE BAG 2 cells passively loaded with the membrane-impermeant polar tracer Alexa Fluor® 594 hydrazide (A10438, A10442). The image on top illustrates the relatively uniform, cytoplasmic labeling one can obtain with the Influx™ pinocytotic cell-loading reagent (I14402), compared to the punctate labeling that results from pinocytotic uptake in normal growth medium (bottom). Both images were acquired using a bandpass filter set appropriate for rhodamine dyes.

Signal Amplification of Polar Tracers

Polar tracers such as Cascade Blue® hydrazide, lucifer yellow CH, Alexa Fluor® 488 hydrazide and biocytin penetrate even the finest structures of neurons and other cells; however, as the thickness of the sample is decreased, the fluorescence signal is reduced. Consequently, it may be necessary to further amplify the signal by secondary detection methods.

We provide rabbit polyclonal antibodies to the Alexa Fluor® 488, Alexa Fluor® 405/Cascade Blue®, lucifer yellow, fluorescein, BODIPY® FL, tetramethylrhodamine and Texas Red® fluorophores (Section 7.4, Table 7.8) and a vast number of dye- or enzyme-labeled anti-rabbit antibodies (Section 7.2, Table 7.1). Our polyclonal and monoclonal antibodies to fluorescein cross-react strongly with the Oregon Green® dyes and somewhat with Rhodamine Green™ fluorophores, and our anti-tetramethylrhodamine and anti-Texas Red® antibodies cross-react with tetramethylrhodamine, Lissamine rhodamine B, Rhodamine red and Texas Red® dyes.

Our Tyramide Signal Amplification (TSA™) Kits (Section 6.2, Table 6.1) can also be utilized to detect aldehyde-fixed biotin derivatives or, in combination with antibodies to aldehyde-fixed fluorophore-labeled polar tracers, to further amplify the signal. Following fixation, biotinylated tracers such as biocytin and biotin ethylenediamine, can be detected using the reagents in our TSA™ Kits that contain horseradish peroxidase streptavidin and a fluorescent tyramide.

The relatively small size and easy penetration into tissues makes the streptavidin conjugates of the NANOGOLD®, Alexa Fluor® 488 FluoroNanogold™ and Alexa Fluor® 594 FluoroNanogold™ 1.4 nm gold clusters (N24918, A24926, A24927; Section 7.6) useful for ultrastructural studies of biotinylated tracers, particularly in combination with the LI Silver (LIS) Enhancement Kit (L24919, Section 7.2). Biotinylated polar tracers can also be detected with light microscopy using the Diaminobenzidine (DAB) Histochemistry Kit #3 (D22187, Section 6.2).

Influx™ Pinocytotic Cell-Loading Reagent

Our Influx™ pinocytotic cell-loading reagent (I14402) works via a rapid and simple technique based on the osmotic lysis of pinocytotic vesicles, an approach introduced by Okada and Rechsteiner.¹⁹ The probe is simply mixed at high concentration with the Influx™ reagent blended into growth medium, then incubated with live cells to allow pinocytotic uptake of the surrounding solution. Subsequent transfer of the cells to a slightly hypotonic medium results in bursting of the pinocytotic vesicles within the cells and the release of the probe into the cytosol (Figure 14.3.37, Figure 14.3.38, Figure 14.3.39).

The Influx™ pinocytotic cell-loading reagent is highly effective for loading a diverse array of probes—including calcein (Figure 14.3.38), Alexa Fluor® hydrazides (Figure 14.3.39), dextran conjugates of fluorophores²²⁴ and ion indicators (Figure 14.3.40), fura-2 salts, Oregon Green® 514 dye-labeled tubulin, Alexa Fluor® 488 dye-labeled actin, heparin, hydroxyurea,²²⁵ DNA, oligonucleotides,²²⁶ and Qdot® nanocrystals^{227,228}—into a variety of cell lines.

Figure 14.3.37 Principle of the Influx™ reagent pinocytotic cell-loading method (I14402). Cultured cells are placed in hypertonic Influx™ loading reagent (A), along with the material to be loaded into the cells (yellow fluid, B), allowing the material to be carried into the cells via pinocytotic vesicles. When the cells are placed in hypotonic medium, the pinocytotic vesicles burst (C), releasing their contents into the cytosol (D).

We (or other researchers) have successfully tested the reagent and loading method with:

- Bovine pulmonary artery endothelial cells (BPAEC)
- Human epidermoid carcinoma cells (A431)
- Human T-cell leukemia cells (Jurkat)
- Murine fibroblasts (NIH 3T3 and CRE BAG 2)
- Murine monocyte-macrophages (RAW264.7 and J774A.1)
- Murine myeloma cells (P3x63AG8)
- Rat basophilic leukemia cells (RBL)

More than 80% of the cells remained viable, as determined by subsequent exclusion of propidium iodide.

In addition to the Influx™ pinocytic cell-loading reagent and cell growth medium, all that is required to perform the loading procedure is sterile deionized water and the fluorescent probe or other polar molecule of interest. Cell labeling can be accomplished in a single 30-minute loading cycle and may be enhanced by repetitive loading. Although most types of cells load quickly and easily, optimal conditions for loading must be determined for each cell type. It is also important to note that cell-to-cell variability in the degree of loading is typical (Figure 14.3.39) and that higher variability is generally observed when using large compounds, such as >10,000 MW dextrans and proteins.

The Influx™ pinocytic cell-loading reagent is packaged as a set of 10 tubes (I14402), each containing sufficient material to load 50 samples of cells grown on coverslips following the protocol provided. Cells in suspension or in culture flasks may also be easily loaded; however, the number of possible cell loadings will depend on the cell suspension volume or size of culture flask used. The information provided with the Influx™ reagent includes general guidelines and detailed suggestions for optimizing cell loading. Use of the custom coverslip mini-rack or coverslip maxi-rack (C14784, C24784; Section 23.1) facilitates cell loading and slide handling when using the Influx™ reagent.

Loading P2X₇ Receptor–Expressing Cells

P2X₇ receptor–expressing cells such as macrophages and thymocytes exhibit reversible pore opening that can be exploited to provide an entry pathway for intracellular loading of both cationic and anionic fluorescent dyes with molecular weights of up to 900 daltons.^{18,229–231} Pore opening is induced by treatment with 5 mM ATP for five minutes and subsequently reversed by addition of divalent cations (Ca²⁺ or Mg²⁺). Dyes that have been successfully loaded into macrophage cells by this method include:

- Ca²⁺ indicator: fura-2 (F1200, F6799; Section 19.2)
- pH indicator: HPTS (H348)
- Aqueous tracers: lucifer yellow CH (L453, L682, L1177, L12926) and 6-carboxyfluorescein (C1360, Section 1.5)
- Nucleic acid stain: YO-PRO®-1 (Y3603, Section 8.1)

One of the most potent and widely used P2X receptor agonists, BzBzATP (2'-(or 3')-O-(4-benzoylbenzoyl)adenosine 5'-triphosphate, B22358; Section 17.3), is available.^{232,233} BzBzATP has more general applications for site-directed irreversible modification of nucleotide-binding proteins via photoaffinity labeling;^{234,235} see Section 17.3 for more information on our nucleotide analogs.

Figure 14.3.40 Adherent 3T3 fibroblasts labeled with 3000 MW Texas Red® dextran (D3329) and 70,000 MW Calcium Green™-1 dextran (C3714). Both dextrans were loaded into the fibroblasts using the Influx™ pinocytic cell-loading reagent (I14402). The images were acquired using a fluorescence microscope equipped with a cooled CCD camera and bandpass filter sets appropriate for either the Texas Red® dye (top image) or fluorescein (bottom image). The center image represents a composite of the cells labeled with both dextrans. The 3000 MW Texas Red® dextran is distributed throughout the cell, but the 70,000 MW Calcium Green™-1 dextran is excluded from the nucleus by the nuclear membrane.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Maximum solubility in water is ~8% for A10437 and A10438.
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- The Alexa Fluor® 405 and Cascade Blue® dyes have a second absorption peak at about 376 nm with EC ~80% of the 395–400 nm peak.
- This sulfonated succinimidyl ester derivative is water-soluble and may be dissolved in buffer at ~pH 8 for reaction with amines. Long-term storage in water is NOT recommended due to hydrolysis.
- A30100 is an alternative packaging of A30000 but is otherwise identical.
- Aqueous stock solutions should be used within 24 hours; long-term storage is NOT recommended.
- The fluorescence lifetime (τ) of the Alexa Fluor® 488 dye in pH 7.4 buffer at 20°C is 4.1 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
- Abs and Em of the Alexa Fluor® 488 dye are red-shifted by as much as 16 nm and 25 nm respectively on microarrays relative to aqueous solution values. The magnitude of the spectral shift depends on the array substrate material. (Biotechniques (2005) 38:127)
- Absorption and fluorescence of fluorescein derivatives are pH-dependent. Extinction coefficients and fluorescence quantum yields decrease markedly at pH <7.
- Absorption and fluorescence of dichlorofluorescein derivatives are pH-dependent. Extinction coefficients and fluorescence quantum yields decrease markedly at pH <5.
- C481 fluorescence is strongly quenched by micromolar concentrations of Fe³⁺, Co²⁺, Ni²⁺ and Cu²⁺ at pH 7. (Am J Physiol (1995) 268:C1354, J Biol Chem (1999) 274:13375)
- K_d(Co²⁺) for calcein is 120 nM, determined in 10 mM HEPES, 1 μM Ca²⁺, 1 mM Mg²⁺, 100 mM KCl. (Anal Biochem (1997) 248:31)
- Maximum solubility in water is ~1% for C687, ~1% for C3221 and ~8% for C3239.
- Calcein AM is converted to fluorescent calcein (C481) after acetoxymethyl ester hydrolysis.
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- Unstable in water. Use immediately.
- The absorption and fluorescence spectra of BODIPY® derivatives are relatively insensitive to the solvent.
- The dissociation constant (K_d) for desthiobiotin binding to streptavidin is 1.9 nM. (Bioconjug Chem (2006) 17:366)
- All photoactivatable probes are sensitive to light. They should be protected from illumination except when photolysis is intended.
- This product is colorless and nonfluorescent until it is activated by ultraviolet photolysis. Photoactivation generates a fluorescein derivative with spectral characteristics similar to C1359.
- Spectra of hydroxycoumarins are pH-dependent. Below the pK_a (~7.5), Abs shifts to shorter wavelengths (325–340 nm) and fluorescence intensity decreases.
- H348 spectra are pH-dependent.
- Hydroxystilbamidine in H₂O has a wide emission bandwidth, with a second peak at ~600 nm.
- The fluorescence quantum yield of lucifer yellow CH in H₂O is 0.21. (J Am Chem Soc (1981) 103:7615)
- Maximum solubility in water is ~8% for L453, ~6% for L682 and ~1% for L1177.
- Iodoacetamides in solution undergo rapid photodecomposition to unreactive products. Minimize exposure to light prior to reaction.
- Maximum solubility for M395 in water is ~25%.
- This product is essentially nonfluorescent except when bound to DNA or RNA.
- The active ingredient of this product is an organic dye with MW <1000. The exact MW and extinction coefficient values for this dye are proprietary.
- Absorption and fluorescence of Oregon Green® 514 derivatives are pH-dependent only in moderately acidic solutions (pH <5).
- AbXsorption and fluorescence of Oregon Green® 488 derivatives are pH-dependent only in moderately acidic solutions (pH <5).
- S1129 is converted to a fluorescent product (F1130) after acetate hydrolysis.
- Absorption and luminescence of T1247 are extremely weak unless it is chelated. Data are for dipicolinic acid (DPA) chelate. The luminescence spectrum has secondary peak at 490 nm.
- MW is for the hydrated form of this product.

PRODUCT LIST 14.3 POLAR TRACERS

Cat. No.	Product	Quantity
A12924	Alexa Fluor® 488 biocytin, disodium salt (biocytin Alexa Fluor® 488)	250 μg
A12923	Alexa Fluor® 546 biocytin, sodium salt (biocytin Alexa Fluor® 546)	250 μg
A12922	Alexa Fluor® 594 biocytin, sodium salt (biocytin Alexa Fluor® 594)	250 μg
A30675	Alexa Fluor® 405 cadaverine, trisodium salt	1 mg
A30627	Alexa Fluor® 350 C ₅ -aminoxyacetamide, trifluoroacetate salt (Alexa Fluor® 350 hydroxylamine)	1 mg
A30629	Alexa Fluor® 488 C ₅ -aminoxyacetamide, bis(triethylammonium) salt (Alexa Fluor® 488 hydroxylamine)	1 mg
A30632	Alexa Fluor® 647 C ₅ -aminoxyacetamide, bis(triethylammonium) salt (Alexa Fluor® 647 hydroxylamine)	1 mg
A30000	Alexa Fluor® 405 carboxylic acid, succinimidyl ester	1 mg
A30100	Alexa Fluor® 405 carboxylic acid, succinimidyl ester	5 mg
A10439	Alexa Fluor® 350 hydrazide, sodium salt	5 mg
A10436	Alexa Fluor® 488 hydrazide, sodium salt	1 mg
A20501MP	Alexa Fluor® 555 hydrazide, tris(triethylammonium) salt	1 mg
A10437	Alexa Fluor® 568 hydrazide, sodium salt	1 mg
A10441	Alexa Fluor® 568 hydrazide, sodium salt *for microinjection* *10 mM in 200 mM KCl*	125 μL
A10438	Alexa Fluor® 594 hydrazide, sodium salt	1 mg
A10442	Alexa Fluor® 594 hydrazide, sodium salt *for microinjection* *10 mM in 200 mM KCl*	125 μL
A30634	Alexa Fluor® 633 hydrazide, bis(triethylammonium) salt	1 mg
A20502	Alexa Fluor® 647 hydrazide, tris(triethylammonium) salt	1 mg
A350	8-aminonaphthalene-1,3,6-trisulfonic acid, disodium salt (ANTS)	1 g
A1339	N-(2-aminoethyl)-4-amino-3,6-disulfo-1,8-naphthalimide, dipotassium salt (lucifer yellow ethylenediamine)	25 mg
A1593	N-(2-aminoethyl)biotinamide, hydrobromide (biotin ethylenediamine)	25 mg

PRODUCT LIST 14.2 POLAR TRACERS—continued

Cat. No.	Product	Quantity
A1340	<i>N</i> -(5-aminopentyl)-4-amino-3,6-disulfo-1,8-naphthalimide, dipotassium salt (lucifer yellow cadaverine)	25 mg
A1594	<i>N</i> -(5-aminopentyl)biotinamide, trifluoroacetic acid salt (biotin cadaverine)	25 mg
A6257	8-aminopyrene-1,3,6-trisulfonic acid, trisodium salt (APTS)	10 mg
A22850	aminostilbamidine, methanesulfonate	10 mg
B1592	biocytin (ϵ -biotinoyl-L-lysine)	100 mg
B1603	biocytin hydrazide	25 mg
B10570	biotin-4-fluorescein	5 mg
B1596	biotin-X cadaverine (5-((<i>N</i> -(biotinoyl)amino)hexanoyl)amino)pentylamine, trifluoroacetic acid salt)	10 mg
B1582	6-((biotinoyl)amino)hexanoic acid, succinimidyl ester (biotin-X, SE; biotinamidocaproate, <i>N</i> -hydroxysuccinimidyl ester)	100 mg
B6353	6-((biotinoyl)amino)hexanoic acid, sulfosuccinimidyl ester, sodium salt (Sulfo-NHS-LC-Biotin; biotin-X, SSE)	25 mg
B6352	6-((6-((biotinoyl)amino)hexanoyl)amino)hexanoic acid, sulfosuccinimidyl ester, sodium salt (biotin-XX, SSE)	25 mg
B1370	5-((<i>N</i> -(5-((<i>N</i> -(6-((biotinoyl)amino)hexanoyl)amino)pentyl)thioiureidyl)fluorescein (fluorescein biotin)	5 mg
B1513	D-biotin, succinimidyl ester (succinimidyl D-biotin)	100 mg
B1151	2,7'-bis-(2-carboxyethyl)-5-(and-6)-carboxyfluorescein (BCECF acid) *mixed isomers*	1 mg
C481	calcein *high purity*	100 mg
C1430	calcein, AM	1 mg
C3099	calcein, AM *1 mg/mL solution in anhydrous DMSO*	1 mL
C3100MP	calcein, AM *special packaging*	20 x 50 μ g
C368	5-(and-6)-carboxy-2,7'-dichlorofluorescein *mixed isomers*	100 mg
C1904	5-(and-6)-carboxyfluorescein (5(6)-FAM) *FluoroPure™ grade* *mixed isomers*	100 mg
C194	5-(and-6)-carboxyfluorescein *mixed isomers*	5 g
C2284	Cascade Blue® acetyl azide, trisodium salt	5 mg
C621	Cascade Blue® ethylenediamine, trisodium salt	10 mg
C3239	Cascade Blue® hydrazide, trillithium salt	10 mg
C3221	Cascade Blue® hydrazide, tripotassium salt	10 mg
C687	Cascade Blue® hydrazide, trisodium salt	10 mg
D1306	4',6-diamidino-2-phenylindole, dihydrochloride (DAPI)	10 mg
D21490	4',6-diamidino-2-phenylindole, dihydrochloride (DAPI) *FluoroPure™ grade*	10 mg
D3571	4',6-diamidino-2-phenylindole, dilactate (DAPI, dilactate)	10 mg
D3238	4,4-difluoro-1,3,5,7,8-pentamethyl-4-bora-3a,4a-diaza-s-indacene-2,6-disulfonic acid, disodium salt (BODIPY® 492/515 disulfonate)	10 mg
D20653	DSB-X™ biotin hydrazide	5 mg
F7103	fluorescein bis-(5-carboxymethoxy-2-nitrobenzyl) ether, dipotassium salt (CMNB-caged fluorescein)	5 mg
F1130	fluorescein-5-(and-6)-sulfonic acid, trisodium salt	100 mg
H185	7-hydroxycoumarin-3-carboxylic acid *reference standard*	100 mg
H348	8-hydroxypyrene-1,3,6-trisulfonic acid, trisodium salt (HPTS; pyranine)	1 g
H22845	hydroxystilbamidine, methanesulfonate	10 mg
I14402	Influx™ pinocytic cell-loading reagent *makes 10 x 5 mL*	1 set
L6950	lucifer yellow biocytin, potassium salt (biocytin lucifer yellow)	5 mg
L2601	lucifer yellow cadaverine biotin-X, dipotassium salt	10 mg
L682	lucifer yellow CH, ammonium salt	25 mg
L453	lucifer yellow CH, lithium salt	25 mg
L12926	lucifer yellow CH, lithium salt *for microinjection* *100 mM in water*	100 μ L
L1177	lucifer yellow CH, potassium salt	25 mg
L1338	lucifer yellow iodoacetamide, dipotassium salt	25 mg
M1602	<i>N</i> ^ε -(3-maleimidylpropionyl)biotin	25 mg
N21479	NeuroTrace® 435/455 blue fluorescent Nissl stain *solution in DMSO*	1 mL
N21480	NeuroTrace® 500/525 green fluorescent Nissl stain *solution in DMSO*	1 mL
N21481	NeuroTrace® 515/535 yellow fluorescent Nissl stain *solution in DMSO*	1 mL
N21482	NeuroTrace® 530/615 red fluorescent Nissl stain *solution in DMSO*	1 mL
N21483	NeuroTrace® 640/660 deep-red fluorescent Nissl stain *solution in DMSO*	1 mL
O12920	Oregon Green® 488 biocytin (biocytin Oregon Green® 488)	5 mg
O6146	Oregon Green® 488 carboxylic acid *5-isomer*	5 mg
O6138	Oregon Green® 514 carboxylic acid	5 mg
P1304MP	propidium iodide	100 mg
P21493	propidium iodide *FluoroPure™ grade*	100 mg
P349	1,3,6,8-pyrenetetrasulfonic acid, tetrasodium salt	100 mg
S359	sulforhodamine 101	25 mg
S1307	sulforhodamine B	5 g
T1247	terbium(III) chloride, hexahydrate	1 g
T12921	5-(and-6)-tetramethylrhodamine biocytin (biocytin TMR)	5 mg
T506	4-trimethylammonium-2,2,6,6-tetramethylpiperidine-1-oxyl iodide (CAT 1)	100 mg
T1323	true blue chloride	5 mg
X1525	<i>p</i> -xylene-bis-pyridinium bromide (DPX)	1 g

14.4 Tracers for Membrane Labeling

Cell membranes provide a convenient conduit for loading live and fixed cells with lipophilic dyes. Not only can cells tolerate a high concentration of the lipophilic dye, but also lateral diffusion of the dye within the membrane can serve to stain the entire cell, even if the dye is applied locally. These properties have made lipophilic carbocyanine and aminostyryl dyes particularly important for anterograde and retrograde tracing in neuronal cells.^{1,2} Lipophilic tracers are used to label cells,^{3–5} organelles,^{6,7} liposomes,⁸ viruses⁹ and lipoproteins¹⁰ in a wide variety of long-term tracing applications, including cell transplantation, migration, adhesion and fusion studies. The distinguishing features of these carbocyanine and aminostyryl tracers are summarized in Table 14.3. Other lipophilic probes described in Chapter 13 have also been used as tracers for liposomes. For example, incorporation of a BODIPY® FL cholesterol

derivative (C3927MP, Section 13.3) in liposomes is virtually irreversible and the dye-labeled liposomes have been conjugated to antibodies for immunotargeting applications.¹¹

Long-Chain Carbocyanines: Dil, DiO and Analogs

Dil, DiO, DiD and DiR

The lipophilic carbocyanines DiI (DiIC₁₈(3), Figure 14.4.1), DiO (DiOC₁₈(3), Figure 14.4.2), DiD (DiIC₁₈(5), Figure 14.4.3) and DiR (DiIC₁₈(7), Figure 14.4.4) are weakly fluorescent in water but highly fluorescent and quite photostable when incorporated into membranes (Figure 14.4.5). They have extremely high extinction coefficients

Table 14.3 Summary of our lipophilic carbocyanine and aminostyryl tracers.

Cat. No.	Probe *	Features of Carbocyanine or Aminostyryl Tracers
Dil and Analogs		
D282	DiIC ₁₈ (3) "DiI"	Red-orange-fluorescent lipophilic probe; widely used as a neuronal tracer
D3911	DiIC ₁₈ (3) "DiI"	Large-crystal form of D282 to facilitate direct application of crystals to membranes
N22880	DiIC ₁₈ (3) "DiI"	NeuroTrace® Dil tissue-labeling paste
V22885	DiIC ₁₈ (3) "DiI"	Vybrant® Dil cell-labeling solution
D384	DiIC ₁₆ (3)	Shorter-chain Dil analog that may incorporate into membranes more easily than Dil
D383	DiIC ₁₂ (3)	Shorter-chain Dil analog that may incorporate into membranes more easily than Dil
D3899	FAST DiI™ oil	Unsaturated Dil analog that reportedly migrates ~50% faster than Dil within membranes
D7756	FAST DiI™	Solid form of D3899 to facilitate direct application of crystals to membranes
D3886	Δ ⁹ -Dil oil	Unsaturated Dil analog that may migrate faster than Dil within membranes
C7000 C7001	CellTracker™ CM-Dil	Chloromethylated Dil analog with enhanced solubility in culture medium; potentially retained after fixation and permeabilization
N22883	CellTracker™ CM-Dil	NeuroTrace® CM-Dil tissue-labeling paste
V22888	CellTracker™ CM-Dil	Vybrant® CM-Dil cell-labeling solution
D7777	SP-DiIC ₁₈ (3)	Anionic Dil analog with enhanced solubility in culture medium; potentially retained after fixation and permeabilization
D7776	DiIC ₁₈ (3)-DS	Anionic Dil analog with enhanced solubility in culture medium; potentially retained after fixation
DiD and Analogs		
D307	DiIC ₁₈ (5) oil "DiD"	Much longer-wavelength Dil analog; useful in autofluorescent samples and as a second tracer in combination with Dil
D7757	DiIC ₁₈ (5) "DiD"	Solid form of D307 to facilitate direct application of crystals to membranes
V22887	DiIC ₁₈ (5) "DiD"	Vybrant® DiD cell-labeling solution
D12730	DiIC ₁₈ (5)-DS	Anionic DiD analog with enhanced solubility in culture medium
DiR		
D12731	DiIC ₁₈ (7) "DiR"	Dil analog with absorption and emission in the near-infrared region, where many tissues are optically transparent
DiO and Analogs		
D275	DiOC ₁₈ (3) "DiO"	Yellow-green-fluorescent lipophilic probe; widely used as a second tracer in combination with Dil
N22881	DiOC ₁₈ (3) "DiO"	NeuroTrace® DiO tissue-labeling paste
V22886	DiOC ₁₈ (3) "DiO"	Vybrant® DiO cell-labeling solution
D1125	DiOC ₁₆ (3)	Shorter-chain DiO analog that may incorporate into membranes more easily than DiO
D3898	FAST DiO™	Unsaturated DiO analog that reportedly migrates ~50% faster than DiO within membranes
D7778	SP-DiOC ₁₈ (3)	Anionic DiO analog with enhanced water solubility; potentially retained after fixation
DiA and Analogs		
D3883	4-Di-16-ASP "DiA"	Yellow-green-fluorescent lipophilic probe; useful as a second tracer with Dil
D7758	FAST DiA™	Unsaturated DiA analog

* Probe is in solid form unless otherwise specified.

($EC > 125,000 \text{ cm}^{-1}\text{M}^{-1}$ at their longest-wavelength absorption maximum) though modest quantum yields, and short excited-state lifetimes (~ 1 nanosecond) in lipid environments.¹² Once applied to cells, the dyes diffuse laterally within the plasma membrane, resulting in staining of the entire cell. Transfer of these probes between intact membranes is usually but not always negligible.¹³ DiI and its analogs usually exhibit very low cell toxicity; however, moderate inhibition of electron transport chain activity has been reported for some analogs.¹⁴

DiI, DiO, DiD and DiR exhibit distinct orange, green, red and infrared fluorescence, respectively (Figure 14.4.6), thus facilitating multicolor imaging.¹⁵ DiO (D275) and DiI (D282, D3911) can be used with standard fluorescein and rhodamine optical filters, respectively. Iontophoretic application of these lipophilic dyes to nerve terminals at a single neuromuscular junction in live animals permits tracing of other synaptic terminals of the same motor unit.¹⁶ The He-Ne laser-excitabile DiD (D307, D7757) has much longer-wavelength excitation and emission spectra than those of DiI, providing a valuable alternative for labeling cells and tissues that have significant intrinsic fluorescence at wavelengths in the same range as DiI fluorescence (Figure 14.4.7). DiD was used as a population marker in a flow cytometry study that also employed indo-1 to monitor intracellular Ca^{2+} mobilization.¹⁷ Our heptamethine carbocyanine probe DiIC₁₈(7) (DiR, D12731) has even further red-shifted spectra, with absorption and emission maxima in the near-infrared region (absorption/emission maxima = 748/780 nm in methanol, Figure 14.4.6). Because the fluorescence of this dye is invisible to the human eye, it must be detected using a CCD camera or other near-infrared photosensitive device. The high transmission of infrared light through cells and tissues and low level of autofluorescence in the infrared makes DiR particularly useful as an *in vivo* tracer for labeled cells and liposomes in live organisms.^{12,13} Photoconversion of diaminobenzidine (DAB) by lipid tracers, including DiI and DiO derivatives, produces an insoluble, electron-dense reaction product^{18,19} (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2).

Vybrant® DiI, DiO and DiD Cell-Labeling Solutions

The highly lipophilic nature of DiI, DiO and DiD has often posed an obstacle to uniform cellular labeling in aqueous culture media.²⁰ This technical difficulty has somewhat limited the use of these tracers in cell–cell fusion,^{21,22} cellular adhesion^{23,24} and migration²⁵ applications. The Vybrant® DiI cell-labeling solution (V22885) is a dye-delivery solution that can be added directly to normal culture media to uniformly label suspended or attached culture cells. The complementary Vybrant® DiO and DiD cell-labeling solutions (V22886, V22887) allow cell populations to be marked in distinctive fluorescent colors for identification after mixing (Figure 14.4.6). Cells that have fused or that have formed stable clusters can be identified

Figure 14.4.5 The rear fin of a squid embryo that has been labeled with DiIC₁₈(3) (DiI; D282, D3911), showing selective staining of a population of ciliated sensory neurons whose cell bodies line the periphery of the fin. The dye was applied by soaking the embryos in a solution; no injection was used. Image contributed by Rachel Fink, Mount Holyoke College.

Figure 14.4.12 Persistence of lipophilic tracer fluorescence following fixation. Cultured human B cells were stained with 20 μ M SP-DiOC₁₈(3) (D7778), SP-DiIC₁₈(3) (D7777), CM-DiI (C7000, C7001) or PKH26 and then fixed with 3.7% formaldehyde or 3.7% formaldehyde + acetone. The fixed cells were analyzed by flow cytometry to generate a comparison of their fluorescence with that of the original live-cell population.

by double labeling (Figure 14.4.8). Each 1 mM solution of DiI, DiO or DiD has been filtered through a 0.2 μ m polycarbonate filter. All three cell-labeling solutions are also available in the Vybrant® Multicolor Cell-Labeling Kit (V22889). A Vybrant® CM-DiI labeling solution is also available (V22888, see below under CM-DiI).

NeuroTrace® DiI, DiO and DiD Tissue-Labeling Pastes

NeuroTrace® DiI and NeuroTrace® DiO tissue-labeling pastes (N22880, N22881) consist of DiI and DiO, respectively, mixed into an inert, water-resistant gel. Three formulations—NeuroTrace® DiI, NeuroTrace® DiO and NeuroTrace® DiD—are available in the convenient NeuroTrace® Multicolor Tissue-Labeling Kit (N22884). A NeuroTrace® CM-DiI tissue-labeling paste is also available (N22883, see below under CM-DiI). These pastes are ready to use as supplied and can be applied directly to live or fixed tissue specimens using the tip of a needle. This method of application improves the penetration of the dye into bundled neurons, labeling axons both on and below the surface. In similar situations, direct application of dye crystals or microinjection of concentrated solutions will only label neurons on the surface. This labeling method has also been found to increase the rate of dye transport by 50–80% (H. Richard Koerber, University of Pittsburgh School of Medicine, personal communication).

FAST DiI™ and FAST DiO™

Diffusion of lipophilic carbocyanine tracers from the point of their application to the terminus of a neuron can take several days to weeks.²⁶ The diffusion process appears to be accelerated by introducing unsaturation in the alkyl tails of the probes. FAST DiI™^{27–29} (D3899, D7756; Figure 14.4.9) and FAST DiO™³⁰ (D3898, Figure 14.4.10) have diunsaturated linoleyl (C_{18:2}) tails in place of the saturated octadecyl tails (C_{18:0}) of DiI and DiO. Migration of the unsaturated analogs is reported to be at least 50% faster than that of DiI and DiO (Andrea Elberger, University of Tennessee, personal communication). FAST DiI™ and the shorter chain DiIC₁₂(3) (D383) internalize during endocytic sorting of lipids and are mainly found in the endocytic recycling compartment, whereas the 16-carbon DiIC₁₆(3) (D384) is delivered to late endosomes.³¹ The perchlorate salt of FAST DiI™ does not crystallize and is a viscous oil (D3899); however, the 4-chlorobenzenesulfonate salt of FAST DiI™ (D7756) is a solid, making its crystals suitable for direct application to cells. We also offer a monounsaturated *cis*-9-octadecyl (C_{18:1}) analog of DiI (Δ^9 -DiI, D3886).

CM-DiI

CellTracker™ CM-DiI (C7000, C7001) is a DiI derivative that is somewhat more water-soluble than DiIC₁₈(3), thus facilitating the preparation of staining solutions for cell suspensions and fixed cells. In addition to its improved solubility in culture medium, CellTracker™ CM-DiI contains a thiol-reactive chloromethyl moiety (Figure 14.4.11) that allows the dye to covalently bind to cellular thiols. Thus, unlike other membrane stains, the label is well retained in some cells throughout fixation and permeabilization steps^{32–34} (Figure 14.4.12, Figure 14.4.13). Membrane staining with CellTracker™ CM-DiI persists following routine paraffin processing.³³ CellTracker™ CM-DiI is particularly useful in experiments that combine membrane labeling with subsequent immunohistochemical analysis, fluorescence *in situ* hybridization or electron microscopy³⁵ (Figure 14.4.14). CM-DiI labeling of mesenchymal stem cells has been used to track their

distribution *in vivo* and differentiation following transplantation.³⁶ Similarly, cationic liposome complexes of DNA have been labeled with CM-DiI to identify their organ and cellular distribution following injection into mice.^{37,38}

In addition to providing CM-DiI as a 1 mg solid (C7001) or specially packaged as a set of 20 vials, each containing 50 µg of CM-DiI (C7000), we have available the Vybrant® CM-DiI cell-labeling solution (V22888) and NeuroTrace® CM-DiI tissue-labeling paste (N22883) for efficient labeling of cell suspension and tissues, respectively, with this useful aldehyde-fixable tracer.

Figure 14.4.13 Neural somata from a mouse brain section labeled with NeuroTrace® 500/525 green-fluorescent Nissl stain (N21480). Nuclei are labeled with DAPI (D1306, D3571, D21490). Myelin and other lipophilic areas are illustrated with the aid of the red-orange fluorescence from CellTracker™ CM-DiI (C7000, C7001). The image is a composite of three micrographs acquired using filters appropriate for fluorescein, tetramethylrhodamine and DAPI.

Figure 14.4.14 A 30 µm-thick section of a zebrafish embryo stained with CellTracker™ CM-DiI (C7000, C7001) prior to immunohistochemical analysis. A one-day-old zebrafish embryo was immobilized and impaled in the hindbrain with a microelectrode filled with 1 mg/mL CellTracker™ CM-DiI in 95% ethanol. One day later, the brain was fixed, embedded, frozen in liquid nitrogen and sectioned on a cryostat. After blocking with 0.1% Triton® X-100 in PBS containing 2% BSA and 2% normal goat serum, the 30 µm-thick section was incubated with primary anti-glial antibody in conjunction with fluorescein goat anti-mouse IgG antibody. This section was then viewed sequentially through optical filter sets appropriate for rhodamine and fluorescein, and the resulting images were superimposed. The image was contributed by William Trevarrow, Beckman Institute, California Institute of Technology.

Sulfonated Carbocyanines

Because of poor solubility in water, it is often difficult to load the long-chain carbocyanine dyes such as DiI, DiO and PKH dyes into cells in suspension. To facilitate the staining of cells with long-chain carbocyanine dyes, we have developed sulfonated cyanine dyes³⁹—SP-DiIC₁₈(3)⁴⁰ (D7777, Figure 14.4.15), SP-DiOC₁₈(3) (D7778), DiIC₁₈(3)-DS⁴¹ (D7776, Figure 14.4.16) and DiIC₁₈(5)-DS (D12730)—that retain the 18-carbon lipophilic chains of DiI, DiD and DiO but exhibit improved solubility in culture medium. Cells can be labeled with these dyes by simply diluting a DMSO stock solution of the dye to a labeling concentration of 1–10 µM in unmodified culture medium. We have determined that these sulfonated dyes are completely soluble at 20 µM for at least one hour in Dulbecco's phosphate-buffered saline and Hanks' balanced salt solution; aggregation begins after a few hours in solution. Uptake of the anionic carbocyanine dyes in live cells is usually slower than that of cationic carbocyanine dyes, and the resulting staining patterns may be quite different.

Some applications require retention of the membrane stain in place following aldehyde-mediated fixation and lipid extraction. In contrast to labeling with DiI, DiO or the PKH dyes,⁴² cell labeling with some of these sulfonated carbocyanines appears to be compatible with standard aldehyde-based fixation methods and acetone treatment, at least in some cell lines. Although the mechanism for cell retention of the sulfonated carbocyanines has not been determined, we have observed excellent retention of staining of human B cells with SP-DiIC₁₈(3) and SP-DiOC₁₈(3), whereas virtually all of the PKH26 dye (which is structurally identical to DiIC₁₈(3)) is lost during the lipid extraction step (Figure 14.4.12). CM-DiI (C7000, C7001, N22883, V22888; see above) is also well retained during this processing. Furthermore, we have observed that acetone treatment actually enhances the fluorescence of some cells stained with SP-DiIC₁₈(3) and especially with SP-DiOC₁₈(3), a phenomenon that has not been seen with other carbocyanine-derived membrane stains.

Figure 14.4.20 Fluorescence excitation and emission spectra of DiA bound to phospholipid bilayer membranes.

Other DiO and DiI Analogs

Moderately lipophilic carbocyanines are also useful tracers for labeling cell membranes.^{31,43} Some scientists find the slightly less lipophilic DiIC₁₂(3) (D383, Figure 14.4.17), DiIC₁₆(3) (D384) and DiOC₁₆(3) (D1125) easier to load into cell suspensions than their C₁₈ homologs.

Neuronal Tracing Studies with DiI and DiO Analogs

DiI, DiO and DiD are widely used to label neuronal projections in live and fixed tissue (Figure 14.4.18, Figure 14.4.5, Figure 14.4.7). The dyes insert into the outer leaflet of the plasma membrane and diffuse laterally, producing detailed labeling of fine neuronal projections. DiI has been reported to diffuse about 6 mm/day in live tissue but more slowly in fixed specimens.⁴⁴ The dyes usually do not transfer from labeled to unlabeled cells, unless the membrane of the labeled cell is disrupted, and apparently do not transfer through gap junctions.⁴⁵

Motoneurons labeled with DiI have been reported to remain viable up to four weeks in culture and one year *in vivo*.⁴⁶ Staining of neurons in fixed tissue with DiI has been reported to persist for at least two years.^{47,48} DiI and DiD can be used simultaneously for two-color tracing^{15,49} (Figure 14.4.7) and as a fluorescence donor–acceptor pair in excited-state energy transfer studies.^{50,51} Combinations of DiO, DiI, DiD and DiR may permit three- or even four-color measurements (Figure 14.4.6).

Cell labeling with the lipophilic carbocyanines is generally performed by direct application of a dye crystal or dye-coated paper, metal or glass probe⁵² or by microinjection onto single cells from a solution in dimethylformamide or dimethylformamide/ethanol.^{53,54} A method has been described for iontophoretic loading of cells with DiI and other lipid tracers.⁵⁵ We also offer DiI in the form of extra-large crystals (D3911), which many researchers prefer for direct application to tissue. Detailed protocols for DiI labeling and confocal laser-scanning microscopy have been published.^{56,57} DiI has also been used to mark sites of microinjection by coating the outside of the glass micropipette with the dye.⁵⁸ “DiOlistic labeling” of live or fixed cells and tissues uses a gene gun to deliver pellets coated with lipophilic carbocyanine dyes DiO, DiI and DiD, permitting rapid labeling at high densities with relatively high spatial resolution.^{59–62}

Long-Term Cell Tracing with Membrane Tracers

Lipophilic carbocyanine tracers like DiI are also ideal labels for long-term cell tracing *in vivo* and *in vitro*, including studies of cell migration, transplantation,⁶³ adhesion and fusion.⁴² The presence of DiI and DiO in the cell membrane does not appreciably affect cell viability, development or other basic physiological properties.^{20,64} Labeling of cell suspensions or perfusion of tissues requires aqueous dispersions of the dyes.⁶⁵ Stock solutions of most of the tracers may be prepared in alcohol or dimethylsulfoxide (DMSO) and then added to cell suspensions. Several analogs of DiI that are more soluble in culture medium should facilitate this method of labeling (Table 14.3).

Tissue Processing and Electron Microscopy with Long-Chain Carbocyanines

Methods have been developed to allow immunofluorescent labeling of tissue containing neurons stained with DiI.^{32,66,67} Polyacrylamide has been employed to embed DiI-stained brain tissue for vibratome sectioning⁶⁸—a method that has been reported to preserve DiI labeling better than cryostat sectioning.⁶⁹ Also, see Table 14.3 for a description of DiI and DiO analogs that may be better retained through fixation and permeabilization procedures.

DiA and FAST DiA™

Reports from several researchers indicate that DiA (4-Di-16-ASP, D3883, Figure 14.4.19) is a better neuronal tracer than DiO for multicolor labeling with DiI.^{70–72} DiA diffuses more rapidly in membranes and is more soluble than DiO, thus facilitating cell labeling. For example, DiA and DiI have been used together to investigate the interactions between dorsal root axons and their targets⁷³ and axon outgrowth in the retina.⁷⁴ DiA can be excited between 440 nm and 500 nm, and its maximum emission in DOPC vesicles is at ~590 nm (red-orange fluorescence, Figure 14.4.20). Its fluorescence in cells, however, is usually bright green to yellow-green (depending on the optical filter set used). The polyunsaturated FAST DiA™, offered as a crystalline solid

(D7758) form, may diffuse faster in membranes than DiA. The C₁₀ analog of DiA, 4-Di-10-ASP (D291), has been used as a retrograde tracer to monitor injury-induced degradation of rat neurons *in vivo* and the role of microglial cells in removing debris resulting from natural and axotomy-induced neuronal cell death^{75–77} (Figure 14.4.21). 4-Di-10-ASP staining of microglia can persist for at least 12 months and can be used for DAB photoconversion⁷⁵ (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2). Axonal outgrowth of retinal ganglion cells stained with 4-Di-10-ASP has been observed.⁷⁸

Lipophilic Tracer Sampler Kit

For researchers wishing to investigate the suitability of this group of membrane probes for a particular application, we have prepared a Lipophilic Tracer Sampler Kit (L7781). This kit contains 1 mg samples of nine different membrane stains, including both relatively new and well-established tracers:

- DiIC₁₈(3) (DiI)
- DiIC₁₈(3)-DS
- SP-DiIC₁₈(3)
- 5,5'-Ph₂-DiIC₁₈(3)
- DiOC₁₈(3) (DiO)
- SP-DiOC₁₈(3)
- DiIC₁₈(5) (DiD)
- DiIC₁₈(7) (DiR)
- 4-Di-16-ASP (DiA)

Octadecyl Rhodamine B

Octadecyl rhodamine B (R18, O246) is a lipophilic cation that has been extensively used as a membrane probe^{79–82} (Lipid-Mixing Assays of Membrane Fusion—Note 13.1). Viral particles that have been labeled with high concentrations of R18 have fluorescence that is highly self-quenched; fusion of the particle with host cell membranes therefore results in a fusion-associated fluorescence increase.^{83,84}

Figure 14.4.21 Rat retinal ganglion cells that have been allowed to regenerate for 2 months after transection into a grafted peripheral nerve piece and then labeled with 4-Di-10-ASP (D291), which is retrogradely transported within the regenerated axons and finest dendrites (left). Microglial cells in the retina were transcellularly labeled with 4-Di-10-ASP after phagocytosing degenerated ganglion cells (right). The images were contributed by Solon Thanos, University of Tübingen School of Medicine.

Plasma Membrane Stains

CellMask™ Plasma Membrane Stains

The CellMask™ plasma membrane stains are designed to generate rapid and uniform cell-surface labeling without the cell type-dependent variability exhibited by lectins.⁸⁵ CellMask™ Orange (C10045) and CellMask™ Deep Red (C10046) plasma membrane stains are optimally detected using tetramethylrhodamine (TRITC) and Cy⁵ dye detection configurations, respectively. They are particularly important for cell-surface demarcation in experiments using intracellular targets labeled with Green Fluorescent Protein (GFP), Alexa Fluor® 488 dye, BODIPY® FL dye and other green-fluorescent fluorophores.^{86–89} Membrane staining persists through fixation, but not permeabilization. Immunofluorescence detection of intracellular targets in cells labeled with CellMask™ plasma membrane stains must therefore be carried out under non-permeabilizing conditions⁸⁶

Fluorescent Protein-Based Plasma Membrane Markers

CellLight® plasma membrane expression vectors (C10606, C10607, C10608) generate cyan-, green- or red-autofluorescent proteins fused to a plasma membrane targeting sequence consisting of the 10 N-terminal amino acids of LcK tyrosine kinase (Lck10). These fusion proteins are lipid raft markers with well established utility,⁹⁰ providing alternatives to cholera toxin B conjugates (Section 14.7) or BODIPY® FL C₅-ganglioside G_{M1}⁹¹ (B13950, B34401; Section 13.3) with the inherent advantages of long-lasting and titratable expression conferred by BacMam 2.0 vector technology (BacMam Gene Delivery and Expression Technology—Note 11.1).

FM® and RH Dyes

Although the lipophilic cyanine and styryl dyes described above are useful for staining cell membranes, they are relatively difficult to apply to cells and they do eventually internalize, staining all cell membranes. In contrast, FM® 1-43 (T3163, T35356), FM® 1-43FX (F35355), FM® 4-64 (T3166, T13320), FM® 4-64FX (F34653) and RH 414 (T1111) are easily applied to cells, where they bind rapidly and reversibly to the plasma membrane with strong fluorescence enhancement.^{92–94} These probes have large Stokes shifts and can be excited by the argon-ion laser. Because we have found that small differences in the polarity of these probes can play a large role in their rates of uptake and their retention properties, we have introduced FM® 5-95 (T23360), a slightly less lipophilic analog of FM® 4-64 with essentially identical spectroscopic properties.

FM® 1-43 is efficiently excited with standard fluorescein optical filters but poorly excited with standard tetramethylrhodamine optical filters (Figure 14.4.22). FM® 1-43 has been used to outline membranes

Figure 14.4.22 Absorption and fluorescence emission spectra of FM® 1-43 bound to phospholipid bilayer membranes.

Figure 14.4.23 Absorption and fluorescence emission spectra of FM® 4-64 bound to zwitterionic detergent (CHAPS) micelles.

Figure 14.4.24 The morphology of sporulating *Bacillus subtilis* in the early stages of forespore engulfment. The membranes and chromosomes of both the forespore and the larger mother cell are stained with FM® 4-64 (red; T3166, T13320) and DAPI (blue; D1306, D3571, D21490), respectively. The small green-fluorescent patch indicates the localization of a GFP fusion to SPoIIIE, a protein essential for translocation of the forespore chromosome that may also regulate membrane fusion events (see Proc Natl Acad Sci U S A (1999) 96:14553). The background contains sporangia at various stages in the engulfment process stained with MitoTracker® Green FM® (green, M7514) and FM® 4-64 (red).

Figure 14.4.25 Cultured olfactory bulb neuron stained with RH 414 (T1111) and DM-BODIPY®(-)-dihydropyridine (D7443). Left: image at greater than 580 nm; Middle: image at 510–580 nm; Right: ratio of the middle image divided by the left image. Images were acquired with a Leica confocal laser-scanning microscope. The images were contributed by D. Schild, H. Geiling and J. Bischofberger, Physiologisches Institut, Universität Göttingen.

in sea urchin eggs.⁹⁵ This styryl dye has also proven extremely valuable for identifying actively firing neurons and for investigating the mechanisms of activity-dependent vesicle cycling in widely different species^{96–100} (Section 16.1). We offer FM® 1-43 in a 1 mg vial (T3163) or specially packaged in 10 vials of 100 µg each (T35356).

FM® 1-43FX is an FM® 1-43 analog that has been modified to contain an aliphatic amine. This modification makes the probe fixable with aldehyde-based fixatives including formaldehyde and glutaraldehyde. FM® 1-43FX has been used to study synaptic vesicle cycling in cone photoreceptor terminals⁹⁶ and to investigate the functional maturation of glutamatergic synapses.¹⁰¹ FM® 1-43FX is available specially packaged in 10 vials of 100 µg each (F35355).

Membranes labeled with FM® 4-64 exhibit long-wavelength red fluorescence (Figure 14.4.23) that can be distinguished from the green fluorescence of FM® 1-43 staining (Figure 14.4.22) with the proper optical filter sets, thus permitting two-color observation of membrane recycling in real time.^{102,103} FM® 4-64 selectively stains yeast vacuolar membranes and is an important tool for visualizing vacuolar organelle morphology and dynamics and for studying the endocytic pathway in yeast¹⁰⁴ (Section 12.3). In addition, FM® 4-64 staining has been used to visualize membrane migration and fusion during *Bacillus subtilis* sporulation—movements that can be correlated with the translocation of GFP-labeled proteins¹⁰⁵ (Figure 14.4.24). We offer FM® 4-64 in a 1 mg vial (T3166) or specially packaged in 10 vials of 100 µg each (T13320). Additionally, we offer the fixable analog FM® 4-64FX specially packaged in 10 vials of 100 µg each (F34653).

Membranes stained with RH 414 (T1111) exhibit orange fluorescence when observed through a longpass optical filter that permits passage of light beyond 510 nm.^{94,106,107} In a confocal laser-scanning microscopy study, the subcellular distribution of L-type Ca²⁺ channels in olfactory bulb neurons was determined using intensity ratio measurements of the green fluorescence of DM-BODIPY® dihydropyridine (D7443, Section 16.3) to the red fluorescence of RH 414–stained plasma membranes¹⁰⁸ (Figure 14.4.25). In this method, staining of the plasma membrane by RH 414 was used to control for optical artifacts and differences in membrane surface area in the optical section. RH 414 has also been used as to follow vacuolization of the transverse tubules of frog skeletal muscle¹⁰⁹ and to measure membrane potential (Chapter 22).

Image-iT® LIVE Plasma Membrane and Nuclear Labeling Kit

The Image-iT® LIVE Plasma Membrane and Nuclear Labeling Kit (I34406) provides two stains—red-fluorescent Alexa Fluor® 594 wheat germ agglutinin (WGA) (excitation/emission maxima ~590/617 nm) and blue-fluorescent Hoechst 33342 dye (excitation/emission maxima when bound to DNA ~350/461 nm)—for highly selective staining of the plasma membrane and nucleus, respectively, of live, Green Fluorescent Protein (GFP)–transfected cells (Figure 14.4.26). These dyes can be combined into one staining solution using the protocol provided, saving labeling time and wash steps while still providing optimal staining. Cell-impermeant Alexa Fluor® 594 WGA binds selectively to *N*-acetylglucosamine and *N*-acetylneuraminic (sialic) acid residues.¹¹⁰ When used according to the protocol, Alexa Fluor® 594 WGA provides highly selective labeling of the plasma membrane with minimal background, although labeling may not be as distinct for flat cell types when viewed using standard epifluorescence microscopy or

low magnification. Alexa Fluor® 594 WGA is retained after formaldehyde fixation and permeabilization with Triton® X-100. This fluorescent lectin conjugate can also be used to label fixed cells; however, to avoid labeling intracellular components, formaldehyde-fixed cells should not be permeabilized before labeling. It is important to note that Alexa Fluor® 594 WGA can stimulate biological activity, including clustering of glycosylated cell-surface proteins. The kit also includes Hoechst 33342 dye, a cell-permeant nucleic acid stain that is selective for DNA and is spectrally similar to DAPI. This dye does not interfere with GFP fluorescence and is retained after fixation and permeabilization.

The Image-iT® LIVE Plasma Membrane and Nuclear Labeling Kit contains:

- Alexa Fluor® 594 wheat germ agglutinin (WGA)
- Hoechst 33342 nucleic acid stain
- Detailed experimental protocols

Each kit provides enough staining solution for 360 assays using the protocol provided for labeling live, cultured cells that are adhering to coverslips.

Vybrant® Lipid Raft Labeling Kits

The Vybrant® Lipid Raft Labeling Kits (V34403, V34404, V34405) are designed to provide convenient, reliable and extremely bright fluorescent labeling of lipid rafts in live cells. Lipid rafts are detergent-insoluble, sphingolipid- and cholesterol-rich membrane microdomains that form lateral assemblies in the plasma membrane.^{111–117} Lipid rafts also sequester glycosylated phosphatidylinositol (GPI)-linked proteins and other signaling proteins and receptors, which may be regulated by their selective interactions with these membrane microdomains.^{118–123} Recent research has demonstrated that lipid rafts play a role in a variety of cellular processes—including the compartmentalization of cell-signaling events,^{124–131} the regulation of apoptosis^{132–134} and the intracellular trafficking of certain membrane proteins and lipids^{135–137}—as well as in the infectious cycles of several viruses and bacterial pathogens.^{138–143} Examining the formation and regulation of lipid rafts is a critical step in understanding these aspects of eukaryotic cell function.

The Vybrant® Lipid Raft Labeling Kits provide the key reagents for fluorescently labeling lipid rafts *in vivo* with our bright and extremely photostable Alexa Fluor® dyes (Figure 14.4.27). Live cells are first labeled with the green-fluorescent Alexa Fluor® 488, orange-fluorescent Alexa Fluor® 555 or red-fluorescent Alexa Fluor® 594 conjugate of cholera toxin subunit B (CT-B). This CT-B conjugate binds to the pentasaccharide chain of plasma membrane ganglioside G_{M1}, which selectively partitions into lipid rafts.^{122,144,145} All Molecular Probes® CT-B conjugates are prepared from recombinant CT-B and are completely free of the toxic subunit A, thus eliminating any concern for toxicity or ADP-ribosylating activity. An antibody that specifically recognizes CT-B is then used to crosslink the CT-B-labeled lipid rafts into distinct patches on the plasma membrane, which are easily visualized by fluorescence microscopy.^{146,147}

Each Vybrant® Lipid Raft Labeling Kit contains sufficient reagents to label 50 live-cell samples in a 2 mL assay, including:

- Recombinant cholera toxin subunit B (CT-B) labeled with the Alexa Fluor® 488 (in Kit V34403), Alexa Fluor® 555 (in Kit V34404) or Alexa Fluor® 594 (in Kit V34405) dye
- Anti-cholera toxin subunit B antibody (anti-CT-B)
- Concentrated phosphate-buffered saline (PBS)
- Detailed labeling protocols

Because they are compatible with various multilabeling schemes, the Vybrant® Lipid Raft Labeling Kits can also serve as important tools for identifying physiologically significant membrane proteins that associate with lipid rafts. Cells can be labeled with other live-cell probes during the lipid raft labeling protocol or immediately following the antibody crosslinking step, depending on the specific labeling requirements of the other probes. Alternatively, once the lipid rafts have been labeled and crosslinked, the cells can be fixed for long-term storage or fixed and permeabilized for subsequent labeling with antibodies or other probes that are impermeant to live cells.

Figure 14.4.26 Live, highly confluent HeLa cells were transfected using pShooter™ vector pCMV/myc/mito/GFP and Lipofectamine® 2000 transfection reagent and stained with the reagents in the Image-iT® LIVE Plasma Membrane and Nuclear Labeling Kit (I34406). Plasma membranes were labeled with Alexa Fluor® 594 wheat germ agglutinin and nuclei were stained with Hoechst 33342. Cells were visualized using epifluorescence microscopy.

Figure 14.4.27 A J774 mouse macrophage cell sequentially stained with BODIPY® FL ganglioside G_{M1} (B13950) and then with Alexa Fluor® 555 dye-labeled cholera toxin subunit B (C22843, C34776; also available as a component of V34404). The cell was then treated with an anti-CT-B antibody (a component of V34404) to induce crosslinking. Alexa Fluor® 555 dye fluorescence (top, red) and BODIPY® FL dye fluorescence (center, green) were imaged separately and overlaid to emphasize the coincident staining (bottom, yellow). Nuclei were stained with blue-fluorescent Hoechst 33342 (H1399, H3570, H21492).

Figure 14.4.28 Normalized absorption (—) and fluorescence emission (---) spectra of enhanced Green Fluorescent Protein (EGFP) and CellTrace™ BODIPY® TR methyl ester (C34556).

Figure 14.4.29 Live HeLa cells were transfected using pShooter™ vector pCMV/myc/mito/GFP and Lipofectamine® 2000 transfection reagent and stained with the reagents in the Image-iT® LIVE Intracellular Membrane and Nuclear Labeling Kit (I34407). Intracellular membranes were stained with CellTrace™ BODIPY® TR methyl ester, and nuclei were stained with Hoechst 33342. Cells were visualized using epifluorescence microscopy.

Image-iT® LIVE Intracellular Membrane and Nuclear Labeling Kit

Many research and biotechnological applications require detailed three- and four-dimensional visualization of embryonic cells labeled with Green Fluorescent Protein (GFP) within their native tissue environments. Fluorescent counterstains that label all the cells in a live embryo provide a histological context for the GFP-expressing cells in the specimen. The red-fluorescent CellTrace™ BODIPY® TR methyl ester (C34556)—available separately or as part of our Image-iT® LIVE Intracellular Membrane and Nuclear Labeling Kit (I34407)—is an excellent counterstain for cells and tissues that are expressing GFP.¹⁴⁸ This dye readily permeates cell membranes and selectively stains mitochondria and endomembranous organelles such as endoplasmic reticulum and the Golgi apparatus, but does not appear to localize in the plasma membrane. These localization properties make the dye an ideal vital stain that can be used to reveal: (1) the location and shapes of cell nuclei,¹⁴⁹ (2) the shapes of cells within embryonic tissues and (3) the boundaries of organ-forming tissues within the whole embryo. Furthermore, CellTrace™ BODIPY® TR methyl ester staining is retained after formaldehyde fixation and permeabilization with Triton® X-100, and the dye does not appear to produce any teratogenic effects on embryonic development. The emission spectra of enhanced GFP (EGFP) and CellTrace™ BODIPY® TR methyl ester are well separated, with peaks at 508 nm and 625 nm, respectively (Figure 14.4.28), allowing simultaneous dual-channel confocal imaging without significant overspill of GFP fluorescence into the CellTrace™ BODIPY® TR methyl ester detection channel.

The Image-iT® LIVE Intracellular Membrane and Nuclear Labeling Kit provides:

- CellTrace™ BODIPY® TR methyl ester, for staining intracellular membranes
- Hoechst 33342 dye for staining nuclei
- Detailed experimental protocols

These two fluorescent stains were especially chosen for their compatibility with live GFP-expressing cells (Figure 14.4.29), and they can be combined into one staining solution to save labeling time and wash steps while still providing optimal staining. Each kit provides enough staining solution for 250 assays using the protocol provided for labeling live, cultured cells that are adhering to coverslips.

FluoroMyelin™ Fluorescent Myelin Stains

The FluoroMyelin™ Green and FluoroMyelin™ Red fluorescent myelin stains (F34651, F34652) enable quick and selective labeling of myelin in brain cryosections. Visualization of myelin is useful for understanding myelin distribution, for identifying brain structures and relative location of other labels and for mapping a particular section within the brain. Traditional methods require the use of antibodies, such as anti-myelin basic protein, or chromogenic (transmitted-light) methods, such as the Loyez method or Schmued's gold chloride technique, all of which are time consuming, requiring multiple steps over one to three days. The FluoroMyelin™ stains, in contrast, require only a single 20-minute labeling step plus washes. A standard FITC filter set is suitable for imaging the FluoroMyelin™ Green stain, with little or no bleedthrough into standard DAPI, TRITC or far-red filter sets. A standard TRITC or Texas Red® filter set is suitable for imaging the FluoroMyelin™ Red stain, with little or no bleedthrough into standard DAPI, FITC or far-red filter sets. These stains can be used in combination with antibodies and other dyes, and with standard histochemical methods for brain cryosections; they are ideal for studying demyelinating diseases such as multiple sclerosis.^{150–152} In addition to being used on their own, FluoroMyelin™ stains can be combined with other dyes in a single labeling step as in our BrainStain™ Imaging Kit described below, which includes NeuroTrace® 530/615 red fluorescent Nissl stain and DAPI nucleic acid stain for three-color visualization.

BrainStain™ Imaging Kit

The BrainStain™ Imaging Kit (B34650) enables three-color combinatorial labeling of myelin, neurons and nuclei in brain cryosections in a single 20-minute staining step plus washes (Figure 14.4.30, Figure 14.4.31). This kit contains novel stains that can be used separately or together in one staining solution, replacing traditional methods that can take one to three days. Standard histochemical

methods such as immunohistochemistry are compatible with these stains. Each BrainStain™ Kit provides:

- FluoroMyelin™ Green fluorescent myelin stain
- NeuroTrace® 530/615 red-fluorescent Nissl stain
- DAPI nuclear counterstain
- Detailed protocols for staining mouse brain cryosections

Figure 14.4.30 Mouse hippocampus and corpus callosum sagittal cryosection stained with reagents from the BrainStain™ Imaging Kit (B34650). Neuronal cell bodies were stained with NeuroTrace® red-fluorescent Nissl stain, white matter was stained with FluoroMyelin™ Green dye, and nuclei were stained with DAPI.

Figure 14.4.31 Mouse cerebellum cryosection stained with reagents from the BrainStain™ Imaging Kit (B34650). Neuronal cell bodies were stained with NeuroTrace® 530/615 red-fluorescent Nissl stain, white matter was stained with FluoroMyelin™ Green dye, and nuclei were stained with DAPI.

Notes

1. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
2. Abs and Em of styryl dyes are at shorter wavelengths in membrane environments than in reference solvents such as methanol. The difference is typically 20 nm for absorption and 80 nm for emission, but varies considerably from one dye to another. Styryl dyes are generally nonfluorescent in water.
3. This product is intrinsically a liquid or an oil at room temperature.
4. This product is intrinsically a sticky gum at room temperature.
5. Abs, EC and Em determined for dye bound to detergent micelles (20 mg/mL CHAPS in H₂O). These dyes are essentially nonfluorescent in pure water.
6. FM® 4-64 and FM® 5-95 are nonfluorescent in water. For two-color imaging in GFP-expressing cells, these dyes can be excited at 568 nm with emission detection at 690–730 nm. (*Am J Physiol Cell Physiol* (2001) 281:C624)
7. FM® 1-43 Abs = 479 nm, Em = 598 nm bound to phospholipid bilayer membranes (FM® 1-43/lipid Absorption and fluorescence emission spectra of FM® 1-43 bound to phospholipid bilayer membranes.). Em = 565 nm bound to synaptosomal membranes. (*Neuron* (1994) 12:1235)
8. This product consists of a tracer dye mixed into an inert gel for direct application to tissues. Molecular weight and spectroscopic data are for the free dye.
9. RH 414 Abs ~500 nm, Em ~635 nm when bound to phospholipid bilayer membranes.
10. This product is supplied as a ready-made staining solution.

PRODUCT LIST 14.4 TRACERS FOR MEMBRANE LABELING

Cat. No.	Product	Quantity
B34650	BrainStain™ Imaging Kit	1 kit
C10606	CellLight® Plasma Membrane-CFP *BacMam 2.0*	1 mL
C10607	CellLight® Plasma Membrane-GFP *BacMam 2.0*	1 mL

14.5 Fluorescent and Biotinylated Dextrans

Dextrans are hydrophilic polysaccharides characterized by their moderate to high molecular weight, good water solubility and low toxicity. They are widely used as both anterograde and retrograde tracers in neurons^{1,2} and for many other applications. Dextrans are biologically inert due to their uncommon poly-(α -D-1,6-glucose) linkages, which render them resistant to cleavage by most endogenous cellular glycosidases. They also usually have low immunogenicity.

We offer a broad range of fluorescent and biotinylated dextran conjugates in several molecular weight ranges. Because the source and molecular weight of the dextran, as well as the net charge, degree of substitution and nature of the dye may significantly affect the application, references citing the use of Molecular Probes® dextrans may not be directly applicable to dextrans obtained from other sources and should be considered guides rather than definitive protocols. In most cases, Molecular Probes® fluorescent dextrans are much brighter and have higher negative charge than dextrans available from other sources. Furthermore, we use rigorous methods for removing as much unconjugated dye as practical, and then assay our dextran conjugates by thin-layer chromatography to help ensure the absence of low molecular weight contaminants.

Properties of Molecular Probes® Dextran Conjugates

A Wide Selection of Substituents

Molecular Probes® dextrans are conjugated to biotin or a wide variety of fluorophores, including seven of our Alexa Fluor® dyes (Table 14.4). In particular, we would like to highlight the dextran conjugates of Alexa Fluor® 488, Oregon Green® and Rhodamine Green™ dyes, which are significantly brighter and more photostable than most fluorescein dextrans. Dextran-conjugated fluorescent indicators for calcium and magnesium ions (Section 19.4) and for pH (Section 20.4) are described with their corresponding ion indicators in other chapters.

Dextran Size

Molecular Probes® dextrans include those with nominal molecular weights (MW) of 3000; 10,000; 40,000; 70,000; 500,000; and 2,000,000 daltons (Table 14.4). Because unlabeled dextrans are polydisperse—and may become more so during the chemical processes required for their modification and purification—the actual molecular weights present in a particular sample may have a broad distribution. For example, our “3000 MW” dextran preparations contain polymers with molecular weights predominantly in the range of ~1500–3000 daltons, including the dye or other label.

Degree of Substitution of Molecular Probes® Dextrans

Dextrans from other commercial sources usually have a degree of substitution of 0.2 or fewer dye molecules per dextran molecule for dextrans in the 10,000 MW range. Molecular Probes® dextrans, however, typically contain 0.3–0.7 dyes per dextran in the 3000 MW range, 0.5–2 dyes per dextran in the 10,000 MW range, 2–4 dyes in the 40,000 MW range and 3–6 dyes in the 70,000 MW range. The actual degree of substitution is indicated on the product’s label. If too many fluorophores

are conjugated to the dextran molecule, quenching and undesired interactions with cellular components may occur. We have found our degree of substitution to be optimal for most applications, yielding dextrans that are typically much more fluorescent than the labeled dextrans available from other sources, thus permitting lower quantities to be used for intracellular tracing.

It has been reported that some commercially available fluorescein isothiocyanate (FITC) dextrans yield spurious results in endocytosis studies because of the presence of free dye or metal contamination.^{3,4} To overcome this problem, we remove as much of the free dye as possible by a combination of precipitation, dialysis, gel filtration and other techniques. The fluorescent dextran is then assayed by thin-layer chromatography (TLC) to help ensure that it is free of low molecular weight dyes. We prepare several unique products that have two or even three different labels, including the fluoro-ruby, mini-ruby and micro-ruby dextrans, described below. Not all of the individual dextran molecules of these products are expected to have all the substituents, or to be equally fixable, particularly in conjugates of the lowest molecular weight dextrans.

Dextran Net Charge and Method of Substitution

The net charge on the dextran depends on the fluorophore and the method of preparing the conjugate. We prepare most Molecular Probes® dextrans by reacting a water-soluble amino dextran (D1860, D1861, D1862, D3330, D7144) with the succinimidyl ester of the appropriate dye, rather than reacting a native dextran with isothiocyanate derivatives such as FITC. This method provides superior amine selectivity and yields an amide linkage, which is somewhat more stable than the corresponding thioureas formed from isothiocyanates. Except for the Rhodamine Green™ and Alexa Fluor® 488 conjugates, once the dye has been added, the unreacted amines on the dextran are capped to yield a neutral or anionic dextran. In the case of the Rhodamine Green™ and Alexa Fluor® 488 dextrans, the unreacted amines on the dextran are not capped after dye conjugation. Thus, these dextran conjugates may be neutral, anionic or cationic. The Alexa Fluor®, Cascade Blue®, lucifer yellow, fluorescein and Oregon Green® dextrans are intrinsically anionic, whereas most of the dextrans labeled with the zwitterionic rhodamine B, tetramethylrhodamine and Texas Red® dyes are essentially neutral. To produce more highly anionic dextrans, we have developed a proprietary procedure for adding negatively charged groups to the dextran carriers; these products are designated “polyanionic” dextrans.

Dextran Fixability

Some applications require that the dextran tracer be treated with formaldehyde or glutaraldehyde for subsequent analysis.^{5,6} For these applications, we offer “lysine-fixable” versions of most of our dextran conjugates of fluorophores or biotin. These dextrans have covalently bound lysine residues that permit dextran tracers to be conjugated to surrounding biomolecules by aldehyde-mediated fixation for subsequent detection by immunohistochemical and ultrastructural techniques. We have also shown that all of our 10,000 MW Alexa Fluor® dextran conjugates can be fixed with aldehyde-based fixatives.

Loading Cells with Dextran and Subsequent Tissue Processing

Unless taken up by an endocytic process, dextran conjugates are membrane impermeant and usually must be loaded by relatively invasive techniques⁷ (Table 14.1). As with the lipophilic tracers in Section 14.4, crystals of the dextran conjugates have been successfully loaded by simply placing them directly on some kinds of samples.⁸ We have found the Influx™ pinocytic cell-loading reagent (I14402, Section 19.8) to be useful for loading dextrans into a variety of adherent and nonadherent cells.⁹ Sterile filtration of dextran solutions before use with live cells is highly recommended.¹⁰ Biotin and biotinylated biomolecules with molecular weights up to >100,000 daltons are taken up by some plant cells through an endocytic pathway.^{11,12}

Our lysine-fixable dextrans and 10,000 MW Alexa Fluor® dextrans can be fixed in place with formaldehyde or glutaraldehyde, permitting subsequent tissue processing, such as sectioning. A protocol has been published for embedding tissues in plastic for high-resolution characterization of neurons filled with lysine-fixable fluorescent dextrans.¹³ Fixation of biotinylated or fluorescent dextrans also permits the use of fluorescent- or enzyme-labeled conjugates of avidin and streptavidin (Section 7.6, Table 7.9) or of anti-dye antibodies (Section 7.4, Table 7.8), respectively. These techniques can amplify the signal, which is important for detecting fine structure in sections or for changing the detection mode.¹⁴ We provide antibodies to the Alexa Fluor® 488, Alexa Fluor® 405/Cascade Blue®, lucifer yellow, fluorescein, BODIPY® FL, tetramethylrhodamine and Texas

Red® fluorophores and to the 2,4-dinitrophenyl (DNP) and nitrotyrosine haptens (Section 7.4).

Photoconversion of neurons labeled with lysine-fixable fluorescent dextrans in the presence of diaminobenzidine (DAB) using the Diaminobenzidine (DAB) Histochemistry Kits (Section 7.2, Section 7.6) can be used to produce electron-dense products for electron microscopy¹⁵ (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2). Electron-dense products can also be generated from peroxidase or colloidal gold conjugates of avidin, streptavidin or anti-dye antibodies.¹⁶ NANOGOLD® and Alexa Fluor® FluoroNanogold™ conjugates of secondary antibodies (Section 7.2) and streptavidin (Section 7.6) can be utilized to allow detection of labeled dextrans in fixed-cell preparations by light microscopy or, following silver enhancement with the LI Silver Enhancement Kit (L24919, Section 7.2), by electron microscopy.

Neuronal Tracing with Dextrans

Fluorescent and biotinylated dextrans are routinely employed to trace neuronal projections. Dextrans can function efficiently as anterograde or retrograde tracers,^{2,17-19} depending on the study method and tissue type used. Active transport of dextrans occurs only in live, not fixed tissue.²⁰ Comparative studies of rhodamine isothiocyanate, rhodamine B dextran (D1824) and lysinated tetramethylrhodamine dextran (fluoro-ruby, D1817) have shown that the dextran conjugates produce less diffusion at injection sites and more permanent labeling

Table 14.4 Molecular Probes® dextran conjugates.

Label(s) (Absorption/Emission Maxima) *	3000 MW	10,000 MW	40,000 MW	70,000 MW	500,000 MW	2,000,000 MW

* Approximate absorption and emission maxima, in nm, for conjugates. † "Lysine-fixable" dextrans contain lysines and can therefore be fixed in place with formaldehyde or glutaraldehyde. ‡ "Fixable" dextrans contain free amines (but not lysines) and can be fixed in place with formaldehyde or glutaraldehyde.

than do the corresponding free dyes.⁵ Dextran conjugates with molecular weights up to 70,000 daltons have been employed as neuronal tracers in a wide variety of species. The availability of fluorescent dextran conjugates with different sizes and charges permitted the analysis of direction and rate of axonal transport in the squid giant axon.²¹

Multilabeled Dextran

Molecular Probes® fixable dextrans, most of which are lysinated dextrans (see the products marked by a single dagger (†) in Table 14.4), are generally preferred for neuronal tracing because they may transport more effectively and can be fixed in place with aldehydes after labeling. We prepare a number of multilabeled dextrans that are fixable, including some that have acquired the distinction of unique names in various publications:

- Fluoro-ruby^{5,15,22–27}—a red-orange-fluorescent, aldehyde-fixable 10,000 MW dextran labeled with both tetramethylrhodamine and lysine (D1817). 3000 MW, 70,000 MW and 2,000,000 MW versions of fluoro-ruby are also available (D3308, D1818, D7139).
- Fluoro-emerald^{23,27,28}—a green-fluorescent, aldehyde-fixable 10,000 MW dextran labeled with both fluorescein and lysine (D1820; Figure 14.5.1, Figure 14.5.2, Figure 14.5.3). This labeled dextran is also available in molecular weights from 3000 daltons up to 2,000,000 daltons^{29,30} (D3306, D1845, D1822, D7136, D7137).
- Micro-ruby (D7162) and mini-ruby^{31–35} (D3312)—red-orange-fluorescent, aldehyde-fixable 3000 MW and 10,000 MW dextrans simultaneously labeled with tetramethylrhodamine, biotin and lysine.
- Micro-emerald (D7156) and mini-emerald (D7178)—green-fluorescent, aldehyde-fixable dextrans simultaneously labeled with fluorescein, biotin and lysine.
- Biotinylated dextran amine (BDA)^{1,10,36–43}—nonfluorescent, aldehyde-fixable dextrans simultaneously labeled with biotin and lysine

Figure 14.5.1 Lineage tracing of three dorsal blastomeres of 32-cell *Xenopus laevis* embryos injected with Molecular Probes® fluorescent dextran conjugates. The tier 1 dorsal (A1) blastomere was injected with lysine-fixable 10,000 MW fluorescein dextran (D1820), the tier 2 dorsal (B1) blastomere with lysine-fixable 10,000 MW Texas Red® dextran (D1863), and the tier 3 dorsal (C3) blastomere with lysine-fixable 10,000 MW Cascade Blue® dextran (D1976). Embryos were fixed in formaldehyde, embedded and sectioned. The image on the left shows a 13 µm-thick section of a stage 6 (32-cell) embryo fixed right after injection; this section exhibits significant autofluorescence due to the presence of residual yolk. The image on the right is a stage 10 (early gastrula) embryo. Triple-exposure photographs of the sectioned embryos were taken on a Zeiss® Axiophot with a 10× objective. Images contributed by Marie Vodicka, University of California, Berkeley.

and available in several molecular weights (D1956, D1957, D7135, D7142). A useful review has been published on the BDA products.⁴⁴

Fluoro-ruby and fluoro-emerald (Figure 14.5.3) have been extensively employed for retrograde and anterograde neuronal tracing,⁵ transplantation²⁵ and cell-lineage tracing.^{2,24,26,45} Both products can be used to photoconvert DAB into an insoluble, electron-dense reaction product.¹⁵ Like fluoro-ruby and fluoro-emerald, micro-ruby and mini-ruby are brightly fluorescent, making it easy to visualize the electrode during the injection process. DiI (D282, Section 14.4) or other lipophilic probes in Section 14.4 can be used to mark the sites of microinjection.⁴⁶ In addition, because these dextrans include a covalently linked biotin, filled cells can be probed with standard enzyme-labeled avidin or streptavidin conjugates or with NANOGOLD® and Alexa Fluor® FluoroNanogold™ streptavidin (Section 7.6) to produce a permanent record of the experiment.⁴⁷ Mini-ruby has proven useful for intracellular filling in fixed brain slices³² and has been reported to produce staining comparable to that achieved with lucifer yellow CH³¹ (L453, L682, L1177, L12926; Section 14.3). Moreover, the use of mini-ruby in conjunction with standard peroxidase-mediated avidin-biotin methods does not cause co-conversion of lipofuscin granules found in adult human brain, a common problem during photoconversion of lucifer yellow CH.³¹ The lysine-fixable micro-emerald and mini-emerald dextrans (triply labeled with fluorescein, biotin and lysine) provide a contrasting color that is better excited by the argon-ion laser of confocal laser-scanning microscopes; they have uses similar to micro-ruby and mini-ruby, respectively.

3000 MW Dextrans

The nominally 3000 MW dextrans offer several advantages over higher molecular weight dextrans, including faster axonal diffusion and greater access to peripheral cell processes²⁹ (Figure 14.5.4). Our “3000 MW” dextran preparations contain polymers with molecular weight predominantly in the range of ~1500–3000 daltons, including the dye

Figure 14.5.2 Development of the leech central nervous system into segments was characterized with the cell lineage tracer lysine-fixable 10,000 MW fluorescein dextran (fluoro-emerald, D1820). Fluoro-emerald was injected into a neuroectodermal cell of a leech embryo. The teloblast eventually differentiated into 5 segmentally iterated ganglia labeled with fluoro-emerald (pseudocolored blue in this image). Associated muscle fibers were identified with a Lan 3-14 monoclonal antibody and visualized with a Cy3 antibody (pseudocolored red). Nuclei were counterstained with TOTO®-3 dye (T3604, pseudocolored green). Image reprinted from the cover of Development (2000) 127 (4), used with the permission of The Company of Biologists Ltd.

or other label. Our selection of 3000 MW dextrans includes Alexa Fluor®, fluorescein, Rhodamine Green™, tetramethylrhodamine, Texas Red® and biotin conjugates. We also offer lysine-fixable 3000 MW dextrans that are simultaneously labeled with both fluorescein and biotin (micro-emerald, D7156) or tetramethylrhodamine and biotin (micro-ruby, D7162).

The 3000 MW fluorescein dextran and tetramethylrhodamine dextran (D3306, D3308; Figure 14.5.5, Figure 14.5.6) have been observed to readily undergo both anterograde and retrograde movement in live cells.^{23,29} These 3000 MW dextrans appear to passively diffuse within the neuronal process, as their intracellular transport is not effectively inhibited by colchicine or nocodazole, both of which disrupt active transport by depolymerizing microtubules.²⁹ Moreover, these small dextrans diffuse at rates equivalent to those of smaller tracers such as sulforhodamine 101 and biocytin (~2 millimeters/hour at 22°C) and about twice as fast as 10,000 MW dextrans. The relatively low molecular weight of the dextrans may result in transport of some labeled probes through gap junctions (see below). The signal from tetramethylrhodamine-conjugated dextrans can be detected in the fine dendrite configuration of cortical projection neurons using anti-tetramethylrhodamine antibodies (A6397, Section 7.4) and peroxidase-anti-peroxidase complex staining.¹⁴

NeuroTrace® BDA-10,000 Neuronal Tracer Kit

The NeuroTrace® BDA-10,000 Neuronal Tracer Kit (N7167) contains convenient amounts of each of the components required for neuroanatomical tracing using BDA methods,⁴⁴ including:

- Lysine-fixable, biotinylated 10,000 MW dextran amine (BDA-10,000)
- Horseradish peroxidase avidin (HRP avidin)
- 3,3'-Diaminobenzidine (DAB)
- Rigorously tested protocols for fast and simple tracing experiments

The neuronal tracer BDA-10,000 is transported over long distances and fills fine processes bidirectionally, including boutons in the anterograde direction and dendritic structures in the retrograde direction.^{10,40-43} Two days to two weeks after BDA-10,000 is injected into the

Figure 14.5.3 A whole mount of the embryonic brain of *Xenopus laevis* that has been double-labeled with our lysine-fixable 10,000 MW fluorescein dextran (fluoro-emerald, D1820) and lysine-fixable 10,000 MW tetramethylrhodamine dextran (fluoro-ruby, D1817). The tetramethylrhodamine dextran was used to label the neurons projecting from the retina, whereas the fluorescein dextran was applied to the transected spinal cord, thus allowing the detailed evaluation of the topological relationship of these two populations of neurons. Image contributed by Martina Manns and Bernd Fritzs, Creighton University.

Figure 14.5.4 Secondary motor neurons in a spinal cord whole mount of a male western mosquitofish (*Gambusia affinis affinis*) that have been labeled with lysine-fixable 3000 MW Texas Red® dextran (D3328). The dextran crystals were applied to the bipinnate inclinator muscles of the anal appendicular support fin, and the dye was transported from the axons to cell body and dendrites. Motor neurons were visualized and photographed through a bandpass optical filter appropriate for Texas Red® dye, by epifluorescence microscopy. Image contributed by E. Rosamolin, University of Nebraska Medical Center, and Bernd Fritzs, Creighton University.

Figure 14.5.5 The attached eighth nerve from the vestibular labyrinth of a turtle, *Pseudemys scripta*, exposed to lysine-fixable 3000 MW tetramethylrhodamine dextran (D3308) and incubated with F-actin-specific BODIPY® FL phalloidin (B607). F-actin-labeled ciliary bundles were stained green by the phalloidin, and the calyceal and bouton endings of their primary afferents were stained red by the dextran. This image is a projection of 40 confocal images. Image contributed by Laura DiCaprio and Ellengene Peterson, Ohio University.

Figure 14.5.6 The antero-ventral and antero-dorsal lateral line nerves in an *Ambystoma mexicanum* whole-mounted brain after labeling with 3000 MW Rhodamine Green™ dextran (D7163) and lysine-fixable 3000 MW tetramethylrhodamine dextran (D3308), respectively. In both cases, the dextran was applied to the respective cut cranial nerves. This photomicrograph shows the four segregated ventral fascicles of the mechanosensory lateral line fibers and the intermingling of the dorsal electrosensory fibers. Image contributed by Bernd Fritzs, Creighton University.

Figure 14.5.7 A mitral cell in the olfactory bulb of a chinook salmon that has been retrogradely labeled using the NeuroTrace® BDA-10,000 Neuronal Tracer Kit (N7167).

desired region of the brain, the brain tissue can be fixed and sectioned. BDA-10,000 can also be applied to cut nerves and allowed to transport. Following incubation with HRP avidin and then DAB, the electron-dense DAB reaction product can be viewed by either light or electron microscopy^{44,47} (Figure 14.5.7). The NeuroTrace® BDA-10,000 labeling method can be readily combined with other anterograde or retrograde labeling methods or with immunohistochemical techniques. BDA-10,000 is available as a separate product (D1956), as are BDA derivatives with other molecular weights—BDA-3000⁴⁸ (D7135), BDA-70,000 (D1957) and BDA-500,000 (D7142). A detailed protocol that utilizes Molecular Probes® BDA-10,000 probe, HRP streptavidin (S911, Section 7.6) and tetramethylbenzidine to anterogradely label fine processes in neurons has been published.¹

Cell Lineage Tracing with Dextrans

Fluorescent dextrans—particularly the fluorescein and rhodamine conjugates—have been used extensively for tracing cell lineage.^{26,49} Our Alexa Fluor® 647 and Alexa Fluor® 680 dextrans (D22914, D34680, D34681) provide longer-wavelength detection options for specimens with high levels of autofluorescence or low transparency. In this technique, the dextran is microinjected into a single cell of the developing embryo, and the fate of that cell and its daughters can be followed *in vivo* (Figure 14.5.1). The lysine-fixable tetramethylrhodamine and Texas Red® dextran conjugates (Table 14.4) are most frequently cited for lineage tracing studies. As a second color, particularly in combination with the Texas Red® dextrans, researchers have most often used Molecular Probes® lysine-fixable fluorescein dextrans⁴⁹ (e.g., D3306, D1820, D1822). Although these fixable conjugates can be employed with long-term preservation of the tissue, some researchers prefer to co-inject a fluorescent, nonlysinated dextran along with a nonfluorescent, lysine-fixable biotin dextran (BDA). The nonfluorescent BDA can then be fixed in place with aldehyde-based fixatives and probed with any of our fluorescent or enzyme-labeled streptavidin and avidin conjugates described in Section 7.6 (Table 7.9).

Our 500,000 and 2,000,000 MW fluorescent dextrans (Table 14.4) may be particularly useful for lineage tracing at early stages of development, although these biopolymers have lower water solubility and a greater tendency to precipitate or clog microinjection needles than our lower molecular weight dextrans. Some studies suggest that lower molecular weight dextrans may leak from blastomeres, complicating analysis. Injection of 2,000,000 MW fluorescein dextran and 2,000,000 MW Texas Red® dextran into separate cells of the two-cell stage zebrafish embryo allowed the construction of a fate map.⁵⁰ The 500,000 MW and 2,000,000 MW dextrans are labeled with fluorescein, tetramethylrhodamine or Texas Red® dyes or with biotin, and all contain aldehyde-fixable lysine groups. The nonfluorescent 500,000 MW aminodextran (D7144) can be conjugated with the researcher's choice of amine-reactive reagents.⁵¹

Figure 14.5.8 Dual-tracer technique for identifying gap junction-coupled cells. **A**) Cells are labeled with a mixture of a small polar tracer such as lucifer yellow CH (green circles) and a relatively large tetramethylrhodamine-labeled dextran (red circles). **B**) Adjoining gap junction-coupled cells are accessible to the low molecular weight tracer whereas the much larger dextran conjugate is excluded. Coupled cells with single-color lucifer yellow CH labeling are readily distinguished from initially labeled cells with dual fluorescence.

Studying Intercellular Communication with Dextrans

The size of dextrans can be exploited to study connectivity between cells.⁵² Examples include studies of the passage of 3000 MW dextrans through plasmodesmata³⁰ and modulation of gap junctional communication by transforming growth factor- β_1 and forskolin.⁵³ However, the dispersion of molecular weights in our “3000 MW” dextran preparations, which contain polymers with total molecular weights predominantly in the range of ~1500–3000 daltons but may also contain molecules <1500 daltons, may complicate such analyses.

An important experimental approach to identifying cells that form gap junctions makes use of simultaneous introduction of the polar tracer lucifer yellow CH (~450 daltons) and a tetramethylrhodamine 10,000 MW dextran. Because low molecular weight tracers like lucifer yellow CH (L453, L12926; Section 14.3) pass through gap junctions and dextrans do not, the initially labeled cell exhibits red fluorescence, whereas cells connected through gap junctions have yellow fluorescence⁵³ (Figure 14.5.8). This technique has been used to follow the loss of intercellular communication in adenocarcinoma cells,⁵⁴ to show the re-establishment of communication during wound healing in *Drosophila*⁵⁵ and to investigate intercellular communication at different stages in *Xenopus* embryos.^{56,57} Simultaneous loading of cells with two (or more) dextrans that differ in both their molecular weight and in the dye's fluorescence properties has been used to assess subcellular heterogeneities in the submicroscopic structure of cytoplasm.⁵⁸

Probing Membrane Permeability with Dextrans

Labeled dextrans are often used to investigate vascular permeability and blood–brain barrier integrity.^{59,60} Fluorescein dextrans with molecular weights ranging from 4000 to 150,000 daltons have been used to determine the effect of electroporation variables—pulse size, shape and duration—on plasma-membrane pore size in chloroplasts,⁶¹ red blood cells⁶² and fibroblasts.⁶³ Fluorescence recovery after photobleaching (FRAP) techniques have been used to monitor nucleocytoplasmic transport of fluorescent dextrans of various molecular weights, allowing the determination of the size-exclusion limit of the nuclear pore membrane,^{64–66} as well as to study the effect of epidermal growth factor and insulin on the nuclear membrane and on nucleocytoplasmic transport.^{67,68}

Microinjected 3000 MW fluorescent dextrans concentrate in interphase nuclei of *Drosophila* embryos, whereas 40,000 MW dextrans remain in the cytoplasm and enter the nucleus only after breakdown of the nuclear envelope during prophase. This size-exclusion phenomenon was used to follow the cyclical breakdown and reformation of the nuclear envelope during successive cell divisions.⁶⁹ Similarly, our 10,000 MW Calcium Green™ dextran conjugate (C3713, Section 19.4) was shown to diffuse across the nuclear membrane of isolated nuclei from *Xenopus laevis* oocytes, but the 70,000 MW and 500,000 MW conjugates could not.⁷⁰ Significantly, depletion of nuclear Ca²⁺ stores by inositol 1,4,5-triphosphate (Ins 1,4,5-P₃, I3716; Section 17.2) or by calcium chelators (Section 19.8) blocked nuclear uptake of the 10,000 MW Calcium Green™ dextran conjugate but not entry of lucifer yellow CH. Our 3000 MW Calcium Green™ dextran conjugate (C6765) is actively transported in adult nerve fibers over a significant distance and is retained in presynaptic terminals in a form that allows monitoring of presynaptic Ca²⁺ levels.⁷¹

Following Endocytosis with Dextrans

Fluorescent Dextrans

Tracing internalization of extracellularly introduced fluorescent dextrans is a standard method for analyzing fluid-phase endocytosis.^{72–75} We offer dextrans with nominal molecular weights ranging from 3000 to 2,000,000 daltons, many of which can also be used as pinocytosis or phagocytosis markers (Table 14.4). Discrimination of internalized fluorescent dextrans from dextrans in the growth medium is facilitated by use of reagents that quench the fluorescence of the external probe. For

example, most of our anti-fluorophore antibodies (Section 7.4, Table 7.8) strongly quench the fluorescence of the corresponding dyes.⁷⁶

Negative staining produced by fluorescent dextrans that have been intracellularly infused via a patch pipette is indicative of nonendocytic vacuoles in live pancreatic acinar cells; extracellular addition of a second, color-contrasting dextran then allows discrimination of endocytic and nonendocytic vacuoles.⁷⁷ An *in vitro* assay for homotypic fusion of early endosomes has been described in which two cell populations are labeled with Alexa Fluor® 488 and Alexa Fluor® 594 10,000 MW dextrans (D22910, D22914) by fluid phase uptake, followed by subcellular fractionation and analysis of endosomal fluorescence colocalization.⁷⁸ Intracellular fusion of endosomes has also been monitored with a BODIPY® FL avidin conjugate by following the fluorescence enhancement that occurs when it complexes with a biotinylated dextran.⁷⁹

pH Indicator Dextrans

Some of the dyes we use to prepare Molecular Probes® dextran conjugates exhibit fluorescence that is sensitive to the pH of the medium; pH indicator dextrans and their optical responses are described in detail in Section 20.4. Consequently, internalization of labeled dextrans into acidic organelles of cells can often be tracked by measuring changes in the fluorescence of the dye. The fluorescein dextrans (pK_a ~6.4) are frequently used to investigate endocytic acidification.^{80,81} Fluorescence of fluorescein-labeled dextrans is strongly quenched upon acidification; however, fluorescein's lack of a spectral shift in acidic solution makes it difficult to discriminate between an internalized probe that is quenched and residual fluorescence of the external medium. Dextran conjugates that either shift their emission spectra in acidic environments, such as the SNARF® dextrans (Section 20.4), or undergo significant shifts of their excitation spectra, such as BCECF and Oregon Green® dextrans (Section 20.4), provide alternatives to fluorescein. The Oregon Green® 488 and Oregon Green® 514 dextrans exhibit a pK_a of approximately 4.7, facilitating measurements in acidic environments.^{80,82} In addition to these pH indicator dextrans, we prepare a dextran that is double-labeled with fluorescein and tetramethylrhodamine (D1951; Section 20.4), which has been used as a ratiometric indicator (Figure 14.5.9) to measure endosomal acidification in Hep G2 cells⁸³ and murine alveolar macrophages.⁸⁴

In contrast to fluorescein and Oregon Green® 488 dextrans, pHrodo™ 10,000 MW dextran (P10361) exhibits increasing fluorescence in response to acidification⁸⁴ (Figure 14.5.10). The minimal fluorescent signal from pHrodo™ dextran at neutral pH prevents the detection of noninternalized and nonspecifically bound conjugates and eliminates

Figure 14.5.9 The excitation spectra of double-labeled fluorescein-tetramethylrhodamine dextran (D1951), which contains pH-dependent (fluorescein) and pH-independent (tetramethylrhodamine) dyes.

Figure 14.5.10 The pH sensitivity of pHrodo™ dextran. pHrodo™ 10,000 MW dextran (P10361) was reconstituted in HEPES (20 mM)-buffered PBS and adjusted to pH values from pH 4 to pH 10. The intensity of fluorescence emission increases with increasing acidity, particularly in the pH 5–8 range.

Figure 14.5.11 Tracking endocytosis inhibition with pHrodo™ dextran conjugates. HeLa cells were plated in 96-well format and treated with dyasore for 3 hours at 37°C prior to the pHrodo™ endocytosis assay. Next, 40 μg/mL of pHrodo™ 10,000 MW dextran (P10361) was incubated for 30 minutes at 37°C, and cells were then stained with HCS NuclearMask™ Blue Stain (H10325) for 10 minutes to reveal total cell number and demarcation for image analysis. Images were acquired on the BD Pathway 855 High-Content Bioimager (BD Biosciences).

the need for quenching reagents and extra wash steps, thus providing a simple fluorescent assay for endocytic activity. pHrodo™ dextran's excitation and emission maxima of 560 and 585 nm, respectively, facilitate multiplexing with other fluorophores including blue-, green- and far-red-fluorescent probes. Although pHrodo™ dextran is optimally excited at approximately 560 nm, it is also readily excited by the 488 nm spectral line of the argon-ion laser found on flow cytometers, confocal microscopes and imaging microplate readers (Figure 14.5.11).

Tracing Fluid Transport with Dextrans

Fluorescent dextrans are important tools for studying the hydrodynamic properties of the cytoplasmic matrix. The intracellular mobility of these fluorescent tracers can be investigated using fluorescence recovery after photobleaching (FRAP) techniques. We offer a range of dextran sizes, thus providing a variety of hydrodynamic radii for investigating both the nature of the cytoplasmic matrix and the permeability of the surrounding membrane. Because of their solubility and biocompatibility, fluorescent dextrans have been used to monitor *in vivo* tissue permeability and flow in the uveoscleral tract,^{85,86} capillaries^{87,88} and proximal tubules,⁸⁹ as well as diffusion of high molecular weight substances in the brain's extracellular environment.⁹⁰

PRODUCT LIST 14.5 FLUORESCENT AND BIOTINYLATED DEXTRANS

Cat. No.	Product	Quantity
D34682	dextran, Alexa Fluor® 488; 3,000 MW, anionic	2 mg
D22910	dextran, Alexa Fluor® 488; 10,000 MW, anionic, fixable	5 mg
D22911	dextran, Alexa Fluor® 546; 10,000 MW, anionic, fixable	5 mg
D34679	dextran, Alexa Fluor® 555; 10,000 MW, anionic, fixable	5 mg
D22912	dextran, Alexa Fluor® 568; 10,000 MW, anionic, fixable	5 mg
D22913	dextran, Alexa Fluor® 594; 10,000 MW, anionic, fixable	5 mg
D22914	dextran, Alexa Fluor® 647; 10,000 MW, anionic, fixable	2 mg
D34681	dextran, Alexa Fluor® 680; 3,000 MW, anionic	2 mg
D34680	dextran, Alexa Fluor® 680; 10,000 MW, anionic, fixable	5 mg

PRODUCT LIST 14.5 FLUORESCENT AND BIOTINYLATED DEXTRANS—*continued*

Cat. No.	Product	Quantity
D3330	dextran, amino, 3000 MW	100 mg
D1860	dextran, amino, 10,000 MW	1 g
D1861	dextran, amino, 40,000 MW	1 g
D1862	dextran, amino, 70,000 MW	1 g
D7144	dextran, amino, 500,000 MW	100 mg
D7135	dextran, biotin, 3000 MW, lysine fixable (BDA-3000)	10 mg
D1956	dextran, biotin, 10,000 MW, lysine fixable (BDA-10,000)	25 mg
D1957	dextran, biotin, 70,000 MW, lysine fixable (BDA-70,000)	25 mg
D7142	dextran, biotin, 500,000 MW, lysine fixable (BDA-500,000)	10 mg
D7168	dextran, BODIPY® FL, 10,000 MW, fixable	5 mg
D7132	dextran, Cascade Blue®, 3000 MW, anionic, lysine fixable	10 mg
D1976	dextran, Cascade Blue®, 10,000 MW, anionic, lysine fixable	25 mg
D3305	dextran, fluorescein, 3000 MW, anionic	10 mg
D3306	dextran, fluorescein, 3000 MW, anionic, lysine fixable	10 mg
D1821	dextran, fluorescein, 10,000 MW, anionic	25 mg
D1820	dextran, fluorescein, 10,000 MW, anionic, lysine fixable (fluoro-emerald)	25 mg
D1844	dextran, fluorescein, 40,000 MW, anionic	25 mg
D1845	dextran, fluorescein, 40,000 MW, anionic, lysine fixable	25 mg
D1823	dextran, fluorescein, 70,000 MW, anionic	25 mg
D1822	dextran, fluorescein, 70,000 MW, anionic, lysine fixable	25 mg
D7136	dextran, fluorescein, 500,000 MW, anionic, lysine fixable	10 mg
D7137	dextran, fluorescein, 2,000,000 MW, anionic, lysine fixable	10 mg
D7156	dextran, fluorescein and biotin, 3000 MW, anionic, lysine fixable (micro-emerald)	5 mg
D7178	dextran, fluorescein and biotin, 10,000 MW, anionic, lysine fixable (mini-emerald)	10 mg
D1825	dextran, lucifer yellow, 10,000 MW, anionic, lysine fixable	25 mg
D7170	dextran, Oregon Green® 488; 10,000 MW, anionic	5 mg
D7171	dextran, Oregon Green® 488; 10,000 MW, anionic, lysine fixable	5 mg
D7172	dextran, Oregon Green® 488; 70,000 MW, anionic	5 mg
D7173	dextran, Oregon Green® 488; 70,000 MW, anionic, lysine fixable	5 mg
D7176	dextran, Oregon Green® 514; 70,000 MW, anionic	5 mg
D1824	dextran, rhodamine B, 10,000 MW, neutral	25 mg
D1841	dextran, rhodamine B, 70,000 MW, neutral	25 mg
D7163	dextran, Rhodamine Green™, 3000 MW	5 mg
D7153	dextran, Rhodamine Green™, 10,000 MW, lysine fixable	10 mg
D3307	dextran, tetramethylrhodamine, 3000 MW, anionic	10 mg
D3308	dextran, tetramethylrhodamine, 3000 MW, anionic, lysine fixable	10 mg
D1868	dextran, tetramethylrhodamine, 10,000 MW, anionic, fixable	25 mg
D1817	dextran, tetramethylrhodamine, 10,000 MW, lysine fixable (fluoro-ruby)	25 mg
D1816	dextran, tetramethylrhodamine, 10,000 MW, neutral	25 mg
D1842	dextran, tetramethylrhodamine, 40,000 MW, neutral	25 mg

Scarlet (645/680)	F8843	

* Fluorescence excitation and emission maxima of the encapsulated dye measured in 2-ethoxyethyl acetate. All FluoSpheres® microspheres for blood flow determination are supplied as suspensions containing 1.0×10^6 beads/mL (15 µm microspheres) or 3.6×10^6 beads/mL (10 µm microspheres) in a unit size of 10 mL.

FluoSpheres® and TransFluoSpheres® polystyrene microspheres satisfy several prerequisites of ideal long-term biological tracers. Because the dyes in our microspheres are incorporated throughout the microsphere rather than just on its surface, the fluorescence output per microsphere is significantly greater than that obtained from protein or dextran conjugates (Table 6.6) and is relatively immune to photobleaching and other environment-dependent effects. FluoSpheres® and TransFluoSpheres® microspheres are also biologically inert and physically durable, and they are available with a large number of uniform sizes and surface properties. Furthermore, their spectral properties can be freely manipulated during manufacture without altering their surface properties. See Section 6.5 for an extensive discussion of the properties of our FluoSpheres® and TransFluoSpheres® polystyrene beads.

Measuring the effect of various interventions on regional blood flow is an important quantitative application of fluorescent microspheres. Relatively large radiolabeled microspheres (10–15 µm in diameter) have long been used for regional blood flow studies in tissues and organs. Fluorescent microspheres, however, have been shown to be superior to radioactive microspheres in chronic blood flow measurements.¹ In most cases, the microspheres are injected at desired locations in the circulatory system and eventually lodge in the capillaries, where they can later be counted in dissected tissue sections. To eliminate the hazards, expense and disposal problems of the radiolabeled microspheres,² researchers have turned to fluorescent and colored microspheres for measuring myocardial and cortical blood flow.^{3–6} Blood flow measurements using fluorescent microspheres in other organs, including the kidney,^{7,8} lung,^{9–15} spleen,¹⁶ adrenal glands,¹⁷ bone^{18,19} and teeth,²⁰ are equally feasible. Our 0.2 µm FluoSpheres® microspheres have been used to trace new blood vessel development, which is important for the study of tumor angiogenesis and microvascular continuity.⁹

FluoSpheres® Microspheres for Blood Flow Determination

We have used Molecular Probes® fluorescent dye technology to produce a range of intensely fluorescent FluoSpheres® microspheres specifically designed for regional blood flow determination (Table 14.5). Regional blood flow studies using our FluoSpheres® polystyrene microspheres for blood flow determination (Figure 14.6.1) have been validated in several side-by-side comparisons with radioactively labeled microspheres.^{21–25} The two methods exhibit equivalent detection

Table 14.6 FluoSpheres® blood flow and color kits.

Cat. No.	Application	Bead Size	Concentration	Number of Colors
F8890	Blood flow determination	10 µm	3.6×10^6 beads/mL	7 colors, 10 mL each

sensitivity, and excellent correlation between the flow measurements has been reported. In addition, techniques have been developed to extract the microspheres and the fluorescent dyes they contain from tissue samples, allowing blood flow quantitation to be performed using readily available instrumentation such as spectrofluorometers and fluorescence microplate readers.⁵ Up to seven simultaneously circulating tracers can be discriminated based on uncompensated fluorescent color differences. With spectral spillover corrections, the number of simultaneously detectable tracers can be increased to thirteen.²⁶ Microspheres that have been perfused or injected into tissues and organs retain their fluorescence following histological serial sectioning.^{3,4} Our FluoSpheres® microspheres for blood flow determination, which are available in eleven distinguishable fluorescent colors (Figure 14.6.1), are also compatible with blood flow analyzer systems that perform automated extraction and analysis.²⁷

FluoSpheres® Color Kits for Regional Blood Flow Studies

We offer four different FluoSpheres® Blood Flow Determination Fluorescent Color Kits (Table 14.6):

- **Kit #1 (F8890)** contains 10 mL vials of 10 µm microspheres in seven fluorescent colors (blue, blue-green, yellow-green, orange, red, crimson and scarlet).
- **Kit #2 (F8891)** contains 10 mL vials of 15 µm microspheres in seven fluorescent colors (blue, blue-green, yellow-green, orange, red, crimson and scarlet).
- **Kit #3 (F8892)** contains 10 mL vials of 15 µm microspheres in five fluorescent colors (blue-green, yellow-green, orange, red and crimson).
- **Kit #4 (F21015)** contains 10 mL vials of 15 µm microspheres in four additional fluorescent colors (green, yellow, carmine and red-orange), which are spectrally distinguishable from the dyes in Kits #2 and #3 (Figure 14.6.1).

Figure 14.6.2 Schematic diagram of the advantages of the large Stokes shift exhibited by our TransFluoSpheres® beads. A1 and E1 represent the absorption and emission bands of a typical TransFluoSpheres® bead. The large separation of the absorption and emission maxima (Stokes shift) is characteristic of our TransFluoSpheres® beads. Unlike most low molecular weight fluorescent dyes, which show considerable overlap of their absorption and emission spectra, the TransFluoSpheres® beads can be excited (EX) across the entire absorption band A1 and the resulting fluorescence can be detected across the full emission band E1, thereby allowing the researcher to maximize the signal (S1). Moreover, because of the large Stokes shifts of the TransFluoSpheres® beads, researchers can often avoid problems associated with autofluorescence. The absorption and emission bands of a typical autofluorescent component are represented in this figure by A2 and E2. Although the endogenous fluorescent species will be excited simultaneously with the TransFluoSpheres® beads, the resulting emission (E2) does not coincide with E1 and is therefore readily rejected by suitably chosen optical filters.

The aqueous suspensions of 10 µm and 15 µm beads contain 3.6 million and 1 million microspheres per mL, respectively. All kits include a detailed protocol. Each of the colors of FluoSpheres® microspheres for blood flow studies can also be purchased separately (Table 14.5).

Fluorescent Microsphere Resource Center

More information, including a detailed applications manual on the use of fluorescent microspheres for blood flow determination, is available from the Fluorescent Microsphere Resource Center (FMRC) at the University of Washington, Seattle (fmrc.pulmcc.washington.edu).

Particle and Cell Tracking with Fluorescent Microspheres

Availability of intensely fluorescent, highly uniform microspheres in different colors and sizes permits diverse applications in tracking particles and cells, tracing fluid dynamics and amplifying signals. Using a mixture of beads of different sizes, each labeled with a different fluorescent color, researchers can discriminate the size dependence of uptake or transport of microspheres *in vivo* in cells, capillaries, lung or other tissues.²⁸ In addition to our microspheres specially designed for blood flow studies, we offer a wide range of fluorescent FluoSpheres® carboxylate-modified microspheres in different fluorescent colors, bead diameters and surface functional groups (see Table 6.7 in Section 6.5 for a complete list). Of particular interest are our FluoSpheres® beads with 0.04 µm diameters and FluoSpheres® beads for tracer studies with 1 µm diameters, which have been specially formulated to perform well in cell tracking and particle tracking studies, respectively. Our smallest microspheres can be microinjected into cells (see below) or are actively taken up by phagocytosis (Section 16.1).

FluoSpheres® Beads with 0.04 µm Diameters for Microinjection

Unlike our other fluorescent microspheres, most of which come in aqueous suspensions containing 2% solids and 2 mM sodium azide as a preservative, FluoSpheres® beads with 0.04 µm diameters are prepared as aqueous suspensions containing 5% solids without preservatives. At more than double the concentration of our standard FluoSpheres® microspheres, these carboxylate-modified 0.04 µm beads (F8795, F8792, F8794, F8793, F8789, F8794) are well suited to applications requiring microinjectable tracers. Yellow-green-, orange-, red-orange-, red- and dark red-fluorescent colors are available in the FluoSpheres® Fluorescent Color Kit (F10720). In many biological systems, the concentrated fluorescence and spherical shape of the FluoSpheres® beads permit them to be detected against a relatively high but diffuse background fluorescence. However, our TransFluoSpheres® microspheres (Table 14.7)—microspheres with extremely large Stokes shifts—are preferred for some studies because their fluorescence may be better resolved from the tissue's autofluorescence (Figure 14.6.2).

FluoSpheres® Beads with 1.0 µm Diameters for Tracer Studies

Our FluoSpheres® fluorescent microspheres for tracer studies are 1.0 µm polystyrene beads for analysis by tissue extraction (Table 14.7). Because the dye content of these microspheres is much higher than that of other fluorescent microspheres, stronger signals can be generated using fewer microspheres per tracing experiment. These heavily

Figure 14.6.3 Fluorescence excitation and emission maxima of the FluoSpheres® europium luminescent microspheres.

Figure 14.6.4 Luminescence excitation and emission spectra of the FluoSpheres® platinum luminescent microspheres.

dye-loaded beads are available in four well-resolved fluorescent colors: blue-green (F13080), yellow-green (F13081), orange (F13082) and red (F13083), with excitation/emission maxima at approximately 430/465, 505/515, 540/560 and 580/605 nm, respectively (the emission spectra are shown as peaks 2, 4, 6 and 8 of Figure 14.6.1). Aerosols containing these fluorescent microspheres have been used to acquire high-resolution maps of regional pulmonary ventilation.¹⁴ Transport of these fluorescent microspheres through tissues can be determined using methods that have been developed for regional blood flow determination or by confocal laser-scanning microscopy.²⁹ As with the FluoSpheres® beads for blood flow determination, the microspheres and the fluorescent dyes they contain are first extracted from the tissue sample, and then the fluorescence is quantitated on a spectrofluorometer or fluorescence microplate reader.

SAIVI™ 715 Injectable Contrast Agents with 0.1 µm and 2 µm Diameters

SAIVI™ 715 injectable contrast agents (S31201, S31203) are specially formulated for small-animal *in vivo* imaging of regions of inflammation, blood pooling and wound healing. These contrast agents are polymeric microspheres that have been labeled with a fluorescent dye; each microsphere particle contains many dye molecules protected within the polymer sphere. Their use for *in vivo* imaging offers many advantages over existing contrast agents, including 1) no known intrinsic toxicity, 2) a high degree of localization within diseased vasculature and 3) longer *in vivo* residence times than organic dye-labeled proteins. Formulated to resist liver accumulation, SAIVI™ injectable contrast agents have been observed to circulate throughout the blood and to accumulate in tissues that exhibit damaged, excessive or otherwise abnormal blood vessel development as part of the disease process. These agents are optimized for long-wavelength emission and tested by *in vivo* imaging after injection in disease models established in mice. We also offer a set of complementary contrast agents (SAIVI™ Alexa Fluor® 680 and SAIVI™ Alexa Fluor® 750 conjugates of transferrin and albumin, Section 14.7) for rapid imaging of early-onset events.

Europium and Platinum Luminescent Microspheres for Time-Resolved Fluorometry

Detecting a low level of protein or DNA targets in a tissue sample or on a membrane using classic fluorochromes is sometimes difficult and prone to errors because specific fluorescence signals tend to be low and are usually mixed with nonspecific signals and autofluorescence. One approach to improve detectability is the use of time-resolved luminescence reagents, such as our FluoSpheres® europium luminescent microspheres and FluoSpheres® platinum luminescent microspheres (Table 14.8). The FluoSpheres® europium beads contain Eu^{3+} coordination complexes with luminescence decay times of >600 microseconds—much longer than the <50 nanosecond decay time of conventional fluorophores and autofluorescence. The luminescence of the Pt^{2+} chelate in the FluoSpheres® platinum luminescent microspheres has a decay time of >40 microseconds. Thus, time-gated fluorescence detection using these microspheres results in complete rejection of autofluorescence signals.^{30–38} In addition, the europium luminescent microspheres feature long-wavelength emission (610–650 nm) that is well separated from their excitation peak (340–390 nm) (Figure 14.6.3). The platinum luminescent microspheres are maximally excited near 390 nm with narrow emission that is maximal near 650 nm (Figure 14.6.4). Because of these unusually large Stokes shifts, filter combinations can be chosen that effectively isolate the desired luminescence signal. The narrow emissions and different lifetimes permit simultaneous

Table 14.8 Molecular Probes® europium and platinum luminescent FluoSpheres® microspheres.

Type of Microsphere*	Size	
	0.04 µm	0.2 µm

Europium (365/610)	F20883	F20884

* Luminescent FluoSpheres® microspheres are supplied as aqueous suspensions containing 0.5% solids. † See Section 7.6 for more information on our avidin and streptavidin conjugates.

use of the europium and platinum luminescent microspheres as tracers. These microspheres are available with nominal diameters of 0.04 μm or 0.2 μm (Table 14.7).

Microspheres for Monitoring Airflow

A cubic foot of air may contain hundreds of thousands of airborne particles such as viruses, bacteria, pollen, mold spores and gaseous chemicals (Figure 14.6.5). To combat harmful airborne particles, many types of air filters and instruments for detecting airborne particles have been developed for medical and defense purposes. Because most airborne particles are small (typically 10–150 nm, below microscopic resolution) and are difficult to detect, verification of the function of these filters and instruments can be a challenge. Our FluoSpheres® microspheres are specially stained fluorescent polystyrene beads that can mimic airborne particles¹⁴ and be used as unique markers to verify equipment reliability. A single “virus-sized” 20 nm diameter FluoSpheres® microsphere carries 100–200 fluorophore molecules and thus emits sufficiently bright fluorescence for easy detection.

Transplantation and Migration Studies with Fluorescent Microspheres

Labeling cells with fluorescent microspheres prior to transplantation enables researchers to distinguish cell types and analyze graft migration in the host over extended time periods. Unlike other tracers, most of which rapidly diffuse or leach from their site of application in tissues, fluorescent microspheres tend to remain in place for periods of at least months. Their stability and biological inertness give them considerable potential for transplantation studies. Moreover, the intense fluorescence, high uniformity and low debris content of our FluoSpheres® polystyrene microspheres will circumvent many of the problems encountered in use of fluorescent microspheres from other sources. Cells are generally labeled with microspheres by microinjection or other invasive methods (Table 14.1). Potential problems of sterility, unequal uptake and translocation of the beads by the cells need to be considered before using fluorescent microspheres in transplantation and other cell tracing studies.³⁹ It has been reported that polystyrene microspheres for transplantation studies can be sterilized by heating below their softening temperature.⁴⁰

Neuronal Tracing with Fluorescent Microspheres

Katz, the first scientist to use fluorescent microspheres as neuronal tracers, demonstrated that rhodamine-labeled microspheres could undergo retrograde transport.⁴¹ Although the mechanism of microsphere transport is not completely understood, the process can apparently be facilitated by using a high concentration of particles with small diameters (<0.05 μm) and high negative surface-charge densities.^{42–44} Fluorescent microspheres are also suitable for retrograde tracing because they are not cytotoxic and persist for extraordinarily long periods in nerve cells. The fluorescence intensity of microsphere-labeled neuronal perikarya in rats was found to be undiminished one year after injection.⁴⁵ Adsorption of neuroactive proteins, including neurotrophins, on small-diameter fluorescent microspheres provides a means of locating their *in vivo* and *in vitro* microinjection sites and of following retrograde transport in the central nervous system.⁴⁶ Our fluorescent microspheres are also becoming important tracers in ophthalmological studies^{47–49} where they undergo retrograde transport.^{50,51}

Our red-fluorescent, carboxylate-modified FluoSpheres® beads^{52,53} (F8793) are retrogradely transported in rat lumbosacral ventral root axons that have been subjected to peripheral crush injury.⁵⁴ In this study, the fluorescent beads were used to photoconvert diaminobenzidine (DAB) into an insoluble, electron-dense reaction product in order to facilitate ultrastructural analysis by electron microscopy (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2).

Following Phagocytosis with Fluorescent Microspheres

Many cell types actively ingest opsonized or nonopsonized fluorescent microspheres (Section 16.1). The preferred microspheres are about 0.5–2 μm in diameter. Confocal laser-scanning microscopy can distinguish between ingested beads and those simply bound to the surface.⁵⁵ Flow cytometry, fluorescence microscopy and fluorescence spectrometry have been used to quantitate phagocytosis by macrophage cells^{56–60} and protozoan cells.⁶¹ Macrophage cells in primary cultures of rat cerebral cortex have been identified by their ability to selectively phagocytose fluorescent microspheres;⁶² macrophage cells have also been sorted based on the absolute number of microspheres phagocytosed.⁶⁰ Fluorescent microsphere uptake has been used as a model for alveolar macrophage cell translocation and clearance of inhaled aerosols containing environmental particulates.^{29,63,64} As with our fluorescent microspheres for blood flow determination (see above), solvent extraction of the fluorescent dye from the beads can be used to quantitate microsphere uptake by macrophage cells.⁶⁵

For the study of collagen phagocytosis, we manufacture yellow-green-fluorescent FluoSpheres® collagen I-labeled microspheres in either 1.0 μm or 2.0 μm diameters (F20892, F20893; Section 16.1). Fibroblasts phagocytose and then intracellularly digest collagen. These activities play an important role in the remodeling of the extracellular matrix during normal physiological turnover of connective tissues, in development, in wound repair and possibly in aging and various disorders. A well-established procedure for observing collagen phagocytosis by either flow cytometry or fluorescence microscopy involves the use of collagen-coated fluorescent microspheres, which attach to the cell surface and become engulfed by fibroblasts.^{66–68}

Tracking the Movement of Proteins and Other Biomolecules with Fluorescent Microspheres

FluoSpheres® microspheres can serve as bright, inert and extremely photostable labels for tracking particle movement and other dynamic processes over extended time periods. The intense fluorescence of our

Figure 14.6.5 FluoSpheres® microsphere sizes relative to common airborne particles.

Figure 14.6.6 Superimposed time sequence image (2.3-second intervals) showing a single bead moving through a biofilm channel. Autofluorescence of the cell clusters can be seen as lighter areas relative to the channels. The direction of bulk fluid flow is indicated by the arrow. Photo contributed by Paul Stoodley, Exeter University, and Dirk DeBeer, Max Planck Institute of Marine Biology.

Figure 14.6.7 Distribution of Qdot® nanocrystals in cytoplasmic vesicles after labeling cells with the Qtracker® 655 Cell Labeling Kit (Q25021MP). HeLa cells were labeled with the Qtracker® 655 Cell Labeling Kit and then observed using a Leica TCS SP2 confocal microscope (excitation at 488 nm). This representative image shows the Qdot® nanocrystals distributed in vesicles throughout the cytoplasm.

FluoSpheres® beads permits the detection and tracking of very small single particles in three dimensions.^{69–71} Examples of the diverse applications of fluorescent microspheres include studies designed to track or quantitate:

- Binding of kinetochores to microtubules *in vitro*^{71,72}
- Brownian motion in protein⁷³ and dextran solutions⁷⁴
- Exchangeable GTP-binding sites on paclitaxel-stabilized fluorescent microtubules⁷⁵
- Direction and rate of axonal transport in the squid giant axon⁷⁶
- Fluid dynamics and flow in mucus⁷⁷ and peripheral lymph⁷⁸
- Injection sites in tissues^{79,80}
- Lateral diffusion of lipids and receptors in membranes^{70,81–83}
- Movement of microinjected microspheres poleward during mitosis of sea urchin eggs⁸⁴ and sand dollar eggs⁸⁵
- Particle flow through a model biofilm containing *Pseudomonas aeruginosa*, *P. fluorescens* and *Klebsiella pneumoniae* using confocal laser-scanning microscopy⁸⁶ (Figure 14.6.6)
- Sentinel lymph node detection⁸⁷
- Three-dimensional motion of microspheres in order to assess water permeability in individual Chinese hamster ovary (CHO) cells expressing CHIP28 water channels⁶⁹

Fluorescent microspheres have been used with optical tweezers⁸⁸ to control the movement of single myosin filaments⁸⁹ or kinesin molecules⁹⁰ and for imaging at suboptical resolution by scanning luminescence X-ray microscopy.⁹¹ In addition, our 0.1 μm red-fluorescent carboxylate-modified microspheres (F8801, Section 6.5) have been used to model particle distribution and penetration of adenovirus-mediated gene transfer in human bronchial submucosal glands using xenografts.⁹²

Qdot® Nanocrystal Tracers

Qtracker® Cell Labeling Kits

Qtracker® Cell Labeling Kits provide spectrally distinct Qdot® nanocrystals that have been functionalized on their surface with polyarginine peptides to facilitate spontaneous uptake by live cells.⁹³ We offer the following eight kits:

- Qtracker® 525 Cell Labeling Kit (Q25041MP)
- Qtracker® 565 Cell Labeling Kit (Q25031MP)
- Qtracker® 585 Cell Labeling Kit (Q25011MP)
- Qtracker® 605 Cell Labeling Kit (Q25001MP)
- Qtracker® 625 Cell Labeling Kit (A10198)
- Qtracker® 655 Cell Labeling Kit (Q25021MP)
- Qtracker® 705 Cell Labeling Kit (Q25061MP)
- Qtracker® 800 Cell Labeling Kit (Q25071MP)

The mechanism whereby such cell penetrating peptides induce the cellular uptake of cargoes including oligonucleotides and proteins as well as Qdot® nanocrystals remains a topic of active investigation and considerable debate.^{94,95} It is, however, reasonably well established that the uptake is passive and does not require specific receptors or active transport processes. Therefore, labeling of live cells is a simple matter of adding the Qtracker® cell labeling reagents supplied in the kits to adherent or suspension cells in complete growth medium, incubating at 37°C for 45–60 minutes, followed by a wash step to remove the labeling reagents. The Qdot® nanocrystals are stably incorporated in cytoplasmic vesicles (Figure 14.6.7) and are passed to daughter cells upon cell division but are not transferred to adjacent cells in mixed cultures or host tissues. Fluorescence is not impacted by complex and varying cellular environments including changes in intracellular pH, temperature and metabolic activity. A wide range of applications for Qtracker® Cell Labeling Kits have been reported, including fiducial marking of cell populations for identification during or after downstream analysis,^{93,96} labeling of mouse cerebral vascular tissue for visualization of explantation,⁹⁷ imaging the assembly of cultured pulmonary artery

adventitial fibroblasts and endothelial cells into three-dimensional structures⁹⁸ and tracking embryonic and mesenchymal stem cells.^{99–101}

Qtracker® Non-Targeted Quantum Dots

Qtracker® non-targeted quantum dots are designed for small-animal *in vivo* imaging, and especially for studying vascular structure after microinjection^{102,103} (Figure 14.6.8). Our selection includes:

- Qtracker® 565 non-targeted quantum dots (Q21031MP)
- Qtracker® 655 non-targeted quantum dots (Q21021MP)
- Qtracker® 705 non-targeted quantum dots (Q21061MP)
- Qtracker® 800 non-targeted quantum dots (Q21071MP)

These nanocrystals exhibit intense red or near-infrared fluorescence emission for maximum transmission through tissues and avoidance of background autofluorescence. Qtracker® non-targeted quantum dots have polyethylene glycol (PEG) surface coatings to minimize nonspecific binding interactions and associated inflammatory responses.^{104,105} Because the PEG surface coating does not contain reactive functional groups, the Qtracker® non-targeted quantum dots are retained in circulation longer and can be imaged for up to 3 months without additional injections.¹⁰⁶ Qtracker® non-targeted quantum dots are supplied as 2 µM solutions in 50 mM borate buffer, pH 8.3 in units of 200 µL.

Figure 14.6.8 Chick embryo injected through the major vitelline vein with Qtracker® non-targeted quantum dots. Following a few minutes of circulation of the Qtracker® 705 non-targeted quantum dots (Q21061MP), fluorescence images of the embryo were captured at increasing magnification using 460 nm excitation and a digital imaging system equipped with appropriate emission filters. These Qtracker® reagents revealed highly detailed vascular structure at all levels of magnification. Images contributed by Greg Fisher, Carnegie Mellon University.

PRODUCT LIST 14.6 MICROSPHERES AND QDOT® NANOCRYSTALS FOR TRACING

Cat. No.	Product	Quantity
F8890	FluoSpheres® Blood Flow Determination Fluorescent Color Kit #1, polystyrene microspheres, 10 µm *seven colors, 10 mL each* *3.6 x 10 ⁶ beads/mL*	1 kit
F8891	FluoSpheres® Blood Flow Determination Fluorescent Color Kit #2, polystyrene microspheres, 15 µm *seven colors, 10 mL each* *1.0 x 10 ⁶ beads/mL*	1 kit
F8892	FluoSpheres® Blood Flow Determination Fluorescent Color Kit #3, polystyrene microspheres, 15 µm *five colors, 10 mL each* *1.0 x 10 ⁶ beads/mL*	1 kit
F21015	FluoSpheres® Blood Flow Determination Fluorescent Color Kit #4, polystyrene microspheres, 15 µm *four colors, 10 mL each* *1.0 x 10 ⁶ beads/mL*	1 kit
F8789	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, dark red fluorescent (660/680) *5% solids, azide free*	1 mL
F20880	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, europium luminescent (365/610) *0.5% solids*	2 mL
F8792	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, orange fluorescent (540/560) *5% solids, azide free*	1 mL
F20886	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, platinum luminescent (390/650) *0.5% solids*	2 mL
F8793	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, red fluorescent (580/605) *5% solids, azide free*	1 mL
F8794	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, red-orange fluorescent (565/580) *5% solids, azide free*	1 mL
F8795	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, yellow-green fluorescent (505/515) *5% solids, azide free*	1 mL
F10720	FluoSpheres® Fluorescent Color Kit, carboxylate-modified microspheres, 0.04 µm *four colors, 1 mL each* *5% solids, azide free*	1 kit
F20881	FluoSpheres® carboxylate-modified microspheres, 0.2 µm, europium luminescent (365/610) *0.5% solids*	2 mL
F13080	FluoSpheres® polystyrene microspheres, 1.0 µm, blue-green fluorescent (430/465) *for tracer studies* *1.0 x 10 ¹⁰ beads/mL*	5 mL
F13082	FluoSpheres® polystyrene microspheres, 1.0 µm, orange fluorescent (540/560) *for tracer studies* *1.0 x 10 ¹⁰ beads/mL*	5 mL
F13083	FluoSpheres® polystyrene microspheres, 1.0 µm, red fluorescent (580/605) *for tracer studies* *1.0 x 10 ¹⁰ beads/mL*	5 mL
F13081	FluoSpheres® polystyrene microspheres, 1.0 µm, yellow-green fluorescent (505/515) *for tracer studies* *1.0 x 10 ¹⁰ beads/mL*	5 mL
F8829	FluoSpheres® polystyrene microspheres, 10 µm, blue fluorescent (365/415) *for blood flow determination* *3.6 x 10 ⁶ beads/mL*	10 mL
F8830	FluoSpheres® polystyrene microspheres, 10 µm, blue-green fluorescent (430/465) *for blood flow determination* *3.6 x 10 ⁶ beads/mL*	10 mL
F8831	FluoSpheres® polystyrene microspheres, 10 µm, crimson fluorescent (625/645) *for blood flow determination* *3.6 x 10 ⁶ beads/mL*	10 mL
F8833	FluoSpheres® polystyrene microspheres, 10 µm, orange fluorescent (540/560) *for blood flow determination* *3.6 x 10 ⁶ beads/mL*	10 mL
F8834	FluoSpheres® polystyrene microspheres, 10 µm, red fluorescent (580/605) *for blood flow determination* *3.6 x 10 ⁶ beads/mL*	10 mL
F8836	FluoSpheres® polystyrene microspheres, 10 µm, yellow-green fluorescent (505/515) *for blood flow determination* *3.6 x 10 ⁶ beads/mL*	10 mL
F8837	FluoSpheres® polystyrene microspheres, 15 µm, blue fluorescent (365/415) *for blood flow determination* *1.0 x 10 ⁶ beads/mL*	10 mL
F8838	FluoSpheres® polystyrene microspheres, 15 µm, blue-green fluorescent (430/465) *for blood flow determination* *1.0 x 10 ⁶ beads/mL*	10 mL
F21013	FluoSpheres® polystyrene microspheres, 15 µm, carmine fluorescent (580/620) *for blood flow determination* *1.0 x 10 ⁶ beads/mL*	10 mL
F8839	FluoSpheres® polystyrene microspheres, 15 µm, crimson fluorescent (625/645) *for blood flow determination* *1.0 x 10 ⁶ beads/mL*	10 mL
F21010	FluoSpheres® polystyrene microspheres, 15 µm, green fluorescent (450/480) *for blood flow determination* *1.0 x 10 ⁶ beads/mL*	10 mL
F8841	FluoSpheres® polystyrene microspheres, 15 µm, orange fluorescent (540/560) *for blood flow determination* *1.0 x 10 ⁶ beads/mL*	10 mL
F8842	FluoSpheres® polystyrene microspheres, 15 µm, red fluorescent (580/605) *for blood flow determination* *1.0 x 10 ⁶ beads/mL*	10 mL
F21012	FluoSpheres® polystyrene microspheres, 15 µm, red-orange fluorescent (565/580) *for blood flow determination* *1.0 x 10 ⁶ beads/mL*	10 mL
F8843	FluoSpheres® polystyrene microspheres, 15 µm, scarlet fluorescent (645/680) *for blood flow determination* *1.0 x 10 ⁶ beads/mL*	10 mL
F21011	FluoSpheres® polystyrene microspheres, 15 µm, yellow fluorescent (515/534) *for blood flow determination* *1.0 x 10 ⁶ beads/mL*	10 mL
F8844	FluoSpheres® polystyrene microspheres, 15 µm, yellow-green fluorescent (505/515) *for blood flow determination* *1.0 x 10 ⁶ beads/mL*	10 mL
Q25041MP	Qtracker® 525 Cell Labeling Kit	1 kit
Q25031MP	Qtracker® 565 Cell Labeling Kit	1 kit
Q25011MP	Qtracker® 585 Cell Labeling Kit	1 kit
Q25001MP	Qtracker® 605 Cell Labeling Kit	1 kit
A10198	Qtracker® 625 Cell Labeling Kit	1 kit
Q25021MP	Qtracker® 655 Cell Labeling Kit	1 kit
Q25061MP	Qtracker® 705 Cell Labeling Kit	1 kit
Q25071MP	Qtracker® 800 Cell Labeling Kit	1 kit
Q21031MP	Qtracker® 565 non-targeted quantum dots *2 µM solution*	200 µL
Q21021MP	Qtracker® 655 non-targeted quantum dots *2 µM solution*	200 µL
Q21061MP	Qtracker® 705 non-targeted quantum dots *2 µM solution*	200 µL
Q21071MP	Qtracker® 800 non-targeted quantum dots *2 µM solution*	200 µL
S31201	SAIVI™ 715 injectable contrast agent *0.1 µm microspheres*	1 mL
S31203	SAIVI™ 715 injectable contrast agent *2 µm microspheres*	1 mL

14.7 Protein Conjugates

Unlike the polydisperse dextrans (Section 14.5), fluorescent protein tracers have molecular weights that are reasonably well defined (bovine serum albumin (BSA) ~66,000 daltons; ovalbumin ~45,000; codfish parvalbumin 12,328 daltons, casein ~23,600 daltons; monomeric subunit B of cholera toxin ~12,000 daltons; horseradish peroxidase (HRP) ~40,000 daltons; soybean trypsin inhibitor ~21,500 daltons; *Phaseolus vulgaris* leucoagglutinin (PHA-L) ~126,000 daltons). Some of their applications are similar to those of dextran tracers, although protein conjugates may be more susceptible to proteolysis. Through creative modifications of the proteins, however, researchers have been able to use these conjugates to target receptors, to detect protease activity and to measure intracellular pH.

Albumin Conjugates

Fluorescent BSA, Ovalbumin and Parvalbumin

For use as protein tracers, we supply bovine serum albumin (BSA) fluorescently labeled with:

- Alexa Fluor® 488 dye (A13100)
- Alexa Fluor® 555 dye (A34786)
- Alexa Fluor® 594 dye (A13101)
- Alexa Fluor® 647 dye (A34785)
- Alexa Fluor® 680 dye (A34787, S34788)
- Alexa Fluor® 750 dye dye (S34789)
- Fluorescein (A23015)
- BODIPY® FL dye (A2750)
- Tetramethylrhodamine (A23016)
- Texas Red® dye (A23017)

In addition to these BSA conjugates, we prepare fluorescein and Texas Red® conjugates of ovalbumin (O23020, O23021), as well as the intensely fluorescent Alexa Fluor® 488, Alexa Fluor® 555, Alexa Fluor® 594 and Alexa Fluor® 647 conjugates (O34781, O34782, O34783, O34784). Ovalbumin is a protein with a relatively low molecular weight (~45,000 daltons) that is primarily useful as an antigen for activation of dendritic cells, macrophages and B cells.^{1,2}

We also offer the Alexa Fluor® 488 conjugate of codfish parvalbumin (P23012), which is the smallest fluorescent protein tracer in this section. Parvalbumin, a stable and protease-resistant protein with a molecular weight of 12,328 daltons, is found in the skeletal muscle of vertebrates and the endocrine glands of mammals.³

Dinitrophenylated Bovine Serum Albumin

We offer BSA that has been conjugated to multiple dinitrophenyl hapten molecules (DNP-BSA, A23018), a reagent that is commonly used to study Fc receptor-mediated immune function⁴⁻⁶ and the IgE- and IgG-mediated responses to crosslinking of DNP-specific antibodies.^{7,8} Our dinitrophenylated BSA typically has ~25 dinitrophenyl substituents per molecule of BSA. For detection of DNP-BSA, we offer unlabeled rabbit anti-DNP antibody prepared against DNP-conjugated keyhole limpet hemocyanin (anti-DNP-KLH antibody) and the Alexa Fluor® 488 dye, fluorescein and biotin-XX antibody conjugates (A6430, A11097, A6423, A6435; Section 7.4), as well as a Qdot® 555 rat monoclonal anti-dinitrophenol antibody (Q17421MP).

DQ™ BSA, DQ™ Ovalbumin and DQ™ Collagen

DQ™ substrates, including the DQ™ Green BSA and DQ™ Red BSA (D12050, D12051) and DQ™ ovalbumin (D12053) are based on the strong fluorescence quenching effect observed when proteins are heavily conjugated with BODIPY® dyes or, in the case of DQ™ collagen conjugates (D12052, D12060), with multiple fluorescein dyes. Upon hydrolysis of the proteins to single dye-labeled peptides by proteases, this quenching is relieved (Figure 14.7.1). This technology provides an easy continuous assay for numerous proteases (Section 10.4). When complexed with an anti-BSA rabbit IgG antibody (A11133), the DQ™ BSA products are phagocytosed into live cells via the Fc receptor (Section 16.1, Figure 14.7.2), where they are broken down into fluorescent peptides^{9,10}

Figure 14.7.1 Principle of enzyme detection via the disruption of intramolecular self-quenching. Enzyme-catalyzed hydrolysis of the heavily labeled and almost totally quenched substrates provided in our EnzChek® Protease Assay Kits (E6638, E6639), EnzChek® Ultra Amylase Assay Kit (E33651), EnzChek® Gelatinase/Collagenase Assay Kit (E12055), EnzChek® Elastase Kit (E12056), EnzChek® Lysozyme Assay Kit (E22013)—as well as the stand-alone quenched substrates DQ™ BSA (D12050, D12051), DQ™ collagen (D12052, D12060), DQ™ ovalbumin (D12053) and DQ™ gelatin (D12054)—relieves the intramolecular self-quenching, yielding brightly fluorescent reaction products.

Figure 14.7.2 Immune complex of DQ™ BSA conjugate (D12050, D12051) with an anti-bovine serum albumin (BSA) antibody (A11133) for the fluorescent detection of the Fc receptor-mediated phagocytosis pathway. The DQ™ BSA is a derivative of BSA that is labeled to such a high degree with either the green-fluorescent BODIPY® FL or red-fluorescent BODIPY® TR-X dye that the fluorescence is self-quenched. Upon binding to an Fc receptor, the nonfluorescent immune complex is internalized and the protein is subsequently hydrolyzed to fluorescent peptides within the phagosome.

(Figure 14.7.1). DQ™ Green BSA, which gives bright green fluorescence upon proteolysis, and DQ™ Red BSA, which yields red-fluorescent hydrolysis products, are packaged in sets of five vials, each containing 1 mg of the substrate. Our Fc OxyBURST® Green assay reagent (F2902, Section 16.1), which is based on a similar concept, comprises BSA that has been conjugated to a dihydrofluorescein derivative and then complexed with anti-BSA IgG. Upon binding to the Fc receptor, the immune complex is internalized and oxidized to a fluorescent product within the phagosome.^{11,12}

We have found our highly quenched DQ™ ovalbumin (D12053) to be particularly useful for antigen processing and presentation studies. Ovalbumin conjugates are internalized via the mannose receptor-mediated endocytosis pathway and are recognized by antigen-presenting cells. BSA that was heavily labeled with fluorescein (FITC) has been used for these studies.¹³ However, fluorescence of the intracellular hydrolysis products of FITC BSA is significantly decreased by the acidity of the phagosome. In contrast, the bright fluorescence of the BODIPY® FL fluorophore in DQ™ ovalbumin is completely independent of the pH. The fluorescence generated after DQ™ collagen (D12052) is hydrolyzed by cellular collagenase has been used to visualize the migratory pathway followed by tumor cells during invasion of a gelatin matrix and to image proteolysis by living breast cancer cells.^{14,15}

Injectable Contrast Reagents for Small Animal *in vivo* Imaging Applications

The study of vascularization—often in tumors—requires a probe that will adequately distribute throughout the system under study without being cleared from the tissue prior to the time needed to perform imaging. For this purpose, bovine serum albumin (BSA) and human serum transferrin labeled with near-infrared-fluorescent Alexa Fluor® 680 (S34788, S34790) and Alexa Fluor® 750 (S34789, S34791) dyes are offered as injectable contrast agents in small animal *in vivo* imaging.¹⁶ These SAIVI™ injectable contrast agents have been optimized for emission intensity and tested as reagents for the *in vivo* imaging of regions of blood pooling and vascularization in an inflammatory disease model in mice. Infrared fluorescent microspheres (Section 6.5) can also be used in a similar manner.

Casein Conjugates

BODIPY® FL casein and BODIPY® TR-X casein, which are components of our EnzChek® Protease Assay Kits (E6638, E6639), are substrates for metallo-, serine, acid and sulfhydryl proteases, including cathepsin, chymotrypsin, elastase, papain, pepsin, thermolysin and trypsin¹⁷ (Section 10.4). These casein-based substrates are heavily labeled and therefore highly quenched conjugates; they typically exhibit <3% of the fluorescence of the corresponding free dyes. Protease-catalyzed hydrolysis relieves this quenching, yielding brightly fluorescent peptides (Figure 14.7.1).

The EnzChek® Protease Assay Kit (E6638, E6639) includes:

- BODIPY® FL casein (in Kit E6638) or BODIPY® TR-X casein (in Kit E6639)
- Concentrated digestion buffer
- Detailed protocols

Each kit provides sufficient reagents for ~100 assays using 2 mL assay volumes and standard fluorescence cuvettes or ~1000 assays using 200 µL assay volumes and 96-well microplates.

The EnzChek® Protease Assay Kits, as well as the DQ™ BSA and DQ™ ovalbumin substrates mentioned above, have significant potential as:

- Indicators of protease contamination in culture media
- Fluorogenic substrates for circulating or secreted proteases in extracellular fluids
- Nontoxic, pH-insensitive markers for phagocytic cells, which will ingest and eventually cleave the quenched casein substrates to yield fluorescent BODIPY® FL- or BODIPY® TR-X-labeled peptides
- Microinjectable tracers to detect enhanced protease activity associated with cell activation and fusion
- Nontoxic markers for assessing various cell-loading and cell-transfection techniques, including electroporation (Table 14.1)

The peptide hydrolysis products of BODIPY® FL casein exhibit green fluorescence that is optimally excited by the argon-ion laser at 488 nm, permitting flow sorting of the cells. The red-fluorescent BODIPY® TR-X-labeled peptides, with excitation and emission spectra similar to those of the Texas Red® fluorophore, should be useful for multilabeling experiments or measurements in the presence of green autofluorescence. Following intracellular hydrolysis, some of the lower molecular weight fluorescent peptides may diffuse into other organelles or pass through gap junctions.

PHA-L: An Important Anterograde Tracer

Our Alexa Fluor® 488, Alexa Fluor® 594 and Alexa Fluor® 647 conjugates (L11270, L32456, L32457) of *Phaseolus vulgaris* leucoagglutinin (PHA-L) are excellent fluorescent anterograde tracers.^{18,19} Iontophoretically injected PHA-L clearly demonstrates the morphological features of the filled neurons at the injection site and the labeled axons and axon terminals. Furthermore, PHA-L that has been transported is not degraded over long periods. PHA-L has been used in combination with our biotin dextran amines^{20–23} (BDA dextrans, Section 14.5) or the fluorescent dextrans fluoro-ruby and mini-ruby^{22,24,25} (D1817, D3312; Section 14.5) to demonstrate their similar transport properties and to show the distribution of anterograde-labeled fibers.^{26–28} PHA-L has been simultaneously injected with the retrograde tracer hydroxystilbamidine (H22845, Section 14.3) for double-labeling experiments.^{29,30}

Cholera Toxin Subunit B

Cholera toxin comprises two subunits, A and B, arranged in an AB₅ conformation. Subunit A is an ADP-ribosyltransferase, which disrupts the proper signaling of G proteins and eventually leads to dehydration of the cell.³¹ The 12,000-dalton nontoxic subunit B ("choleraenoid"), which is assembled into a 60,000-dalton pentamer above pH 2,³² allows the protein complex to bind to cellular surfaces via the pentasaccharide chain of ganglioside G_{M1}.³³ All Molecular Probes® cholera toxin subunit B conjugates are prepared from recombinant cholera toxin subunit B, which is completely free of the toxic subunit A, thus eliminating any concern for toxicity or ADP-ribosylating activity.

Cholera toxin subunit B and its conjugates are established as superior tracers for retrograde labeling of neurons.^{34,35} Cholera toxin subunit B conjugates bind to the pentasaccharide chain of ganglioside G_{M1} on neuronal cell surfaces and are actively taken up and transported; alternatively, they can be injected by iontophoresis. Unlike the carbocyanine-based neuronal tracers such as DiI (D282, D3911, V22885; Section 14.4), cholera toxin subunit B conjugates can be used on tissue sections that will be fixed and frozen.³⁶ Our Alexa Fluor® 488 (C22841, C34775), Alexa Fluor® 555 (C22843, C34776), Alexa Fluor® 594 (C22842, C34777) and Alexa Fluor® 647 (C34778) conjugates of cholera toxin subunit B combine this versatile tracer with the superior brightness of our Alexa Fluor® dyes to provide sensitive and selective receptor labeling and neuronal tracing.^{35,37} We also offer biotin-XX (C34779) and horseradish peroxidase (C34780) conjugates of cholera toxin subunit B for use in combination with diaminobenzidine (DAB) oxidation,³⁸ tyramide signal amplification (TSA™) techniques (Section 6.2) and Qdot® nanocrystal–streptavidin conjugates.³⁹

Fluorescent cholera toxins are also markers of lipid rafts—regions of cell membranes high in ganglioside G_{M1} that are thought to be important in cell signaling.^{40,41} The Vybrant® Lipid Raft Labeling Kits (V34403, V34404, V34405; Section 14.4) provide the key reagents, including fluorescent cholera toxin subunit B conjugates, for fluorescently labeling lipid rafts *in vivo* with our bright and extremely photostable Alexa Fluor® dyes (Figure 14.7.3).

Fluorescent Protein–Based Cytosol Marker

Fluorescent protein–based cytosolic marker BacMam GFP transduction control (B10383) incorporates all the generic advantages of BacMam 2.0 delivery technology (BacMam Gene Delivery and Expression Technology—Note 11.1) to produce nonspecific Green Fluorescent Protein (GFP) expression in a wide range of cell types. Once initiated, GFP expression lasts about 5 days in cell lines such as HeLa and CHO. In cells that divide more slowly or show contact inhibition, such as some stem cells, primary cells and neurons, we have observed useful levels of GFP expression for more than 2 weeks. Within this timeframe, labeled cells can be used for any purpose requiring stable incorporation of a passive fluorescent marker in live cells, including wound healing, migration or adhesion assays. In adoptive transfer applications, cells with undetectable levels of GFP fluorescence can be identified immunohistochemically using our anti-GFP antibodies (Section 7.4).

Phycobiliproteins

Phycobiliproteins make effective polar tracers because they are intensely fluorescent, are very soluble in water and have little tendency to bind nonspecifically to cells (Section 6.4). These intrinsically fluorescent biomolecules are stable proteins that are monodisperse and substantially larger than albumins, with molecular weights of 240,000 daltons (B- and R-phycoerythrin, P800, P801) and 104,000 daltons (allophycocyanin, A803, or crosslinked allophycocyanin, A819). Phycoerythrin has been conjugated to nuclear-localization peptide sequences to follow nuclear import processes.^{42–45} B-phycoerythrin can pass through pores in erythrocyte membranes created by streptolysin O.⁴⁶ Single molecules of R-phycoerythrin have been imaged and tracked within mammalian cells.⁴⁷

Alexa Fluor® 488 Soybean Trypsin Inhibitor

The high water solubility and chemical stability of soybean trypsin inhibitor (SBTI) may make its green-fluorescent Alexa Fluor® 488 conjugate (T23011) a useful polar tracer. This conjugate has been used as a probe for the acrosome reaction of spermatozoa.⁴⁸

Figure 14.7.3 A J774 mouse macrophage cell sequentially stained with BODIPY® FL ganglioside G_{M1} (B13950) and then with Alexa Fluor® 555 dye-labeled cholera toxin subunit B (C22843, C34776; also available as a component of V34404). The cell was then treated with an anti-CT-B antibody (a component of V34404) to induce crosslinking. Alexa Fluor® 555 dye fluorescence (top, red) and BODIPY® FL dye fluorescence (middle, green) were imaged separately and overlaid to emphasize the coincident staining (bottom, yellow). Nuclei were stained with blue-fluorescent Hoechst 33342 (H1399, H3570, H21492).

PRODUCT LIST 14.7 PROTEIN CONJUGATES

Cat. No.	Product	Quantity
A13100	albumin from bovine serum (BSA), Alexa Fluor® 488 conjugate	5 mg
A34786	albumin from bovine serum (BSA), Alexa Fluor® 555 conjugate	5 mg
A13101	albumin from bovine serum (BSA), Alexa Fluor® 594 conjugate	5 mg
A34785	albumin from bovine serum (BSA), Alexa Fluor® 647 conjugate	5 mg
A34787	albumin from bovine serum (BSA), Alexa Fluor® 680 conjugate	5 mg
A2750	albumin from bovine serum (BSA), BODIPY® FL conjugate	5 mg
A23018	albumin from bovine serum (BSA), 2,4-dinitrophenylated (DNP-BSA)	5 mg
A23015	albumin from bovine serum (BSA), fluorescein conjugate	5 mg
A23016	albumin from bovine serum (BSA), tetramethylrhodamine conjugate	5 mg
A23017	albumin from bovine serum (BSA), Texas Red® conjugate	5 mg
A803	allophycocyanin *4 mg/mL*	0.5 mL
A819	allophycocyanin, crosslinked (APC-XL) *4 mg/mL*	250 µL
A11133	anti-albumin (bovine serum), rabbit IgG fraction (anti-BSA) *2 mg/mL*	0.5 mL
B10383	BacMam GFP transduction control *BacMam 2.0*	1 mL
C34775	cholera toxin subunit B (recombinant), Alexa Fluor® 488 conjugate	100 µg
C22841	cholera toxin subunit B (recombinant), Alexa Fluor® 488 conjugate	500 µg
C34776	cholera toxin subunit B (recombinant), Alexa Fluor® 555 conjugate	100 µg
C22843	cholera toxin subunit B (recombinant), Alexa Fluor® 555 conjugate	500 µg
C34777	cholera toxin subunit B (recombinant), Alexa Fluor® 594 conjugate	100 µg
C22842	cholera toxin subunit B (recombinant), Alexa Fluor® 594 conjugate	500 µg
C34778	cholera toxin subunit B (recombinant), Alexa Fluor® 647 conjugate	100 µg
C34779	cholera toxin subunit B (recombinant), biotin-XX conjugate	100 µg
C34780	cholera toxin subunit B (recombinant), horseradish peroxidase conjugate	100 µg
D12060	DQ™ collagen, type I from bovine skin, fluorescein conjugate	1 mg
D12052	DQ™ collagen, type IV from human placenta, fluorescein conjugate	1 mg
D12050	DQ™ Green BSA *special packaging*	5 x 1 mg
D12053	DQ™ ovalbumin *special packaging*	5 x 1 mg
D12051	DQ™ Red BSA *special packaging*	5 x 1 mg
E6638	EnzChek® Protease Assay Kit *green fluorescence* *100–1000 assays*	1 kit
E6639	EnzChek® Protease Assay Kit *red fluorescence* *100–1000 assays*	1 kit
L11270	lectin PHA-L from <i>Phaseolus vulgaris</i> (red kidney bean), Alexa Fluor® 488 conjugate	1 mg
L32456	lectin PHA-L from <i>Phaseolus vulgaris</i> (red kidney bean), Alexa Fluor® 594 conjugate	1 mg
L32457	lectin PHA-L from <i>Phaseolus vulgaris</i> (red kidney bean), Alexa Fluor® 647 conjugate	1 mg
O34781	ovalbumin, Alexa Fluor® 488 conjugate	2 mg
O34782	ovalbumin, Alexa Fluor® 555 conjugate	2 mg
O34783	ovalbumin, Alexa Fluor® 594 conjugate	2 mg
O34784	ovalbumin, Alexa Fluor® 647 conjugate	2 mg
O23020	ovalbumin, fluorescein conjugate	5 mg
O23021	ovalbumin, Texas Red® conjugate	5 mg
P23012	parvalbumin from codfish, Alexa Fluor® 488 conjugate	1 mg
P800	B-phycoerythrin *4 mg/mL*	0.5 mL
P801	R-phycoerythrin *4 mg/mL*	0.5 mL
S34788	SAIVI™ Alexa Fluor® 680 injectable contrast agent *bovine serum albumin*	1 mL
S34789	SAIVI™ Alexa Fluor® 750 injectable contrast agent *bovine serum albumin*	1 mL
S34790	SAIVI™ Alexa Fluor® 680 injectable contrast agent *human serum transferrin*	1 mL
S34791	SAIVI™ Alexa Fluor® 750 injectable contrast agent *human serum transferrin*	1 mL
T23011	trypsin inhibitor from soybean, Alexa Fluor® 488 conjugate	1 mg

CHAPTER 15

Assays for Cell Viability, Proliferation and Function

15.1 Overview of Probes for Cell Viability, Cell Proliferation and Live-Cell Function	655
15.2 Viability and Cytotoxicity Assay Reagents	656
Viability/Cytotoxicity Assays Using Esterase Substrates	657
CellTrace™ Calceins: Calcein AM, Calcein Blue AM, Calcein Violet AM and Calcein Red-Orange AM	657
BCECF AM	658
Fluorescein Diacetate	658
Carboxyfluorescein Diacetate and Its Derivatives	658
Sulfofluorescein Diacetate	659
CellTracker™ Green CMFDA	659
Chloromethyl SNARF®-1 Acetate	660
Carboxynaphthofluorescein Diacetate	660
FilmTracer™ Biofilm Stains	660
Viability/Cytotoxicity and Gram Stain Assays Using Nucleic Acid Stains	660
SYTOX® Nucleic Acid Stains	661
Dimeric and Monomeric Cyanine Dyes	662
Ethidium and Propidium Dyes	663
Ethidium Monoazide	663
Hexidium Iodide: A Fluorescent Gram Stain	664
SYTO® Nucleic Acid Stains	664
SYTO® RNASelect™ Green-Fluorescent Cell Stain	665
FUN® 1 Dye: A Unique Stain for Assessing Viability of Yeast and Fungi	665
7-Aminoactinomycin D	665
Viability/Cytotoxicity Assays That Measure Oxidation or Reduction	666
High-Purity Resazurin	666
Dodecylresazurin: A Superior Probe for Cell Metabolic Studies	666
Dihydrorhodamines and Dihydrofluoresceins	666
Image-iT® LIVE Green Reactive Oxygen Species Detection Kit	667
RedoxSensor™ Red CC-1 Stain	667
Tetrazolium Salts	668
Other Viability/Cytotoxicity Assay Methods	668
Potentiometric Dyes	668
Acidotropic Stains	669
Fluorescent Glucose Analogs	669
Fluorescent Antibiotics and Related Probes	669
Fluorescent Polymyxins	669
Fluorescent Penicillin Analogs	670
BODIPY® FL Vancomycin	670
Antimalarial Agent	670
Data Table 15.2 Viability and Cytotoxicity Assay Reagents	671
Product List 15.2 Viability and Cytotoxicity Assay Reagents	673

15.3 Viability and Cytotoxicity Assay Kits for Diverse Cell Types	675
Viability Assay Kits for Animal Cells	675
LIVE/DEAD® Viability/Cytotoxicity Kit for Animal Cells	675
LIVE/DEAD® Reduced Biohazard Cell Viability Kit	678
LIVE/DEAD® Fixable Dead Cell Stain Kits	679
ArC™ Amine-Reactive Compensation Bead Kit	679
LIVE/DEAD® Cell-Mediated Cytotoxicity Kit	679
LIVE/DEAD® Sperm Viability Kit	680
LIVE/DEAD® Violet Viability/Vitality Kit	681
LIVE/DEAD® Cell Vitality Assay Kit	681
Vybrant® Cell Metabolic Assay Kit	681
Vybrant® Cytotoxicity Assay Kit	682
Viability Assay Kits for Yeast	683
LIVE/DEAD® Yeast Viability Kit	683
LIVE/DEAD® FungaLight™ Yeast Viability Kit	683
FungaLight™ CFDA AM/Propidium Iodide Yeast Vitality Kit	683
Viability Assay and Gram Stain Kits for Bacteria	684
LIVE/DEAD® BacLight™ Bacterial Viability Kits	684
LIVE/DEAD® BacLight™ Bacterial Viability and Counting Kit	686
BacLight™ RedoxSensor™ Green Vitality Kit	687
BacLight™ RedoxSensor™ CTC Vitality Kit	688
BacLight™ Bacterial Membrane Potential Kit	688
LIVE BacLight™ Bacterial Gram Stain Kit	689
ViaGram™ Red ⁺ Bacterial Gram Stain and Viability Kit	690
FilmTracer™ LIVE/DEAD® Biofilm Viability Kit	690
Wheat Germ Agglutinin Sampler Kit	691
Reverse Transcriptase Assay for Retrovirus Titering	691
ATP Determination	691
Product List 15.3 Viability and Cytotoxicity Assay Kits for Diverse Cell Types	692
15.4 Assays for Cell Enumeration, Cell Proliferation and Cell Cycle	693
Cell Enumeration and Cell Proliferation Assays for Animal Cells	693
Click-iT® Tools for Cell Proliferation Analysis	693
Proliferation Assays Using Bromodeoxyuridine Incorporation	694
Proliferation Assays Using ChromaTide® Nucleotides	695
Proliferation Assay Using the Succinimidyl Ester of Carboxyfluorescein Diacetate and Related Probes	696
CellTrace™ Violet Cell Proliferation Kit	697
CyQUANT® Cell Proliferation Assay Kit	697
CyQUANT® NF Cell Proliferation Assay Kit	698
CyQUANT® Direct Cell Proliferation Assay Kit	698
FluoReporter® Blue Fluorometric Nucleic Acid Assay Kit	699
Vybrant® MTT Cell Proliferation Assay Kit	699
Vybrant® Dil Cell-Labeling Solution	699
CountBright™ Absolute Counting Beads	699
Detection and Enumeration Assays for Microorganisms and Viruses	700
Detecting Bacteria, Yeast and Plankton Using Nucleic Acid Stains	700

BacLight™ Bacterial Stains	700
Bacteria Counting Kit	701
Cell Culture Contamination Detection Kit	702
MycoFluor™ Mycoplasma Detection Kit	702
Detecting Viruses Using Nucleic Acid Stains	703
Countess® Automated Cell Counter	703
Premo™ FUCCI Cell Cycle Sensor	704
Nucleic Acid Probes for Cell-Cycle Analysis	705
Vybrant® DyeCycle™ Stains	705
FxCycle™ Stains for Cell-Cycle Analysis	706
SYTOX® Green Nucleic Acid Stain	706
Hoechst 33258, Hoechst 33342 and DAPI	706
HCS Mitotic Index Kit	707
Data Table 15.4 Assays for Cell Enumeration, Cell Proliferation and Cell Cycle	708

15.5 Assays for Apoptosis and Autophagy	710
Apoptosis Assays Using Nucleic Acid Stains	710
DNA Stains for Detecting Apoptotic Cells	710
Membrane Permeability/Dead Cell Apoptosis Kit	710
Chromatin Condensation/Dead Cell Apoptosis Kit	711
Chromatin Condensation/Membrane Permeability/Dead Cell Apoptosis Kit	713
Violet Membrane Permeability/Dead Cell Apoptosis Kit	713
Comet (Single-Cell Gel Electrophoresis) Assay to Detect Damaged DNA	713
Apoptosis Assays that Detect DNA Strand Breaks	713
Click-iT® TUNEL Alexa Fluor® Imaging Assays	713
APO-BrdU™ TUNEL Assay Kit	714
Detecting DNA Strand Breaks with ChromaTide® Nucleotides	715
High-Content Analysis of Genotoxicity and Cytotoxicity	715
Apoptosis Assays that Detect Membrane Asymmetry	716
Violet Ratiometric Membrane Asymmetry Probe/Dead Cell Apoptosis Kit	716
Annexin V Conjugates	716
Single Channel Annexin V/Dead Cell Apoptosis Kit	717
Alexa Fluor® 488 Annexin V/Dead Cell Apoptosis Kit	718
FITC Annexin V/Dead Cell Apoptosis Kit	718
Vybrant Apoptosis Assay Kit #6	718
PE Annexin V/ Dead Cell Apoptosis Kit and APC Annexin V/Dead Cell Apoptosis Kit	718
Metabolic Activity/Annexin V/Dead Cell Apoptosis Kit	719
Mitochondrial Membrane Potential/Annexin V Apoptosis Kit	719
Violet Chromatin Condensation/Dead Cell Apoptosis Kit	719
Violet Annexin V/Dead Cell Apoptosis Kit	719
Apoptosis Assays Based on Protease Activity	720
Caspase-3 Substrates	720
Caspase-8 Substrates	720
Other Caspase and Granzyme B Substrates	720
EnzChek® Caspase-3 Assay Kits	721

RediPlate™ 96 EnzChek® Caspase-3 Assay Kit	721
Image-iT® LIVE Green Caspase Detection Kits for Fluorescence Microscopy	722
Image-iT® LIVE Red Caspase Detection Kits for Fluorescence Microscopy	722
Vybrant® FAM Caspase Assay Kits for Flow Cytometry	722
Cathepsins and Calpains	723
Apoptosis Assays Using Mitochondrial Stains	723
Image-iT® LIVE Mitochondrial Transition Pore Assay Kit for Fluorescence Microscopy	723
MitoProbe™ Transition Pore Assay Kit for Flow Cytometry	723
MitoProbe™ JC-1 Assay Kit for Flow Cytometry	724
MitoProbe™ DiIC ₁ (5) and MitoProbe™ DiOC ₂ (3) Assay Kits for Flow Cytometry	724
Assays for Autophagy	725
Autophagy Analysis Through Observation of LC3B	725
Imaging Autophagic Organelles	725
Visualizing Autolysosome Formation	726

15.1 Overview of Probes for Cell Viability, Cell Proliferation and Live-Cell Function

Cell viability, cell proliferation and many important live-cell functions—including apoptosis, cell adhesion, chemotaxis, multi-drug resistance, endocytosis, secretion and signal transduction—can be stimulated or monitored with various chemical and biological reagents. Many of these processes lead to changes in intracellular radicals (Chapter 18), free-ion concentrations (Chapter 19, Chapter 20, Chapter 21) or membrane potential (Chapter 22) that can be followed with appropriately responsive fluorescent indicators. This chapter discusses Molecular Probes® reagents and assays for detecting these diverse cell processes in live cells. Many of the assays in this chapter can be analyzed on a cell-by-cell basis and some are equally suitable for detection with a fluorescence microscope, flow cytometer or microplate reader. Most of the assays have the capacity for high-throughput analysis.

Our viability and cytotoxicity assay reagents (Section 15.2) and kits (Section 15.3) are principally used to enumerate the proportion of live and dead cells in a population.¹ In contrast, proliferation assays such as the Click-iT® EdU cell proliferation assay (Section 15.4) are primarily designed to monitor the growth rate of a cell population or to detect daughter cells in a growing population. Fluorescence-based cell viability and proliferation assays are generally less hazardous and less expensive than radioisotopic techniques, more sensitive than colorimetric methods and more convenient than animal testing methods. Unlike ⁵¹Cr-release assays, fluorescence-based assays of cell-mediated cytotoxicity do not require large samples, which can be difficult to obtain.² Furthermore, fluorescence-based protocols are more convenient than the trypan blue-based exclusion assay. This common colorimetric method for determining cell viability must be completed within 3–5 minutes because the number of blue-staining cells increases with time after addition of the dye.³

Fluorescent dye-based assays for cell viability and cytotoxicity are reliable and easy to perform. Our stand-alone reagents for these assays are described in Section 15.2, whereas our kits for viability and cytotoxicity analysis are discussed in Section 15.3. Molecular Probes® LIVE/DEAD® Viability Assay Kits (Section 15.3) give researchers a choice of viability/cytotoxicity assays suitable for bacteria, fungi or higher eukaryotic cells. Our LIVE/DEAD® Reduced Biohazard Cell Viability Kit and LIVE/DEAD® Fixable Dead Cell Stain Kits (Section 15.3) permit the original viability status of a mixed-cell population to be determined following aldehyde fixation of the sample in order to kill pathogens or in preparation for antibody staining. In each case, these viability assay kits provide the reagents and a simple protocol for simultaneous quantitation of live and dead cells. We also offer several proliferation assay kits that enable researchers to rapidly monitor numbers of adherent or nonadherent cells based on the presence of newly replicated DNA, total nucleic acid content or total protein content (Section 15.4). Section 15.5 focuses on our probes for monitoring apoptosis, including reagents for selectively detecting apoptotic cells based on their cell-permeability properties, as well as conjugates of annexin V phosphatidylserine-binding protein for detecting phosphatidylserine externalization. Additionally, our Premo™ Autophagy Sensors and other fluorescent probes are useful for examining the role of autophagy in normal and diseased cells.

In addition to our probes for cell viability, cell proliferation, apoptosis and autophagy, several of the reagents for live-cell function described in Section 15.6 can be used to develop assays that measure a particular biochemical parameter of interest. There is a significant overlap between probes for cell viability and probes for live-cell functions. For example, fluorogenic esterase substrates are commonly used to detect viability and proliferation, as well as to monitor cell adhesion, apoptosis and multidrug resistance. Likewise, cell-permeant and cell-impermeant nucleic acid stains are widely applicable to many live-cell function assays. We have organized discussions in this chapter according to several commonly studied cell processes in order to highlight the many published applications for these probes and foster the development of new applications.

The diversity of live cells and their environments (Figure 15.1.1) makes it impossible to devise a single viability or enumeration assay applicable to all cell types. Because viability is not easily defined in terms of a single physiological or morphological parameter,¹ it is often desirable to combine several different measures, such as enzymatic activity, membrane permeability and oxidation–reduction (redox) potential. Each assay method has inherent advantages and limitations and may introduce specific biases into the experiment; thus, different applications often call for different approaches.

Figure 15.1.1 Collage of images of cyanobacteria stained with various blue- or green-fluorescent probes to complement the natural red autofluorescence from chlorophyll and phycobilisomes. The round cells are *Synechocystis* sp. (strain PCC 6803), and their membranes were labeled with green-fluorescent BODIPY® FL propionic acid (D2183). The cylindrical cells are *Synechococcus* sp. (strain PCC 7942), stained with blue-fluorescent DAPI (D1306, D3571, D21490). The filamentous cyanobacteria, *Anabaena cylindrica*, were labeled with either the green-fluorescent cytosolic stain, CellTracker™ Green BODIPY® (C2102), or with the lipophilic membrane stain BODIPY® FL propionic acid (D2183). The image was contributed by Mary Sarcina, University College, London.

15.2 Viability and Cytotoxicity Assay Reagents

Fluorometric assays of cell viability and cytotoxicity are easy to perform with the use of a fluorescence microscope, fluorometer, fluorescence microplate reader or flow cytometer,¹ and they offer many advantages over traditional colorimetric and radioactivity-based assays. This section describes our numerous reagents for conducting viability and cytotoxicity assays in a wide variety of cells, including those of animal origin as well as bacteria and yeast. Following this discussion of individual reagents is Section 15.3, which contains a thorough description of each of our viability and cytotoxicity kits, including the:

- LIVE/DEAD® Viability/Cytotoxicity Kit (L3224)
- LIVE/DEAD® Reduced Biohazard Cell Viability Kit (L7013)
- LIVE/DEAD® Fixable Dead Cell Stain Kits (8 different fluorescent stain kits and the Sampler Kit L34960)
- LIVE/DEAD® Cell-Mediated Cytotoxicity Kit (L7010)
- LIVE/DEAD® Sperm Viability Kit (L7011)
- LIVE/DEAD® Cell Vitality Assay Kit (L34951)

- LIVE/DEAD® Violet Viability/Vitality Kit (L34958)
- Vybrant® Cell Metabolic Assay Kit, with C₁₂-resazurin (V23110)
- Vybrant® Cytotoxicity Assay Kit, G6PD release assay (V23111)
- LIVE/DEAD® Yeast Viability Kit (L7009)
- LIVE/DEAD® *FungaLight*™ Yeast Viability Kit (L34952)
- *FungaLight*™ CFDA AM/Propidium Iodide Yeast Vitality Kit (F34953)
- LIVE/DEAD® *BacLight*™ Bacterial Viability Kits (L7007, L7012, L13152, L34856)
- *BacLight*™ RedoxSensor™ Vitality Kits (B34954, B34956)
- *BacLight*™ Bacterial Membrane Potential Kit (B34950)
- *ViaGram*™ Red⁺ Bacterial Gram Stain and Viability Kit (V7023)

Also discussed both in this section and Section 15.3 are our unique single-step reagents and kits for assessing gram sign and for simultaneously determining gram sign and viability of bacteria, as well as our novel fluorescent antibiotics. Section 15.4 describes our important probes for quantitating cell proliferation, analyzing the cell cycle and detecting the presence of bacteria and mycoplasma.

Table 15.1 Esterase substrates for cell viability studies.

Esterase Substrate (Cat. No.)	Properties in Cells	pK _a of Product *
BCECF AM (B1150, B1170, B3051)	<ul style="list-style-type: none"> • Quite well retained • Released during cytolysis • pH-sensitive fluorescence 	7.0

Viability/Cytotoxicity Assays Using Esterase Substrates

We prepare a wide variety of fluorogenic esterase substrates—including calcein AM, BCECF AM and various fluorescein diacetate derivatives—that can be passively loaded into adherent and nonadherent cells. These cell-permeant esterase substrates serve as viability probes that measure both enzymatic activity, which is required to activate their fluorescence, and cell-membrane integrity, which is required for intracellular retention of their fluorescent products.

As electrically neutral or near-neutral molecules, the esterase substrates freely diffuse into most cells. In general, cell loading of acetate or acetoxymethyl ester derivatives is accomplished by initially preparing a 1–10 mM stock solution of the dye in dimethylsulfoxide (DMSO) and then diluting the stock solution into the cell medium to a final concentration of 1–25 μM (Loading and Calibration of Intracellular Ion Indicators—Note 19.1). Once inside the cell, these nonfluorescent substrates are converted by nonspecific intracellular esterases into fluorescent products that are retained by cells with intact plasma membranes. In contrast, both the unhydrolyzed substrates and their products rapidly leak from dead or damaged cells with compromised membranes, even when the cells retain some residual esterase activity. Low incubation temperatures and highly charged esterase products usually favor retention, although the rate of dye loss from viable cells also depends to a large extent on cell type (see “Multidrug Resistance” in Section 15.6). For example, mast cells and epithelial cells actively secrete many polar products.^{2,3} Table 15.1 lists Molecular Probes® esterase substrates that have been used for cell viability studies and compares their cell loading, retention and pH sensitivity. Many of the applications of these esterase substrates—for example, viability, cytotoxicity and adhesion assays—closely parallel those of ⁵¹Cr-release assays, except that the fluorescent probes do not carry the risks or the disposal costs associated with the use of radioactive materials.

CellTrace™ Calceins: Calcein AM, Calcein Blue AM, Calcein Violet AM and Calcein Red-Orange AM

Of the dyes listed in Table 15.1, calcein AM (C1430, C3099, C3100MP; Figure 15.2.1) stands out as the premier indicator of cell viability due to its superior cell retention and the relative insensitivity of its fluorescence to pH in the physiological range.^{4–7} Calcein AM, also called CellTrace™ calcein green AM (C34852), is a widely used probe for assays of cell adhesion, chemotaxis and multidrug resistance (Section 15.6). Calcein (C481, Section 14.3), which is the hydrolysis product of calcein AM, is a polyanionic fluorescein derivative (Figure 15.2.2) that has about six negative charges and two positive charges at pH 7.⁸ Calcein is better retained in viable cells than are fluorescein, carboxyfluorescein and BCECF (Figure 15.2.3) and tends to have brighter fluorescence in a number of mammalian cell types. Calcein AM has the ability to penetrate intact cornea, revealing cell viability, morphology and organization of living cornea.^{9,10} Furthermore, unlike some other dyes—including BCECF AM—calcein AM does not interfere with leukocyte chemotaxis or superoxide production, nor does it affect lymphocyte–target cell conjugation.^{6,11–14} Leakage of calcein from calcein AM–loaded cells has been used to measure the increase in membrane permeability that occurs above physiological temperatures,¹⁵ as well as to assay for cytotoxic T lymphocyte activity.⁵ Fluorescence of extracellular calcein that has leaked from cells or that has been lost during secretion, lysis or ATP-dependent anion transport can be quenched by 5 μM Co^{2+} ion or by Mn^{2+} ion. Heavy-atom quenching of calcein provides a means of detecting dye leakage and quantitating only the intracellular fluorescence.¹⁶

Dihydrocalcein AM (Figure 15.2.4) is a reasonably stable, chemically reduced form of calcein AM that requires *both* hydrolysis by intracellular esterases and oxidation within the cell to produce the green-fluorescent calcein dye. Dihydrocalcein AM resembles 2',7'-dichlorodihydrofluorescein diacetate (D399), the important indicator for oxidative activity in cells (see below), except that its oxidation product (calcein, Figure 15.2.2) should be better retained in cells than is the oxidation product of 2',7'-dichlorodihydrofluorescein diacetate. Dihydrocalcein AM (D23805) is available as a set of 20 vials, each containing 50 μg of the product.

Calcein blue AM, also called CellTrace™ calcein blue AM (C1429, C34853; Figure 15.2.5), is a viability indicator for use with instruments optimized for the detection of blue fluorescence.^{17,18} This tracer possesses AM esters that allow its passive diffusion across cell membranes. Before de-esterification, CellTrace™ calcein blue AM is only weakly fluorescent (excitation/emission maxima ~322/435 nm). Upon cleavage of the AM esters by intracellular esterases, however, this tracer becomes relatively polar and is retained by cells for several hours. In addition, its fluorescence intensity increases and its fluorescence spectra shifts to longer wavelengths, with excitation/emission

Figure 15.2.1 Calcein, AM (C1430).

Figure 15.2.2 Calcein (C481).

Figure 15.2.3 Loading and retention characteristics of intracellular marker dyes. Cells of a human lymphoid line (GePa) were loaded with the following cell-permeant acetoxymethyl ester (AM) or acetate derivatives of fluorescein: 1) calcein AM (C1430, C3099, C3100MP), 2) BCECF AM (B1150), 3) fluorescein diacetate (FDA, F1303), 4) carboxyfluorescein diacetate (CFDA, C1354) and 5) CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate, C2925, C7025). Cells were incubated in 4 μM staining solutions in Dulbecco's modified eagle medium containing 10% fetal bovine serum (DMEM+) at 37°C. After incubation for 30 minutes, cell samples were immediately analyzed by flow cytometry to determine the average fluorescence per cell at time zero (0 hours). Retained cell samples were subsequently washed twice by centrifugation, resuspended in DMEM+, maintained at 37°C for 2 hours and then analyzed by flow cytometry. The decrease in the average fluorescence intensity per cell in these samples relative to the time zero samples indicates the extent of intracellular dye leakage during the 2-hour incubation period.

Figure 15.2.10 Oregon Green® 488 carboxylic acid (O6146).

maxima of ~360/449 nm. Calcein blue AM is useful for viability measurements in combination with our SYTOX® Green nucleic acid stain (see below) and other green- or red-fluorescent probes.

Calcein Violet AM (C34858) is optimized for use in flow cytometry. The enzymatic conversion of the virtually nonfluorescent cell-permeant calcein violet AM to the intensely fluorescent calcein violet (excitation/emission maxima ~400/452 nm) is efficiently excited by the 405 nm violet diode laser.

We also offer CellTrace™ calcein red-orange AM (C34851). Upon cleavage by intracellular esterases, CellTrace™ calcein red-orange (excitation/emission maxima ~576/589 nm) is well retained by live cells that possess intact plasma membranes. Unlike calcein AM, CellTrace™ calcein red-orange AM is intrinsically fluorescent; thus, an additional wash step may be necessary to minimize background fluorescence from dye that is not taken up by cells. CellTrace™ calcein red-orange AM is a useful cell tracer and indicator of cell viability and can be used in combination with green-fluorescent probes such as the Fluo-4 Ca²⁺ indicator (Section 19.3).¹⁹

BCECF AM

BCECF AM (B1150, B1170, B3051) is extensively used for detecting cytotoxicity and for determining the ability of surviving cells to proliferate.^{20,21} The intracellular hydrolysis product of BCECF AM, BCECF (B1151, Section 20.2), has 4–5 negative charges (Figure 15.2.6), a property that considerably improves its cell retention in viable cells over that of fluorescein or carboxyfluorescein (Figure 15.2.3). However, because the emission intensity of BCECF is only half-maximal at pH 7.0 (pK_a = 6.98)—and is even further reduced in a cell's acidic compartments—the signal intensity of BCECF may be less than optimal in some cell viability and cell adhesion assays.

Using monoclonal antibodies known to either enhance or inhibit natural killer (NK) cell function, researchers found that BCECF AM was at least as effective as ⁵¹Cr for measuring NK activity. Furthermore, the fluorescence-based assay could be performed with smaller samples.²² BCECF AM has also been used to screen for trypanocidal activity²³ and viability of islets.

Fluorescein Diacetate

Fluorescein diacetate (FDA, F1303) was one of the first probes to be used as a fluorescent indicator of cell viability.^{24–26} FDA is still occasionally used to detect cell adhesion²⁷ or, in combination with propidium iodide (P1304MP, P3566, P21493), to determine cell viability.^{28,29} However, fluorescein (F1300, Section 20.2), which is formed by intracellular hydrolysis of FDA, rapidly leaks from cells (Figure 15.2.3). Thus, other cell-permeant dyes such as calcein AM and BCECF AM are now preferred for cell viability assays.

Carboxyfluorescein Diacetate and Its Derivatives

The high leakage rate of fluorescein from cells^{26,30} prompted the development of carboxyfluorescein diacetate (CFDA), which was originally used to measure intracellular pH³¹ but was soon adapted for use as a cell viability indicator.^{32,33} Upon hydrolysis by intracellular nonspecific esterases, CFDA forms carboxyfluorescein (C194, C1904; Section 14.3). As compared with fluorescein, carboxyfluorescein contains extra negative charges (Figure 15.2.7) and is therefore better retained in cells⁶ (Figure 15.2.3). CFDA is moderately permeant to most cell membranes, with uptake greater at pH 6.2 than at pH 7.4.³¹ The mixed-isomer preparation of CFDA (5(6)-CFDA, C195) is usually adequate for cell viability measurements; however, we also prepare high-purity single isomers of CFDA (C1361, C1362). In addition, we offer the electrically neutral AM ester of CFDA (5-CFDA, AM; C1354; Figure 15.2.8), which can be loaded into cells at lower concentrations than CFDA. Upon hydrolysis by intracellular esterases, this AM ester also yields carboxyfluorescein.^{34–36} CFDA, CFDA AM and sulfofluorescein diacetate (see below) have been proposed for detection of living organisms on Mars.³⁷ Hemoglobin can be used to quench extracellular fluorescence due to leakage of probes or leakage of products, such as fluorescein or carboxyfluorescein.³⁸ Alternatively, antibodies directed against the fluorescein hapten (Section 7.4, Table 7.8) or the membrane-impermeant reagent trypan blue can be used to quench low levels of extracellular fluorescence of some fluorescein-based dyes.

CFDA has been used as a viability probe with a variety of cells, including bacteria,³⁹ fungi (e.g., *Saccharomyces cerevisiae*),⁴⁰ spermatozoa,⁴¹ natural killer (NK) cells^{19,42} and tumor cells.⁴³ Cytotoxicity assays using either CFDA or 5-(and 6)-carboxy-2',7'-dichlorofluorescein diacetate (carboxy-DCFDA, C369) show good correlation with results obtained using the radioisotopic ⁵¹Cr-release method.^{19,44} With its low pK_a, carboxy-DCFDA is frequently used as a selective

probe for the relatively acidic yeast vacuole.^{45–47} Oregon Green® 488 carboxylic acid diacetate (carboxy-DFFDA, O6151, Figure 15.2.9) also exhibits a low pK_a (~4.7) and may be similarly useful as a vital stain. Its intracellular hydrolysis product—Oregon Green® 488 carboxylic acid (O6146, Section 1.5, Figure 15.2.10)—is more photostable than carboxyfluorescein.

Sulfofluorescein Diacetate

Sulfofluorescein diacetate (SFDA, S1129), which is converted by intracellular esterases to fluorescein sulfonic acid (F1130, Section 14.3), is more polar than CFDA and consequently may be more difficult to load into some viable cells. However, SFDA's polar hydrolysis product, fluorescein sulfonic acid, is better retained in viable cells than is carboxyfluorescein.^{48–51} SFDA was used to stain live bacteria and fungi in soil; little interference from autofluorescence of soil minerals or detritus was observed.^{17,52}

CellTracker™ Green CMFDA

The CellTracker™ dyes are thiol-reactive fluorescent dyes that are retained in many live cells through several generations (Figure 15.2.3) and are not transferred to adjacent cells in a population (Figure 15.2.11, Figure 15.2.12, Figure 15.2.13), except possibly through gap

junctions. These dyes represent a significant breakthrough in the cellular retention of fluorescent probes and are ideal long-term tracers for transplanted cells or tissues (Section 14.2).

CellTracker™ Green CMFDA (C2925, C7025) freely diffuses into the cell, where its weakly thiol-reactive chloromethyl moieties react with intracellular thiols and their acetate groups are cleaved by cytoplasmic esterases (Figure 15.2.14), generating the fluorescent product (Figure 15.2.15). The other CellTracker™ probes (coumarin, BODIPY® and tetramethylrhodamine derivatives; Section 14.2) do not require enzymatic cleavage to activate their fluorescence. Because the CellTracker™ dyes may react with both glutathione and proteins, cells with membranes that become compromised after staining may retain some residual fluorescent conjugates. However, use of a membrane-impermeant probe such as propidium iodide (P1304MP, P3566, P21493), SYTOX® Blue (S11348, S34857), SYTOX® Orange (S11368), SYTOX® Red (S34859), SYTOX® AADvanced™ (S10274, S10349) or one of our "dimeric" or "monomeric" nucleic acid stains (see below) in combination with CellTracker™ Green CMFDA should permit relatively long-term cytotoxicity assays. CellTracker™ Green CMFDA and ethidium homodimer-1 (EthD-1, E1169) have been used to detect viable and nonviable cells in rat and human coronary and internal thoracic arteries sampled at autopsy⁵³ and in connective tissue explants.⁵⁴

Figure 15.2.11 HL60 cells that have been stained with CellTracker™ Orange CMTMR (C2927) and then mixed with WEHI 7.1 cells stained with CellTracker™ Green CMFDA (C2925, C7025) (left). Several minutes after initiating cell–cell electrofusion, a CMTMR-stained HL60 cell is observed fusing with a CMFDA-stained WEHI 7.1 cell; cytoplasmic mixing is evident by the appearance of yellow fluorescence. After electrofusion is complete, dual-fluorescing (yellow) hybrids can be easily distinguished (right). Images contributed by Mark J. Jaroszeski, University of South Florida.

Figure 15.2.12 Individual populations of mouse myeloma (P3X) cells stained with our reactive tracers—CellTracker™ Orange CMTMR (C2927), CellTracker™ Green CMFDA (C2925) and CellTracker™ Blue CMAC (C2110). Each of three cell populations was stained with a different tracer and then the populations were mixed, demonstrating that these tracers allow simultaneous long-term monitoring of different groups of cells in transplantation and other assays.

Figure 15.2.13 Rat basophilic leukemia (RBL) cells labeled in suspension with CellTracker™ Blue CMAC (C2110), CellTracker™ Green CMFDA (C2925, C7025) or CellTracker™ Orange CMTMR (C2927) prior to plating. The image was acquired using optical filter sets appropriate for DAPI, fluorescein and the Texas Red® dye.

Figure 15.2.14 Intracellular reactions of our fixable CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate; C2925, C7025). Once this membrane-permeant probe enters a cell, esterase hydrolysis converts nonfluorescent CMFDA to fluorescent 5-chloromethylfluorescein, which can then react with thiols on proteins and peptides to form aldehyde-fixable conjugates. This probe may also react with intracellular thiol-containing biomolecules first, but the conjugate is nonfluorescent until its acetates are removed.

Figure 15.2.15 Detection of organisms in marine sediments by incubating an intact sediment core sample with the fixable, cell-permeant CellTracker™ Green CMFDA (C2925, C7025). The core sample was subsequently embedded, sectioned and examined for fluorescently labeled organisms. The micrograph reveals the microorganism *Leptohalysis scotti*, a marine benthic foraminifera. FilmTracer™ FM® 1-43 green biofilm cell stain appears to bind to the cell membrane. This stain has been shown to work equally well on *Staphylococcus epidermidis*, *Pseudomonas aeruginosa* and *Escherichia coli*, exhibiting exceptional cell specificity in each case. The image was obtained using a Leica TCS-SP2 AOBs confocal microscope and a 63×/0.9 NA water immersion objective. Image contributed by Betsey Pitts and Ellen Swogger, Center for Biofilm Engineering, Montana State University.

Chloromethyl SNARF®-1 Acetate

Chloromethyl SNARF®-1 acetate (C6826, Figure 15.2.16) is the only cell-tracking dye (and pH indicator) that exhibits bright red cytoplasmic fluorescence (Figure 15.2.17) when excited at the same wavelengths used to excite the green-fluorescent hydrolysis product of CMFDA. The spectral characteristics of these two dyes permit simultaneous tracking of two cell populations by either fluorescence microscopy or flow cytometry. The large Stokes shift of the SNARF® fluorophore also makes chloromethyl SNARF®-1 acetate useful as a viability indicator in cells that exhibit green autofluorescence when excited by the 488 nm spectral line of the argon-ion laser.

Carboxynaphthofluorescein Diacetate

Carboxynaphthofluorescein diacetate (C13196, Figure 15.2.18), which is cleaved by intracellular esterases to yield red-fluorescent carboxynaphthofluorescein (excitation/emission maxima ~598/668 nm), is the only long-wavelength tracer of this type that can be passively loaded into live cells.⁵⁵ Like chloromethyl SNARF®-1 acetate, carboxynaphthofluorescein diacetate is usually used in combination with a green-fluorescent tracer for detecting cell–cell interactions.

FilmTracer™ Biofilm Stains

Bacterial biofilms present a unique set of challenges for fluorescent staining and subsequent imaging. A typical biofilm not only exhibits heterogeneous thickness throughout the surface, placing stringent restrictions on stain penetration, but also contains regions of widely varying environmental conditions. Evidence suggests that bacterial cells exist in various physiological states within these biofilm microenvironments. Furthermore, biofilms contain many poorly defined components (e.g., the extracellular polymeric matrix) that differ with species and conditions.

FilmTracer™ calcein violet, FilmTracer™ calcein green and FilmTracer™ calcein red-orange biofilm stains (F10320, F10322, F10319) are acetoxymethyl (AM) ester derivatives of fluorescent indicators that provide reliable indication of esterase activity in live cells and are of particular use in biofilm applications. FilmTracer™ calcein violet and FilmTracer™ calcein green biofilm stains are colorless and nonfluorescent until the AM ester is hydrolyzed. FilmTracer™ calcein red-orange biofilm stain is fluorescent prior to cleavage; however, the intracellular fluorescence is much brighter than background fluorescence after rinsing.

FM® dyes are lipophilic styryl compounds useful as general-purpose probes for investigating endocytosis and for identifying cell membrane boundaries (Section 14.4). These styryl dyes are easily applied to cells, where they bind rapidly and reversibly to the plasma membrane with strong fluorescence enhancement.^{56–58} FilmTracer™ FM® 1-43 green biofilm cell stain (F10317) has been used successfully to stain the cell bodies in a complex biofilm milieu, including *Pseudomonas aeruginosa* (Figure 15.2.19), *Escherichia coli*, *Staphylococcus* sp., *Acidithiobacillus caldus* and *Vibrio cholerae*.⁵⁹

Our SYPRO® Ruby stain labels most classes of proteins, including glycoproteins, phosphoproteins, lipoproteins, calcium binding proteins, fibrillar proteins and other proteins that are difficult to stain⁶⁰ (Section 9.3). FilmTracer™ SYPRO® Ruby Biofilm Matrix Stain (F10318) is a specially formulated version of the SYPRO® Ruby stain and has been found to stain the matrix of *Pseudomonas aeruginosa* (ATCC 15442) and some strains of *Escherichia coli*; it does not stain *E. coli* K-12, which does not produce cellulose. As with all the biofilm stains, staining patterns may vary depending upon the organism and the matrix composition.

Viability/Cytotoxicity and Gram Stain Assays Using Nucleic Acid Stains

Viability assessments of animal cells, bacteria and yeast frequently employ polar and therefore cell-impermeant nucleic acid stains to detect the dead-cell population. Nucleic acid stains are most often used in combination with intracellular esterase substrates (see above), membrane-permeant nucleic acid stains (see below), membrane potential-sensitive probes (Chapter 22), organelle probes (Chapter 12) or cell-permeant indicators (Chapter 19, Chapter 20 and Chapter 21) to simultaneously detect the live-cell population. Although many other cell-impermeant dyes can be used to detect dead cells, the high concentrations of nucleic acids in cells, coupled with the large fluorescence enhancement exhibited by most of our nucleic acid stains upon binding, make cell-impermeant nucleic acid stains the logical candidates for viability probes. See Table 8.2 for

a list of several cell-impermeant nucleic acid stains and Section 8.1 for a general discussion of dye binding to nucleic acids.

SYTOX® Nucleic Acid Stains

Many polar nucleic acid stains will enter eukaryotic cells with damaged plasma membranes yet will not stain dead bacteria with damaged plasma membranes. SYTOX® Green nucleic acid stain (S7020) is a high-affinity probe that easily penetrates eukaryotic cells and both gram-positive and gram-negative bacteria with compromised plasma membranes, yet is completely excluded from live cells.⁶¹ After brief incubation with the SYTOX® Green nucleic acid stain, dead bacteria fluoresce bright green when excited with the 488 nm spectral line of the argon-ion laser or any other 470–490 nm source (Figure 15.2.20). These properties, combined with its ~1000-fold fluorescence enhancement upon nucleic acid binding, make our SYTOX® Green stain a simple and quantitative dead-cell indicator for use with fluorescence microscopes, fluorimeters, fluorescence microplate readers or flow cytometers

Figure 15.2.20 Absorption and fluorescence emission spectra of the SYTOX® Green nucleic acid stain bound to DNA.

(Figure 15.2.21). We have taken advantage of the sensitivity of the SYTOX® Green nucleic acid stain in our ViaGram™ Red+ Bacterial Gram Stain and Viability Kit (V7023) and in our Single Channel Annexin V/Dead Cell Apoptosis Kit (V13240, Section 15.5). An important application of the SYTOX® Green nucleic acid stain is the high-throughput screening of bacteria for antibiotic susceptibility by fluorescence microscopy, by flow cytometry or in a fluorescence microplate reader.⁶²

The SYTOX® Green nucleic acid stain as a tool for viability assessment is not restricted to bacteria; it is also a very effective cell-impermeant counterstain in eukaryotic systems (Section 12.5). It can be used in conjunction with blue- and red-fluorescent labels for multiparameter analyses in fixed cells and tissue sections (Figure 15.2.22, Figure 15.2.23, Figure 15.2.24). Furthermore, it should be possible to combine the SYTOX® Green nucleic acid stain with one of the membrane-permeant nucleic acid stains in our SYTO® Red-, SYTO® Blue- or SYTO® Orange-Fluorescent Nucleic Acid Stain Sampler Kits (S11340, S11350, S11360) for two-color visualization of dead and live cells.

Figure 15.2.21 Quantitative flow cytometric analysis of *Escherichia coli* viability using the SYTOX® Green nucleic acid stain (S7020). A bacterial suspension containing an equal number of live and isopropyl alcohol-killed *E. coli* was stained with SYTOX® Green and analyzed using excitation at 488 nm. A bivariate frequency distribution for forward light scatter versus log fluorescence intensity (collected with a 510 nm longpass optical filter) shows two clearly distinct populations. When live and dead bacteria were mixed in varying proportions, a linear relationship between the population numbers and the actual percentage of live cells in the sample was obtained (see inset).

Figure 15.2.22 Bovine pulmonary artery endothelial cells (BPAEC) incubated with the fixable, mitochondrion-selective MitoTracker® Red CMXRos (M7512). After staining, the cells were formaldehyde-fixed, acetone-permeabilized, treated with DNase-free RNase and counterstained using SYTOX® Green nucleic acid stain (S7020). Microtubules were labeled with a mouse monoclonal anti- β -tubulin antibody, biotin-XX goat anti-mouse IgG antibody (B2763) and Cascade Blue® NeutrAvidin™ biotin-binding protein (A2663). This photograph was taken using multiple exposures through bandpass optical filters appropriate for Texas Red® dye, fluorescein and DAPI using a Nikon® Labophot 2 microscope equipped with a Quadfluor epi-illumination system.

Figure 15.2.23 A frozen section of zebrafish retina stained with mouse monoclonal antibody FRet 43 in conjunction with Texas Red®-X goat anti-mouse IgG (T6390), Alexa Fluor® 350 wheat germ agglutinin (W11263) and SYTOX® Green nucleic acid stain (S7020).

Figure 15.2.24 The mitochondria of bovine pulmonary artery endothelial cells stained with MitoTracker® Red CM-H2XRos (M7513). The cells were subsequently fixed, permeabilized and treated with RNase. Then the nuclei were stained with SYTOX® Green nucleic acid stain (S7020). The multiple-exposure photomicrograph was acquired using a fluorescence microscope equipped with bandpass filter sets appropriate for fluorescein and Texas Red® dyes.

Like the SYTOX® Green reagent, our SYTOX® Orange (S11368) and SYTOX® Blue nucleic acid stains (5 mM solution in dimethylsulfoxide (DMSO), S11348; 1 mM solution in DMSO, S34857) are high-affinity nucleic acid stains that only penetrate cells with compromised plasma membranes. The SYTOX® Orange nucleic acid stain (S11368, Figure 15.2.25) has absorption/emission maxima of 547/570 nm when bound to DNA and is optimally detected using filters appropriate for rhodamine dyes. As with the other SYTOX® dyes, the SYTOX® Orange stain is virtually nonfluorescent except when bound to nucleic acids and can be used to detect cells that have compromised membranes without a wash step.

Our SYTOX® Blue nucleic acid stain labels both DNA and RNA with extremely bright fluorescence centered near 480 nm (Figure 15.2.26), making it an excellent fluorescent indicator of cell viability (Figure 15.2.27). Unlike many blue-fluorescent dyes, the SYTOX® Blue stain is efficiently excited by the 405 nm violet diode laser. The brightness of the SYTOX® Blue complex with nucleic acids allows sensitive detection of stained cells with fluorometers, fluorescence microplate readers, flow cytometers and epifluorescence microscopes. Quantitation of membrane-compromised bacterial cells carried out with the SYTOX® Blue stain yields results identical to those obtained in parallel assays using the SYTOX® Green stain. Like the SYTOX® Green stain, the SYTOX® Blue stain does not interfere with bacterial cell growth. Because their emission spectra overlap somewhat, we have found that it is not ideal to use SYTOX® Blue stain and green-fluorescent dyes together in the same application, except when the green-fluorescent dye is excited beyond the absorption of the SYTOX® Blue dye (e.g., at >480 nm). However, emission of the SYTOX® Blue complex with nucleic acids permits clear discrimination from red- and orange-fluorescent probes, facilitating development of multicolor assays with minimal spectral overlap between signals.

SYTOX® Red dead cell stain (S34859) is a simple and quantitative single-step dead-cell indicator for use with red laser-equipped flow cytometers. SYTOX® Red dead cell stain is a high-affinity nucleic acid stain that easily penetrates cells with compromised plasma membranes but will not cross uncompromised cell membranes. After brief incubation with SYTOX® Red stain, the nucleic acids of dead cells fluoresce

bright red when excited with 633 or 635 nm red laser light. SYTOX® Red nucleic acid stain has absorption/emission maxima of 633/660 nm when bound to DNA and is optimally detected using filters appropriate for Alexa Fluor® 647 dye. SYTOX® Red dead cell stain is distinct from other dead cell probes like 7-AAD and PI, which require 488 nm excitation.

Unlike the other SYTOX® stains, SYTOX® AADvanced™ Dead Cell Stain Kits (S10274, S10349) provide separate vials of dried dye and anhydrous DMSO to help ensure a stable shelf life. SYTOX® AADvanced™ dead cell stain is a high-affinity nucleic acid stain for the detection of dead cells and analysis of cell cycle using the common 488 nm spectral line of the argon-ion laser in flow cytometry. The dye is spectrally similar to 7-AAD but exhibits rapid uptake kinetics and relatively low cellular staining variability. SYTOX® AADvanced™ dead cell stain penetrates cells more efficiently than does 7-AAD, providing better separation of live and dead cell fluorescence signals. SYTOX® AADvanced™ dead cell stain can also be used with fixed cells for DNA content analysis when paired with RNase treatment.

Dimeric and Monomeric Cyanine Dyes

The dimeric and monomeric cyanine dyes in the TOTO® and TO-PRO® series (Table 8.2) are essentially nonfluorescent unless bound to nucleic acids and have extinction coefficients 10–20 times greater than that of DNA-bound propidium iodide. Spectra of the nucleic acid-bound dyes cover the entire visible spectrum and into the infrared region (Figure 15.2.28). These dyes are typically impermeant to the membranes of live cells⁶³ but brightly stain dead cells that have compromised membranes. However, YO-PRO®-1 and other polar stains are taken up by some live cells via the P2X₁₋₇ receptors⁶⁴ as well as by apoptotic cells (Section 15.5), so care needs to be taken when assaying cell viability with nucleic acid stains. The POPO™-1 and BOBO™-1 dyes may be useful blue-fluorescent dead-cell stains, and the YOYO®-3 and TOTO®-3 dyes and the corresponding YO-PRO®-3 and TO-PRO®-3 dyes have excitation maxima beyond 600 nm when bound to DNA. Our JOJO™-1 and JO-PRO™-1 dyes exhibit orange fluorescence (~545 nm) upon binding to nucleic acids and can be excited with a 532 nm Nd:YAG laser. The LOLO™-1 nucleic acid stain has longer-wavelength fluorescence (~580 nm). Our Nucleic Acid Stains Dimer Sampler Kit (N7565)

Figure 15.2.25 A zebrafish cryosection incubated with the biotin-XX conjugate of mouse monoclonal anti- α -tubulin antibody (A21371). The signal was amplified with TSA™ Kit #22, which includes HRP-streptavidin and Alexa Fluor® 488 tyramide (T20932). The sample was then incubated with the mouse monoclonal FRet 6 antibody and was visualized with Alexa Fluor® 647 goat anti-mouse IgG (A21235), which is pseudocolored magenta. Finally, the nuclei were counterstained with SYTOX® Orange nucleic acid stain (S11368).

Figure 15.2.26 Absorption and fluorescence emission spectra of SYTOX® Blue nucleic acid stain bound to DNA.

Figure 15.2.27 A mixed population of live and isopropyl alcohol-killed *Micrococcus luteus* stained with SYTOX® Blue nucleic acid stain (S11348), which does not penetrate intact plasma membranes. Dead cells exhibit bright blue-fluorescent staining. The image was acquired using a longpass optical filter set appropriate for the Cascade Blue® dye.

provides a total of eight cyanine dyes that span the visible spectrum. This kit should be useful when screening dyes for their utility in viability and cytotoxicity assays.

One cell viability assay utilizes YOYO[®]-1 fluorescence before and after treatment with digitonin as a measure of the dead cells and total cells, respectively, in the sample.⁶⁵ The YOYO[®]-3 dye was used as a stain for dead cells in an assay designed to correlate cell cycle with metabolism in single cells.⁶⁶ In addition to their use as dead-cell stains, both the dimeric and monomeric cyanine dyes are also proving useful for staining viruses. TOTO[®]-1 dye-staining and flow cytometric analysis gave better discrimination of live and dead lactic acid bacteria in several species than did propidium iodide.⁶⁷ Viruses stained with the YOYO[®]-1 and POPO[™]-1 dyes have been employed to identify and quantitate bacteria and cyanobacteria in marine microbial communities.⁶⁸ The YO-PRO[®]-1 dye has been used to count viruses in marine and freshwater environments by epifluorescence microscopy⁶⁹ and is also selectively permeant to apoptotic cells⁷⁰ (Section 15.5). TO-PRO[®]-3 (T3605, Section 15.4) has been utilized to demonstrate transient permeabilization of bacterial cells by sublethal doses of antibiotics.⁷¹

Ethidium and Propidium Dyes

The red-fluorescent, cell-impermeant ethidium and propidium dyes—ethidium bromide (15585-011), ethidium homodimer-1 (EthD-1, E1169; Figure 15.2.29) and propidium iodide (P1304MP, P3566, P21493)—can all be excited by the argon-ion laser and are therefore useful for detecting and sorting dead cells by flow cytometry.^{72,73} Moreover, these dyes have large Stokes shifts and may be used in combination with fluorescein-based probes (such as calcein, CellTracker[™] Green CMFDA or BCECF) or green-fluorescent SYTO[®] dyes (Table 8.3) for two-color applications (Figure 15.2.30). Both propidium iodide and ethidium bromide have been extensively used to detect dead or dying cells,^{74–78} although ethidium bromide may be somewhat less reliable because it is not as highly charged. EthD-1 and propidium iodide are superior to ethidium bromide for two-color flow cytometric viability assays in which either BCECF AM or calcein AM is used as the live-cell stain because their spectra do not overlap as much with those of the green-fluorescent esterase probes.²¹

With its high affinity for DNA and low membrane permeability,^{79–82} EthD-1 is often the preferred red-fluorescent dead-cell indicator. EthD-1 binds to nucleic acids 1000 times more tightly than does ethidium bromide and undergoes about a 40-fold enhancement of fluorescence upon binding.^{81,83} When used as a viability indicator, EthD-1 typically does not require a wash step. Also, the high affinity of EthD-1 permits the use of very low concentrations to stain dead cells, thus avoiding the use of large quantities of the potentially hazardous ethidium bromide or propidium iodide. EthD-1, the dead-cell indicator in our LIVE/DEAD[®] Viability/Cytotoxicity Kit (L3224, Section 15.3), has been used alone⁸⁴ or in combination with calcein AM⁸⁵ to detect tumor necrosis factor activity and to assay neuronal cell death.^{75,86,87} Ethidium homodimer-2 (E3599, Figure 15.2.31), which we use as the DEAD Red[™] necrotic-cell indicator in our LIVE/DEAD[®] Reduced Biohazard Cell Viability Kit #1 (L7013, Section 15.3), has a particularly low dissociation rate from cellular nucleic acids, permitting its use for selective marking of dead-cell populations that need to be observed over several hours. Our DEAD Red[™] nucleic acid stain has proven useful for determining brain stem lesion size *in vivo* in rats following a neurotoxin injection.⁸⁸ Live and dead cells of the yeast-like fungus *Aureobasidium pullulans* have been identified on microscope slides as well as leaf surfaces using CellTracker[™] Blue CMAC (C2110, Section 14.2) in conjunction with the DEAD Red[™] nucleic acid stain.⁸⁹

Ethidium Monoazide

Ethidium monoazide (E1374) is a fluorescent photoaffinity label that, after photolysis, binds covalently to nucleic acids in solution and in cells with compromised membranes.^{90,91} A mixed population of live and dead cells incubated with this membrane-impermeant dye can be illuminated with a visible-light source, washed, fixed and then analyzed in order to determine the viability of the cells at the time of photolysis. Thus, ethidium monoazide reduces some of the hazards inherent in working with pathogenic samples because, once stained, samples can be treated with fixatives before analysis by fluorescence microscopy or flow cytometry.⁹¹ Immunocytochemical analyses requiring fixation are also compatible with this ethidium monoazide-based viability assay. We have developed an alternative two-color fluorescence-based assay for determining the original viability of fixed samples that employs our cell-permeant, green-fluorescent SYTO[®] 10 and cell-impermeant, red-fluorescent DEAD Red[™] nucleic acid stains; the LIVE/DEAD[®] Reduced Biohazard Cell Viability Kit #1 (L7013) is described in Section 15.3.

Figure 15.2.32 Hexidium iodide (H7593).

Figure 15.2.33 Methanol-fixed bovine pulmonary artery endothelial cells treated with RNase, DNase or both, and then labeled with SYTO® RNASelect™ Green cell stain (S32703). Removal of RNA with RNase prevented nucleolar labeling and greatly decreased nuclear and cytoplasmic labeling. Use of DNase resulted in less of a loss of label intensity in these cell compartments, reflecting the RNA-selective nature of this dye.

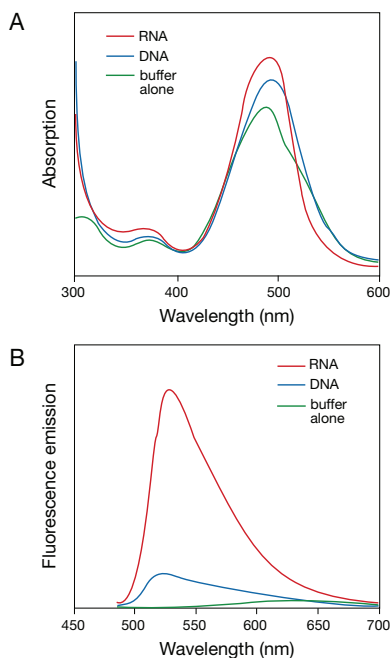

Figure 15.2.34 Absorption (A) and fluorescence emission (B) spectra of SYTO® RNASelect™ green-fluorescent cell stain (S32703) in the presence of *Escherichia coli* DNA or in buffer alone.

Hexidium Iodide: A Fluorescent Gram Stain

Ethidium bromide is only marginally permeant to cell membranes or bacteria; however, we found that our hexidium iodide stain (H7593) has the right combination of polarity and permeability (Figure 15.2.32) to allow it to rapidly stain most gram-positive bacteria while being excluded by the less-permeant membranes of most gram-negative bacteria.⁹² Combining the red-orange-fluorescent hexidium iodide reagent with a green-fluorescent, membrane-permeant nucleic acid stain—as in our LIVE *BacLight*™ Bacterial Gram Stain Kit (L7005, Section 15.3)—enables taxonomic classification of most bacteria in minutes, using a single staining solution, with no fixatives or wash steps. This rapid gram stain assay should be useful in both clinical and research settings. The validity of using hexidium iodide in combination with the SYTO® 13 green-fluorescent nucleic acid stain to correctly predict the gram sign of 45 clinically relevant organisms, including several known to be gram variable, has been demonstrated.⁹² The method of use of hexidium iodide as a gram stain is described further in Section 15.3.

SYTO® Nucleic Acid Stains

Our SYTO® family of dyes, all of which are listed in Table 8.3, are essentially nonfluorescent until they bind to nucleic acids, whereupon their fluorescence quantum yield may increase by 1000-fold or more. These dyes are freely permeant to most cells, although their rate of uptake and ultimate staining pattern may be cell dependent. Their affinity for nucleic acids is moderate and they can be displaced by higher-affinity nucleic acid stains such as SYTOX® Green, propidium iodide, the ethidium dimers and all of the monomeric and dimeric nucleic acid stains described above. Because the membrane of intact cells offers a barrier to entry of these higher-affinity nucleic acid stains, it is common to combine, for instance, a green-fluorescent SYTO® dye with a red-fluorescent, high-affinity nucleic acid stain such as propidium iodide, one of the ethidium homodimers, or TOTO®-3 for simultaneous staining of the live- and dead-cell populations. Although the green-fluorescent SYTO® dye will still bind to nucleic acids in dead cells, it will be displaced or its fluorescence quenched by the red-fluorescent dye, resulting in a yellow-, orange- or red-fluorescent dead-cell population. This principle is the basis of our LIVE/DEAD® *BacLight*™ Bacterial Viability Kits (L7007, L7012, L13152), our LIVE/DEAD® Sperm Viability Kit (L7011) and our LIVE *BacLight*™ Bacterial Gram Stain Kit (L7005), which are all discussed in Section 15.3. Four sampler kits of the SYTO® dyes (S7572, S11340, S11350, S11360) provide a total of 27 SYTO® dyes with emission maxima that range from 441 nm to 678 nm. All of the SYTO® dyes in the sampler kits are also available individually (Section 8.1), as well as several other SYTO® green-fluorescent (S32704, S34854, S34855) nucleic acid stains. The SYTO® 13 green-fluorescent nucleic acid stain (S7575) has been used in combination with:

- Ethidium bromide for studies of tissue cryopreservation⁹³
- Hexidium iodide for simultaneous viability and gram sign of clinically relevant bacteria⁹²
- Ethidium homodimer-1 for quantitation of neurotoxicity^{75,94}
- Propidium iodide to detect the effects of surfactants on *Escherichia coli* viability⁹⁵

Figure 15.2.35 Methanol-fixed MRC-5 cells stained with SYTO® RNASelect™ green-fluorescent cell stain (S32703). Nuclei were stained with DAPI (D1306, D3571, D21490); the densely stained areas are nucleoli.

Figure 15.2.36 Methanol-fixed MRC-5 cells stained with SYTO® RNASelect™ green-fluorescent cell stain (S32703). Nuclei were stained with DAPI (D1306, D3571, D21490); the densely stained areas are nucleoli.

SYTO® RNASelect™ Green-Fluorescent Cell Stain

SYTO® RNASelect™ green-fluorescent cell stain (S32703) is a cell-permeant nucleic acid stain that selectively stains RNA (Figure 15.2.33). Although virtually nonfluorescent in the absence of nucleic acids, SYTO® RNASelect™ stain exhibits bright green fluorescence when bound to RNA (absorption/emission maxima ~490/530 nm), but only weak fluorescence when bound to DNA (Figure 15.2.34). Filter sets that are suitable for imaging cells labeled with fluorescein (FITC) will work well for imaging cells stained with SYTO® RNASelect™ stain (Figure 15.2.35, Figure 15.2.36).

Eukaryotic cells stained with the SYTO® RNASelect™ dye show a staining pattern consistent with that of an RNA-selective probe. Maximal fluorescence is observed in the nucleoli, with faint fluorescence throughout the nucleus. Weak fluorescence is also seen throughout the cytoplasm, predominantly associated with mitochondria. The RNA localization of the SYTO® RNASelect™ stain is further supported by RNase and DNase treatments: 1) upon treatment with RNase, the nucleolar and cytoplasmic intensities are significantly reduced, as compared with control cells; 2) upon treatment with DNase, there is no significant loss of fluorescence; and 3) upon treatment with both RNase and DNase, the staining pattern is the same as that observed with RNase treatment alone.

Because the SYTO® RNASelect™ green-fluorescent cell stain is cell permeant, it is suitable for use in live cells. After the cells have been stained, they may be fixed in methanol with minimal loss of the staining pattern. If desired, cells can also be fixed in methanol before staining RNA with the SYTO® RNASelect™ stain. Fixation with formaldehyde alters the staining pattern and is not recommended.

FUN® 1 Dye: A Unique Stain for Assessing Viability of Yeast and Fungi

While structurally related to the SYTO® dyes, FUN® 1 dye (F7030) contains substituents (Figure 15.2.37) that apparently make them chemically reactive with intracellular components of yeast, provided that the yeast are metabolically active. FUN® 1 dye is freely taken up by several species of yeast and fungi and converted from a diffusely distributed pool of yellow-green-fluorescent intracellular stain into compact red-orange- or yellow-orange-fluorescent intravacuolar structures, respectively (Figure 15.2.38). Conversion of FUN® 1 dye to products with longer-wavelength emission (Figure 15.2.39) requires both plasma membrane integrity and metabolic capability. Only metabolically active cells are marked clearly with fluorescent intravacuolar structures, while dead cells exhibit extremely bright, diffuse, yellow-green fluorescence.^{61,96} The FUN® 1 cell stain is also available as a component in our LIVE/DEAD® Yeast Viability Kit (L7009, Section 15.3).

7-Aminoactinomycin D

7-AAD (7-aminoactinomycin D, A1310; Section 15.4) is a fluorescent intercalator that undergoes a spectral shift upon association with DNA. 7-AAD/DNA complexes can be excited by the argon-ion laser and emit beyond 610 nm (Figure 15.2.40), making this nucleic acid stain useful for multicolor fluorescence microscopy, confocal laser-scanning microscopy and flow cytometry. 7-AAD appears to be generally excluded from live cells, although it has been reported to label the nuclear region of live cultured mouse L cells and salivary gland polytene chromosomes of *Chironomus thummi thummi* larvae.⁹⁷ 7-AAD is also a useful marker for apoptotic cell populations (Section 15.5) and has been utilized to discriminate dead cells from apoptotic and live cells.⁹⁸ In addition, 7-AAD can be used in combination with conjugates of R-phycoerythrin (Section 6.4) in three-color flow cytometry protocols.

Viability/Cytotoxicity Assays That Measure Oxidation or Reduction

The generation of reactive oxygen species (ROS) is inevitable for aerobic organisms and, in healthy cells, occurs at a controlled rate. Under conditions of oxidative stress, ROS production is dramatically increased, resulting in subsequent alteration of membrane lipids, proteins and nucleic acids. Oxidative damage of these biomolecules is associated with aging^{99,100} and with a variety of pathological events, including atherosclerosis, carcinogenesis, ischemic reperfusion injury and neurodegenerative disorders.^{101,102}

Figure 15.2.37 FUN® 1 cell stain (F7030).

Figure 15.2.38 A culture of *Saccharomyces cerevisiae* incubated in medium containing the FUN® 1 viability indicator (F7030) and the counterstain Calcofluor White M2R, both of which are provided in our LIVE/DEAD® Yeast Viability Kit (L7009). Metabolically active yeast process the FUN® 1 dye, forming numerous red-fluorescent cylindrical structures within their vacuoles. Calcofluor stains the cell walls fluorescent blue, regardless of the yeast's metabolic state. The yeast were photographed in a single exposure through an Omega® Optical triple bandpass filter set.

Figure 15.2.39 Fluorescence emission spectra of a *Saccharomyces cerevisiae* suspension that has been stained with the FUN® 1 cell stain, which is available separately (F7030) or in our LIVE/DEAD® Yeast Viability Kit (L7009). After the FUN® 1 reagent was added to the medium, the fluorescence emission spectrum (excited at 480 nm) was recorded in a spectrofluorometer at the indicated times during a 30-minute incubation period. The shift from green (G) to red (R) fluorescence reflects the processing of FUN® 1 by metabolically active yeast cells.

Figure 15.2.43 6-Carboxy-2,7'-dichlorodihydrofluorescein diacetate, di(acetoxymethyl ester), (C2938).

Figure 15.2.44 An oxidative burst was detected by flow cytometry of cells labeled with 5-(and 6)-chloromethyl-2,7'-dichlorodihydrofluorescein diacetate, acetyl ester (CM-H₂DCFDA, C6827). Jurkat cells were incubated with 100 nM CM-H₂DCFDA. The cells were washed and resuspended in either phosphate-buffered saline (PBS, red) or PBS with 0.03% H₂O₂ (blue). The samples were analyzed on a flow cytometer equipped with a 488 nm argon-ion laser and a 525 ± 10 nm band-pass emission filter.

Metabolically active cells can oxidize or reduce a variety of probes, providing a measure of cell viability and overall cell health. This measure of viability is distinct from that provided by probes designed to detect esterase activity or cell permeability. Detecting oxidative activity and ROS in cells is also discussed in Section 18.2.

High-Purity Resazurin

Resazurin (R12204, Figure 15.2.41) has been extensively used as an oxidation–reduction indicator to detect bacteria and yeast in broth cultures and milk,^{103,104} to assess the activity of sperm^{105,106} and to assay bile acids^{107,108} and triglycerides.¹⁰⁹ Resazurin reduction also occurs with other mammalian cells, including neurons,¹¹⁰ corneal endothelial cells,¹¹¹ lymphocytes, lymphoid tumor cells and hybridoma cells.¹¹² Furthermore, resazurin has been used in high-throughput screening assays for compounds that act against *Mycobacterium tuberculosis*.¹¹³ However, correlation of the results obtained with resazurin and bioluminescent assays for ATP has been reported to be poor.¹¹⁴ Resazurin has been reported to be useful for quantitatively measuring cell-mediated cytotoxicity,¹¹⁵ cell proliferation^{116,117} and mitochondrial metabolic activity in isolated neural tissue.¹¹⁸

Dodecylresazurin: A Superior Probe for Cell Metabolic Studies

Dodecylresazurin (C₁₂-resazurin), which is available only as a component of our Vybrant® Cell Metabolic Assay Kit (V23110, Section 15.3), LIVE/DEAD® Cell Vitality Assay Kit (L34951, Section 15.3) and Metabolic Activity/Annexin V/Dead Cell Apoptosis Kit (V35114, Section 15.5), has several properties that make it superior to resazurin (and alamarBlue®) for detecting metabolic activity in cells:

- C₁₂-resazurin is freely permeant to the membranes of most cells.
- Less C₁₂-resazurin is required for equivalent sensitivity relative to resazurin.
- Unlike resazurin, which yields a product (resorufin) that rapidly leaks from viable cells, the product of reduction of C₁₂-resazurin—C₁₂-resorufin—is relatively well retained by single cells, permitting flow cytometric assay of cell metabolism and viability on a single-cell basis.
- The fluorescence developed by reduction of C₁₂-resazurin is directly proportional to cell number, and the assay is capable of detecting very low numbers of cells, even in a high-throughput microplate assay.

Dihydrorhodamines and Dihydrofluoresceins

Fluorescein, rhodamine and various other dyes can be chemically reduced to colorless, non-fluorescent leuco dyes. These "dihydro" derivatives are readily oxidized back to the parent dye by some reactive oxygen species (Section 18.2) and thus can serve as fluorogenic probes for detecting oxidative activity in cells and tissues.^{119–121} Because reactive oxygen species are produced by live but not dead cells, fluorescent oxidation products that are retained in cells can be used as viability indicators for single cells or cell suspensions. Some probes that are useful for detecting oxidative activity in metabolically active cells include:

- H₂DCFDA¹²² (2,7'-dichlorodihydrofluorescein diacetate, D399, Figure 15.2.42), carboxy-H₂DCFDA (5-(and 6)-carboxy-2,7'-dichlorodihydrofluorescein diacetate, C400) and the acetoxymethyl ester of H₂DCFDA (C2938, Figure 15.2.43), all of which require both intracellular deacetylation and oxidation to yield green-fluorescent products^{123–125}
- CM-H₂DCFDA (chloromethyl-2,7'-dichlorodihydrofluorescein diacetate, acetyl ester, C6827), which is analogous to H₂DCFDA, except that it forms a mildly thiol-reactive fluorescent product after oxidation by metabolically active cells (Figure 15.2.44), permitting significantly longer-term measurements^{126,127}
- Dihydrocalcein AM (D23805), our newest dihydrofluorescein derivative, which is converted intracellularly to calcein, a green-fluorescent dye with superior cell retention (Figure 15.2.3)
- Dihydrorhodamine 123 (D632, D23806; Figure 15.2.45) and dihydrorhodamine 6G (D633), which are oxidized in viable cells to the mitochondrial stains rhodamine 123^{128–131} and rhodamine 6G,^{132,133} respectively
- Dihydroethidium (also known as hydroethidine; D1168, D11347, D23107; Figure 15.2.46), which forms the nucleic acid stain ethidium following oxidation^{134,135} and has proven useful for detecting the viability of intracellular parasites¹³⁶

- Luminol (L8455), which is useful for chemiluminescence-based detection of oxidative events in cells rich in peroxidases, including granulocytes^{137–140} and spermatozoa¹⁴¹

These probes are all described in more detail in Section 18.2, which includes products for assaying oxidative activity in live cells and tissues.

Image-iT® LIVE Green Reactive Oxygen Species Detection Kit

The Image-iT® LIVE Green Reactive Oxygen Species Detection Kit (I36007) provides the key reagents for detecting reactive oxygen species (ROS) in live cells, including:

- Carboxy-H₂DCFDA (5-(and 6-)carboxy-2',7'-dichlorodihydrofluorescein diacetate)
- Hoechst 33342
- tert*-Butyl hydroperoxide (TBHP)
- Dimethylsulfoxide (DMSO)
- Detailed protocols for fluorescence microscopy assays

This assay is based on carboxy-H₂DCFDA (5-(and 6-)carboxy-2',7'-dichlorodihydrofluorescein diacetate), a reliable fluorogenic marker for ROS in live cells.^{142,143} In addition to carboxy-H₂DCFDA, this kit provides the common inducer of ROS production *tert*-butyl hydroperoxide (TBHP) as a positive control^{144–147} and the blue-fluorescent, cell-permeant nucleic acid stain Hoechst 33342. Oxidatively stressed and nonstressed cells can be reliably distinguished by fluorescence microscopy using this combination of dyes and the protocol provided (Figure 15.2.47).

RedoxSensor™ Red CC-1 Stain

RedoxSensor™ Red CC-1 stain (2,3,4,5,6-pentafluorotetramethyldihydrorosamine, R14060; Figure 15.2.48) passively enters live cells and is subsequently oxidized in the cytosol to a red-fluorescent product (excitation/emission maxima ~540/600 nm), which then accumulates in the mitochondria. Alternatively, this nonfluorescent probe may be transported to the lysosomes where it is oxidized. The differential distribution of the oxidized product between mitochondria and lysosomes appears to depend on the redox potential of the cytosol.^{148–150} In proliferating cells, mitochondrial staining predominates; whereas in contact-inhibited cells, the staining is primarily lysosomal (Figure 15.2.49).

Tetrazolium Salts

Tetrazolium salts are widely used for detecting redox potential of cells for viability, cytotoxicity and proliferation assays.^{151–156} Following reduction, these water-soluble, colorless compounds form uncharged, brightly colored but nonfluorescent formazans. Several of the formazans precipitate out of solution and are useful for histochemical localization of the site of reduction or, after solubilization in organic solvent, for quantitation by standard spectrophotometric techniques.

Figure 15.2.45 Dihydrorhodamine 123 (D632).

Figure 15.2.46 Dihydroethidium (hydroethidine, D1168).

Figure 15.2.48 RedoxSensor™ Red CC-1 (R14060).

Figure 15.2.47 Detection of oxidative stress in live cells using the Image-iT® LIVE Reactive Oxygen Species (ROS) Kit (I36007). Live bovine pulmonary artery endothelial cells were treated with *tert*-butyl hydroperoxide to induce oxidative stress (right) or were left untreated (left). Cells were then labeled with carboxy-H₂DCFDA, which fluoresces when oxidized by ROS, and nuclei were stained with blue-fluorescent Hoechst 33342. The stressed cells exhibited green fluorescence, signaling an increase in ROS, whereas the untreated cells showed minimal fluorescence.

Figure 15.2.49 Cellular proliferation state determines the distribution of the oxidized product of RedoxSensor™ Red CC-1 (R14060). Normal rat kidney (NRK) cells in different growth states were stained with RedoxSensor™ Red CC-1. In proliferating cells (left), the oxidized dye accumulates in mitochondria. In quiescent cells (right), the oxidized product localizes in the lysosomes.

Figure 15.2.50 5,5',6,6'-Tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarbocyanine iodide (JC-1, T3168)

Figure 15.2.51 Potential-dependent staining of mitochondria in CCL64 fibroblasts by JC-1 (T3168). The mitochondria were visualized by epifluorescence microscopy using a 520 nm longpass optical filter. Regions of high mitochondrial polarization are indicated by red fluorescence due to J-aggregate formation by the concentrated dye. Depolarized regions are indicated by the green fluorescence of the JC-1 monomers. The image was contributed by Lan Bo Chen, Dana Farber Cancer Institute, Harvard Medical School.

Figure 15.2.52 Absorption and fluorescence emission (excited at 488 nm) spectra of JC-1 in pH 8.2 buffer containing 1% (v/v) DMSO.

Reduction of MTT (M6494) remains the most common assay for tetrazolium salt-based viability testing.^{157–159} The Vybrant® MTT Cell Proliferation Assay Kit (V13154, Section 15.4) provides a simple method for determining cell number using standard microplate absorbance readers. MTT has also been used to measure adhesion of HL60 leukemia cells onto endothelial cells.¹⁶⁰ In addition to dehydrogenases, MTT is reduced by glutathione *S*-transferase¹⁶¹ (GST). Therefore, MTT may not always be a reliable cell viability probe in cells treated with compounds that affect GST activity.

Unlike MTT's purple-colored formazan product, the extremely water-soluble, orange-colored formazan product of XTT (X6493) does not require solubilization prior to quantitation, thereby reducing the assay time in many viability assay protocols. Moreover, the sensitivity of the XTT reduction assay is reported to be similar to or better than that of the MTT reduction assay.¹⁵² The XTT reduction assay is particularly useful for high-throughput screening of antiviral and antitumor agents and for assessing the effect of cytokines on cell proliferation.^{156,162–165} NBT (N6495) forms a deep blue-colored precipitate that is commonly used to indicate oxidative metabolism.^{166,167}

Other Viability/Cytotoxicity Assay Methods

A viable cell contains an ensemble of ion pumps and channels that maintain both intracellular ion concentrations and transmembrane potentials. Active maintenance of ion gradients ceases when the cell dies, and this loss of activity can be assessed using potentiometric dyes, acidotropic probes, Ca²⁺ indicators¹²² (Chapter 19) and pH indicators¹²² (Chapter 20).

Potentiometric Dyes

We offer a variety of dyes for detecting transmembrane potential gradients (Chapter 22), including several cationic probes that accumulate in the mitochondria of metabolically active cells (Section 12.2). The mitochondrion-selective rhodamine 123¹²² (R302, R22420) has been used to assess the viability of lymphocytes,¹⁶⁸ human fibroblasts,¹⁶⁹ Simian virus–transformed human cells¹⁷⁰ and bacteria;¹⁷¹ however, rhodamine 123 is not taken up well by gram-negative bacteria.¹⁷¹ Rhodamine 123 has also been used in combination with propidium iodide (P1304MP, P3566, P21493) for two-color flow cytometric viability assessment.¹⁷²

The methyl and ethyl esters of tetramethylrhodamine (T668, T669) accumulate in the mitochondria of healthy cells in an amount related to the membrane potential. The dyes are nontoxic and highly fluorescent and do not form aggregates or display binding-dependent changes in their fluorescence efficiency, permitting continuous monitoring of cell health.¹⁷³

Other potential-sensitive dyes that have proven useful in viability studies include several fast-response styryl dyes and slow-response oxonol and carbocyanine dyes. The fast-response styryl dyes such as di-4-ANEPPS (D1199, Section 22.2) give relatively large fluorescence response to potential changes. Di-4-ANEPPS was used for rapid measurement of toxicity in frog embryos.¹⁷⁴ The symmetrical bis-oxonol dyes¹²² (B413, B438; Section 22.3) have been used for viability assessment by flow cytometry^{175–177} and imaging. These slow-response dyes have also been employed to determine antibiotic susceptibility of bacteria by flow cytometry,^{178,179} and our BacLight™ Bacterial Membrane Potential Kit (B34950, Section 15.3) provides the carbocyanine dye DiOC₂(3) along with the proton ionophore CCCP for detecting membrane potential in both gram-positive and gram-negative bacteria.

The green-fluorescent cyanine dye JC-1 (5,5',6,6'-tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarbocyanine iodide, T3168, M34152; Figure 15.2.50) exists as a monomer at low concentrations or at low membrane potential; however, at higher concentrations (aqueous solutions above 0.1 μM) or higher potentials, JC-1 forms red-fluorescent "J-aggregates" (Figure 15.2.51) that exhibit a broad excitation spectrum and an emission maximum at ~590 nm (Figure 15.2.52). JC-1 has been used to investigate apoptosis,^{180,181} as well as mitochondrial poisoning, uncoupling and anoxia.¹⁸² The ability to make ratiometric emission measurements with JC-1 makes this probe particularly useful for monitoring changes in cell health. We have discovered another carbocyanine dye, JC-9 (3,3'-dimethyl-β-naphthoxazolium iodide, D22421; Figure 15.2.53), with potential-dependent spectroscopic properties.

Acidotropic Stains

Membrane-bound proton pumps are used to maintain low pH within the cell's acidic organelles. Our complete selection of stains for lysosomes and other acidic organelles, including LysoTracker® and LysoSensor™ probes, is described in Section 12.3.

The lysosomal stain neutral red (N3246), which was first used for viability measurements by Ehrlich in 1894, has been employed in numerous cytotoxicity, cell proliferation and adhesion assays.^{183–188} Although usually used as a chromophoric probe, neutral red also fluoresces at ~640 nm in viable cells and has been detected using a fluorescence microplate reader.¹⁸⁹ Furthermore, the fluorescence of neutral red and BCECF AM (or SYTOX® Green nucleic acid stain) can be measured simultaneously using a single excitation wavelength of 488 nm,¹⁸⁹ suggesting that neutral red may be an effective probe for multicolor flow cytometric determination of cell viability. Our neutral red is highly purified to reduce contaminants that might interfere with these observations.

Acridine orange (A1301, A3568) concentrates in acidic organelles in a pH-dependent manner. The metachromatic green or red fluorescence of acridine orange has been used to assess islet viability¹⁹⁰ and bacterial spore viability¹⁹¹ and to monitor physiological activity in *Escherichia coli*.¹⁹²

LysoTracker® Green DND-26 (L7526, Section 12.3) was used in a fluorometric assay of cryopreserved sperm to demonstrate both acrosomal integrity and sperm viability.¹⁹³ Of several methods used, LysoTracker® Green DND-26 staining was the quickest and easiest to use and gave excellent correlation with the SYBR® 14 staining method used in our LIVE/DEAD® Sperm Viability Kit (L7011, Section 15.3). When observed with a fluorescence microscope, sperm appeared to lose their green-fluorescent LysoTracker® Green DND-26 staining and instead exhibited red-fluorescent propidium iodide staining within about 30 seconds after motility ceased.^{194,195}

Fluorescent Glucose Analogs

Measurements of glucose uptake can be used to assess viability in a variety of organisms. 2-NBD-deoxyglucose (2-NBDG, N13195) has been used to monitor glucose uptake in living pancreatic β -cells,¹⁹⁶ the yeast *Candida albicans*¹⁹⁷ and the bacteria *Escherichia coli*.^{198–200} We also offer the fluorescent nonhydrolyzable glucose analog 6-NBD-deoxyglucose (6-NBDG, N23106). Using this probe, researchers have studied glucose uptake and transport in isolated cells^{201–203} and intact tissues.²⁰⁴ Although sensitive to its environment, NBD fluorescence typically displays excitation/emission maxima of ~465/540 nm and can be visualized using optical filters designed for fluorescein.

Figure 15.2.53 A viable bovine pulmonary artery endothelial cell incubated with the ratiometric mitochondrial potential indicator, JC-9 (D22421). In live cells, JC-9 exists either as a green-fluorescent monomer at depolarized membrane potentials, or as a red-fluorescent J-aggregate at hyperpolarized membrane potentials.

Fluorescent Antibiotics and Related Probes

Fluorescent Polymyxins

Polymyxin B is a cyclic cationic peptide antibiotic that binds to the lipopolysaccharide (LPS) component of the outer membrane of gram-negative bacteria and increases its permeability to lysozyme and hydrophobic compounds. Molecular Probes® fluorescent BODIPY® FL (P13235), Oregon Green® 514 (P13236) and dansyl (P13238) derivatives of polymyxin B are available. Dansyl polymyxin B, which fluoresces weakly when free in solution, becomes highly fluorescent (excitation/emission ~340/485 nm) upon binding to intact cells or LPS.²⁰⁵ The binding of dansyl polymyxin B to LPS can be displaced by a variety of polycationic antibiotics, as well as by Mg^{2+} . Consequently, dansyl polymyxin B displacement experiments can be used to assess the binding of various compounds, such as antibiotics and macrophage cationic proteins, to LPS and intact bacterial cells.^{206–208} Dansyl polymyxin has also been used to localize regions of high anionic lipid content in both sperm²⁰⁹ and aggregated human platelets,²¹⁰ and to analyze the morphology of lipid bilayers in preparations of acetylcholine receptor clusters from rat myotubules.²¹¹ Green-fluorescent BODIPY® FL and Oregon Green® 514 polymyxin B provide additional fluorescent color options for these experiments. Our fluorescent LPS is described in Section 13.3 and Section 16.1.

Fluorescent Penicillin Analogs

BOCILLIN™ FL penicillin and BOCILLIN™ 650/665 penicillin (B13233, B13234) are green- and infrared-fluorescent penicillin analogs, respectively, that bind selectively and with high affinity to penicillin-binding proteins present on the cytoplasmic membranes of

Figure 15.2.54 Detection of penicillin-binding proteins (PBPs) from *Escherichia coli* and *Pseudomonas aeruginosa*. The membrane fractions from *E. coli* and *P. aeruginosa* were prepared as previously described and labeled with BOCILLIN™ 650/665 penicillin (B13234). The labeled membranes were separated on an SDS-polyacrylamide gel, stained with SYPRO® Ruby and visualized using a Typhoon imager. The location of PBPs from *E. coli* are labeled to the left of the gels. Lanes 1, 3 and 5 are *E. coli* membrane preparations; lanes 2, 4 and 6 are *P. aeruginosa* membrane preparations; lanes 1 and 2 are overlays of images obtained from total protein (green) and PBP (red) scans; lanes 3 and 4 are total protein visualized with the SYPRO® Ruby protein gel stain; lanes 5 and 6 are PBPs as detected by BOCILLIN™ 650/665. Image used with permission from Wiley-VCH publishers.

eubacteria.^{212,213} When electrophoresed under nonreducing conditions, the dye-labeled penicillin-binding proteins are easily visible in the gel with sensitivity in the low nanograms²¹⁴ (Figure 15.2.54). BOCILLIN™ FL penicillin, synthesized from penicillin V and the BODIPY® FL dye (spectrally similar to fluorescein), has been used to determine the penicillin-binding protein profiles of *Escherichia coli*, *Pseudomonas aeruginosa* and *Streptococcus pneumoniae*, and these binding profiles are found to be similar to those reported by researchers using radioactively labeled penicillin V.²¹² Fluorescently labeled penicillin has also been used for direct labeling and rapid detection of whole *E. coli* and *Bacillus licheniformis*²¹⁵ and of *Enterobacter pneumoniae*.²¹⁶ The β -lactam sensor-transducer (BlaR), an integral membrane protein from *Staphylococcus aureus*, covalently and stoichiometrically reacts with β -lactam antibiotics, including BOCILLIN™ FL penicillin, by acylation of its active-site serine residue.²¹⁷

BODIPY® FL Vancomycin

BODIPY® FL vancomycin (V34850), which contains a single BODIPY® FL dye per vancomycin molecule, is a green-fluorescent analog of this important antibiotic, which is active against gram-positive bacteria, including enterococci. BODIPY® FL vancomycin is useful for detecting vancomycin binding sites^{218,219} and for the study and detection of vancomycin-resistant enterococci^{220,221} (VRE, Section 15.6).

Antimalarial Agent

The phosphonate antibiotic FR-31564 (fosmidomycin, F23103) is an effective antimalarial agent that functions by blocking a mevalonate-independent methylerythritol phosphate (MEP) pathway of isoprene synthesis.^{222–225} The antibiotic activity of fosmidomycin is potentiated by glucose 1-phosphate.^{226,227} This antibiotic is also active against several gram-negative bacteria.^{228,229}

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Spectra represent aqueous solutions of nucleic acid-bound dye. EC values are derived by comparing the absorbance of the nucleic acid-bound dye with that of free dye in a reference solvent (H₂O or MeOH).
- Acridine orange bound to RNA has Abs ~460 nm, Em ~650 nm. (Methods Cell Biol (1994) 41:401, Cytometry (1982) 2:201)
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- MW value is approximate. BCECF AM is a mixture of molecular species. Lot-specific average MW values are printed on product labels.
- BCECF AM is colorless and nonfluorescent until converted to BCECF (B1151) by acetoxymethyl ester hydrolysis.
- Acetate hydrolysis of this compound yields a fluorescent product with similar pH-dependent spectral characteristics to C1904.
- C369 is converted to a fluorescent product (C368) after acetate hydrolysis.
- Dihydrofluorescein diacetates are colorless and nonfluorescent until both of the acetate groups are hydrolyzed and the products are subsequently oxidized to fluorescein derivatives. The materials contain less than 0.1% of oxidized derivative when initially prepared. The oxidation products of C400, C2938, C6827, D399 and D2935 are 2',7'-dichlorofluorescein derivatives with spectra similar to C368.
- Hydrolysis of the acetate and acetoxymethyl ester groups of C1354 yields C1359.
- Acetoxymethyl ester hydrolysis of calcein blue, AM yields the corresponding iminodiacetic acid. The iminodiacetic acid product is water soluble and has similar spectroscopic properties to 7-hydroxy-4-methylcoumarin (H189).
- Calcein AM is converted to fluorescent calcein (C481) after acetoxymethyl ester hydrolysis.
- C6826 is converted to a fluorescent product with spectra similar to C1270 after acetate hydrolysis.
- C13196 is converted to a fluorescent product (C652) after acetate hydrolysis.
- Calcein red-orange, AM is converted to the corresponding nitrilotriacetic acid after acetoxymethyl ester hydrolysis. The nitrilotriacetic acid product is water-soluble and has similar spectroscopic properties to the AM ester form.
- This compound is susceptible to oxidation, especially in solution. Store solutions under argon or nitrogen. Oxidation may be induced by illumination.
- D632, D23806 and D633 are essentially colorless and nonfluorescent until oxidized. Oxidation products are R302 (from D632 and D23806) and R634 (from D633).
- Dihydroethidium has blue fluorescence (Em ~420 nm) until oxidized to ethidium (Ex/Em = 518/605 nm in H₂O/DNA). The reduced dye does not bind to nucleic acids. (FEBS Lett (1972) 26:169)
- JC-9 exhibits long-wavelength J-aggregate emission at ~635 nm in aqueous solutions and polarized mitochondria.
- This product is supplied as a ready-made solution in DMSO with sodium borohydride added to inhibit oxidation.
- D23805 is colorless and nonfluorescent until the AM ester groups are hydrolyzed and the resulting leuco dye is subsequently oxidized. The final product is calcein (C481).
- Although this compound is soluble in water, preparation of stock solutions in water is not recommended because of possible adsorption onto glass or plastic.
- E1169 in H₂O: Abs = 493 nm (EC = 9100 cm⁻¹M⁻¹). E3599 in H₂O: Abs = 498 nm (EC = 10,800 cm⁻¹M⁻¹). Both compounds are very weakly fluorescent in H₂O. QY increases >40-fold on binding to dsDNA.
- E1374 spectral data are for the free dye. Fluorescence is weak, but intensity increases ~15-fold on binding to DNA. After photocrosslinking to DNA, Abs = 504 nm (EC ~4000 cm⁻¹M⁻¹), Em = 600 nm. (Nucleic Acids Res (1978) 5:4891, Biochemistry (1980) 19:3221)
- F7030 is fluorescent when bound to DNA (Em = 538 nm). Uptake and processing of the dye by live yeast results in red-shifted fluorescence (Em ~590 nm).
- H7593 in H₂O: Abs = 482 nm (EC = 5500 cm⁻¹M⁻¹), Em = 625 nm (weakly fluorescent).
- This compound emits chemiluminescence upon oxidation in basic aqueous solutions. Emission peaks are at 425 nm (L8455) and 470 nm (L6868).
- Enzymatic reduction products are water-insoluble formazans with Abs = 505 nm (M6494) and 605 nm (N6495) after solubilization in DMSO or DMF. See literature sources for further information. (Histochemistry (1982) 76:381, Prog Histochem Cytochem (1976) 9:1)
- M6494 also has Abs = 242 nm (EC = 21,000 cm⁻¹M⁻¹) in MeOH.
- Spectra of N3246 are pH-dependent (pK_a ~6.7). Data reported are for 1:1 (v/v) EtOH/1% acetic acid.
- Fluorescence of NBD and its derivatives in water is relatively weak. QY and τ increase and Em decreases in aprotic solvents and other nonpolar environments relative to water. (Biochemistry (1977) 16:5150, Photochem Photobiol (1991) 54:361)
- Acetate hydrolysis of this compound yields a fluorescent product with similar spectral characteristics to O6146.
- Propidium iodide in H₂O: Abs = 493 nm (EC = 5900 cm⁻¹M⁻¹), Em = 636 nm (weakly fluorescent). Fluorescence is enhanced >10-fold on binding to dsDNA.
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- Enzymatic reduction of resazurin yields resorufin (R363).
- R14060 is colorless and nonfluorescent until oxidized. The spectral characteristics of the oxidation product (2,3,4,5,6-pentafluorotetramethylrosamine) are similar to those of T639.
- S1129 is converted to a fluorescent product (F1130) after acetate hydrolysis.
- This product is essentially nonfluorescent except when bound to DNA or RNA.
- MW: The preceding ~ symbol indicates an approximate value, not including counterions.
- The fluorescence quantum yield (QY) of SYTO® 13 dye bound to dsDNA is 0.56 (measured at 22°C).
- JC-1 forms J-aggregates with Abs/Em = 585/590 nm at concentrations above 0.1 μM in aqueous solutions (pH 8.0). (Biochemistry (1991) 30:4480)
- Enzymatic reduction product is a water-soluble formazan, Abs = 475 nm.
- Ethidium bromide in H₂O: Abs = 480 nm (EC = 5600 cm⁻¹M⁻¹), Em = 620 nm (weakly fluorescent). Fluorescence is enhanced >10-fold on binding to dsDNA.

PRODUCT LIST 15.2 VIABILITY AND CYTOTOXICITY ASSAY REAGENTS

Cat. No.	Product	Quantity
A1301	acridine orange	1 g
A3568	acridine orange *10 mg/mL solution in water*	10 mL
B1150	2,7'-bis-(2-carboxyethyl) -5-(and-6)-carboxyfluorescein, acetoxymethyl ester (BCECF, AM)	1 mg
B3051	2,7'-bis-(2-carboxyethyl) -5-(and-6)-carboxyfluorescein, acetoxymethyl ester (BCECF, AM) *1 mg/mL solution in anhydrous DMSO*	1 mL
B1170	2,7'-bis-(2-carboxyethyl) -5-(and-6)-carboxyfluorescein, acetoxymethyl ester (BCECF, AM) *special packaging*	20 x 50 µg
B13234	BOCILLIN™ 650/665 penicillin, sodium salt	1 mg
B13233	BOCILLIN™ FL penicillin, sodium salt	1 mg
C1429	calcein blue, AM	1 mg
C34853	calcein blue, AM *for flow cytometry* *for UV excitation* *special packaging*	20 x 50 µg
C34852	calcein green, AM *for flow cytometry* *for 488 nm excitation* *special packaging*	20 x 50 µg
C34851	calcein red-orange, AM *special packaging*	20 x 50 µg
C34858	calcein violet, AM *for flow cytometry* *for 405 nm excitation* *special packaging*	20 x 25 µg
C1430	calcein, AM	1 mg
C3099	calcein, AM *1 mg/mL solution in anhydrous DMSO*	1 mL
C3100MP	calcein, AM *special packaging*	20 x 50 µg
C2938	6-carboxy-2,7'-dichlorodihydrofluorescein diacetate, di(acetoxymethyl ester)	5 mg
C400	5-(and-6)-carboxy-2,7'-dichlorodihydrofluorescein diacetate (carboxy-H ₂ DCFDA) *mixed isomers*	25 mg
C369	5-(and-6)-carboxy-2,7'-dichlorofluorescein diacetate (carboxy-DCFDA) *mixed isomers*	100 mg
C13196	5-(and-6)-carboxynaphthofluorescein diacetate	10 mg
C2925	CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate)	1 mg
C7025	CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate) *special packaging*	20 x 50 µg
C1361	5-CFDA (5-carboxyfluorescein diacetate) *single isomer*	100 mg
C1362	6-CFDA (6-carboxyfluorescein diacetate) *single isomer*	100 mg
C195	5(6)-CFDA (5-(and-6)-carboxyfluorescein diacetate) *mixed isomers*	100 mg
C1354	5-CFDA, AM (5-carboxyfluorescein diacetate, acetoxymethyl ester)	5 mg
C6827	5-(and-6)-chloromethyl- 2,7'-dichlorodihydrofluorescein diacetate, acetyl ester (CM-H ₂ DCFDA) *mixed isomers* *special packaging*	20 x 50 µg
C6826	5-(and-6)-chloromethyl SNARF®-1, acetate *mixed isomers* *special packaging*	20 x 50 µg
D399	2,7'-dichlorodihydrofluorescein diacetate (2,7'-dichlorofluorescein diacetate; H ₂ DCFDA)	100 mg
D23805	dihydrocalcein, AM *special packaging*	20 x 50 µg
D1168	dihydroethidium (hydroethidine)	25 mg
D23107	dihydroethidium (hydroethidine) *5 mM stabilized solution in DMSO*	1 mL
D11347	dihydroethidium (hydroethidine) *special packaging*	10 x 1 mg
D632	dihydrorhodamine 123	10 mg
D23806	dihydrorhodamine 123 *5 mM stabilized solution in DMSO*	1 mL
D633	dihydrorhodamine 6G	25 mg
D22421	3,3'-dimethyl- α -naphthoxycarbocyanine iodide (JC-9; DiNOC ₁ (3))	5 mg
E1169	ethidium homodimer-1 (EthD-1)	1 mg
E3599	ethidium homodimer-2 (EthD-2) *1 mM solution in DMSO*	200 µL
E1374	ethidium monoazide bromide (EMA)	5 mg
F1303	FDA (fluorescein diacetate)	1 g
F10322	FilmTracer™ calcein green biofilm stain	20 x 50 µg
F10319	FilmTracer™ calcein red-orange biofilm stain	20 x 50 µg
F10320	FilmTracer™ calcein violet biofilm stain	20 x 25 µg
F10317	FilmTracer™ FM® 1-43 green biofilm matrix stain	1 mg
F10318	FilmTracer™ SYPRO® Ruby biofilm matrix stain	200 mL
F23103	fosmidomycin, sodium salt (FR-31564)	25 mg
F7030	FUN® 1 cell stain *10 mM solution in DMSO*	100 µL
H7593	hexidium iodide	5 mg
L8455	luminol (3-aminophthalhydrazide)	25 g
M6494	MTT (3-(4,5-dimethylthiazol- 2-yl)-2,5-diphenyltetrazolium bromide)	1 g
N13195	2-NBDG (2-(N-(7-nitrobenz-2-oxa- 1,3-diazol-4-yl)amino)-2-deoxyglucose)	5 mg
N3246	neutral red *high purity*	25 mg
N23106	6-(N-(7-nitrobenz-2-oxa- 1,3-diazol-4-yl)amino)-6-deoxyglucose (6-NBDG)	5 mg
N6495	nitro blue tetrazolium chloride (NBT)	1 g
N7565	Nucleic Acid Stains Dimer Sampler Kit	1 kit
O6151	Oregon Green® 488 carboxylic acid diacetate (carboxy-DFFDA) *6-isomer*	5 mg
P13235	polymyxin B, BODIPY® FL conjugate, trifluoroacetic acid salt *mixed species*	100 µg
P13238	polymyxin B, dansyl conjugate, trifluoroacetic acid salt *mixed species*	100 µg
P13236	polymyxin B, Oregon Green® 514 conjugate, trifluoroacetic acid salt *mixed species*	100 µg
P1304MP	propidium iodide	100 mg
P3566	propidium iodide *1.0 mg/mL solution in water*	10 mL

PRODUCT LIST 15.2 VIABILITY AND CYTOTOXICITY ASSAY REAGENTS—*continued*

Cat. No.	Product	Quantity
P21493	propidium iodide *FluoroPure™ grade*	100 mg
R14060	RedoxSensor™ Red CC-1 *special packaging*	10 x 50 µg
R12204	resazurin, sodium salt	10 mg
R302	rhodamine 123	25 mg
R22420	rhodamine 123 *FluoroPure™ grade*	25 mg
S1129	SFDA (5-sulfofluorescein diacetate, sodium salt)	25 mg
S32704	SYTO® 10 green fluorescent nucleic acid stain *5 mM solution in DMSO*	100 µL
S7575	SYTO® 13 green fluorescent nucleic acid stain *5 mM solution in DMSO*	250 µL
S34854	SYTO® 9 green fluorescent nucleic acid stain *5 mM solution in DMSO*	100 µL
S34855	SYTO® BC green fluorescent nucleic acid stain *5 mM solution in DMSO*	100 µL
S11350	SYTO® Blue Fluorescent Nucleic Acid Stain Sampler Kit *SYTO® dyes 40–45* *50 µL each*	1 kit
S7572	SYTO® Green Fluorescent Nucleic Acid Stain Sampler Kit *SYTO® dyes 11–14, 16, 21, 24, and 25* *50 µL each*	1 kit
S11360	SYTO® Orange Fluorescent Nucleic Acid Stain Sampler Kit *SYTO® dyes 80–85* *50 µL each*	1 kit
S11340	SYTO® Red Fluorescent Nucleic Acid Stain Sampler Kit *SYTO® dyes 17 and 59–64* *50 µL each*	1 kit
S32703	SYTO® RNASelect™ green fluorescent cell stain *5 mM solution in DMSO*	100 µL
S10349	SYTOX® AADvanced™ Dead Cell Stain Kit *for flow cytometry* *for 488 nm excitation* *100 tests*	1 kit
S10274	SYTOX® AADvanced™ Dead Cell Stain Kit *for flow cytometry* *for 488 nm excitation* *500 tests*	1 kit
S34857	SYTOX® Blue dead cell stain *for flow cytometry* *1000 assays* *1 mM solution in DMSO*	1 mL
S11348	SYTOX® Blue nucleic acid stain *5 mM solution in DMSO*	250 µL
S7020	SYTOX® Green nucleic acid stain *5 mM solution in DMSO*	250 µL
S11368	SYTOX® Orange nucleic acid stain *5 mM solution in DMSO*	250 µL
S34859	SYTOX® Red dead cell stain *for 633 or 635 nm excitation* *5 µM solution in DMSO*	1 mL
T3168	5,5',6,6'-tetrachloro- 1,1',3,3'-tetraethylbenzimidazolylcarboc yanine iodide (JC-1; CBIC ₂ (3))	5 mg
T669	tetramethylrhodamine, ethyl ester, perchlorate (TMRE)	25 mg
T668	tetramethylrhodamine, methyl ester, perchlorate (TMRM)	25 mg
15585-011	UltraPure™ ethidium bromide *10 mg/mL*	10 mL
V34850	vancomycin, BODIPY® FL conjugate (BODIPY® FL vancomycin)	100 µg
X6493	XTT (2,3-bis-(2-methoxy-4- nitro-5-sulphophenyl)-2H- tetrazolium-5-carboxanilide)	100 mg

15.3 Viability and Cytotoxicity Assay Kits for Diverse Cell Types

This section contains a thorough description of Molecular Probes® viability and cytotoxicity kits. Fluorometric assays of cell viability and cytotoxicity are easy to perform with the use of a fluorescence microscope, fluorometer, fluorescence microplate reader or flow cytometer,^{1,2} and they offer many advantages over traditional colorimetric and radioactivity-based assays. Also discussed in this section are our unique single-step kits for assessing gram sign and for simultaneously determining gram sign and viability of bacteria, as well as the FilmTracer™ LIVE/DEAD® Biofilm Viability Kit designed specifically for bacterial biofilms.

Viability Assay Kits for Animal Cells

To facilitate use of our unique cell viability and cytotoxicity assay technology, we have developed several important products (Table 15.2) that combine fluorescent reagents to yield, in most cases, two-color discrimination of the population of live cells from the dead-cell population by simply adding the reagents, incubating for a brief period and observing the results without any wash steps required. These facile assays are ideal for high-throughput screening applications and, in most cases, for imaging, fluorometry and flow cytometry.

LIVE/DEAD® Viability/Cytotoxicity Kit for Animal Cells

Our LIVE/DEAD® Viability/Cytotoxicity Kit (L3224) for animal cells provides an exceptionally easy fluorescence-based method for determining viability of adherent or nonadherent cells and for assaying cytotoxicity. The kit comprises two probes: calcein AM and ethidium homodimer-1. Calcein AM is a fluorogenic esterase substrate that is hydrolyzed to a green-fluorescent product (calcein); thus, green fluorescence is an indicator of cells that have esterase activity as well as an intact membrane to retain the esterase products. Ethidium homodimer-1 is a high-affinity, red-fluorescent nucleic acid stain that is only able to pass through the compromised membranes of dead cells. The LIVE/DEAD® viability/cytotoxicity assay offers several advantages:

- **Simplicity.** The reagents are simultaneously added to the cell suspension, which is then incubated for 30–45 minutes. No wash steps are required before analysis.
- **Specificity and reliability.** Green-fluorescent cells are live; red-fluorescent cells are dead (Figure 15.3.1, Figure 15.3.2).
- **Versatility.** The LIVE/DEAD® viability/cytotoxicity assay is compatible with adherent cells such as astrocytes,³ nonadherent cells and certain tissues.^{4–6} Results can be analyzed by fluorescence microscopy using standard fluorescein longpass filter sets, as well as by flow cytometry (Figure 15.3.3) or fluorometry. The fluorescence emissions of the two probes are easily resolved (Figure 15.3.4).
- **Simple quantitation.** Flow cytometric measurements yield only two populations; there are rarely any doubly stained cells (Figure 15.3.3). Quantitative assays of bulk cells can be made using a fluorescence microplate reader or fluorometer.
- **Suitability for high-throughput screening.** The ease, reliability and low cost of the LIVE/DEAD® Viability/Cytotoxicity Kit make it an economical assay for high-throughput screening of cytotoxic agents.

Figure 15.3.1 Live and dead kangaroo rat (PtK2) cells stained with ethidium homodimer-1 and the esterase substrate calcein AM, both of which are provided in our LIVE/DEAD® Viability/Cytotoxicity Kit (L3224). Live cells fluoresce a bright green, whereas dead cells with compromised membranes fluoresce red-orange.

Figure 15.3.2 A mixture of live and ethanol-killed bovine pulmonary artery epithelial cells stained with the reagents in our LIVE/DEAD® Cell Viability/Cytotoxicity Assay Kit (L3224). Live cells fluoresce bright green, whereas dead cells with compromised membranes fluoresce red-orange.

Figure 15.3.3 Flow cytometric viability assay using the LIVE/DEAD® Viability/Cytotoxicity Kit (L3224). A 1:1 mixture of live and ethanol-fixed human B cells was stained with calcein AM and ethidium homodimer-1 according to the kit protocol. After 5 minutes, flow cytometric analysis was carried out with excitation at 488 nm. The resulting bivariate frequency distribution shows the clear separation of the green-fluorescent (530 nm) live-cell population from the red-fluorescent (585 nm) dead-cell population.

Figure 15.3.4 Normalized fluorescence emission spectra of calcein (C481) and DNA-bound ethidium homodimer-1 (EthD-1, E1169), illustrating the clear spectral separation that allows simultaneous visualization of live and dead eukaryotic cells with the LIVE/DEAD® Viability/Cytotoxicity Kit (L3224).

Cat. No.	Kit Name	Kit Components	# Assays	Assay Principle
Assay Kits for Mammalian Cells				
L3224	LIVE/DEAD® Viability/Cytotoxicity Kit	<ul style="list-style-type: none"> Calcein AM Ethidium homodimer-1 Detailed protocols 	1000 microscopy assays, 1000 microplate assays or 300 flow cytometry assays	Membrane-permeant calcein AM is cleaved by esterases in live cells to yield cytoplasmic green fluorescence, and membrane-impermeant ethidium homodimer-1 labels nucleic acids of membrane-compromised cells with red fluorescence.
L7013	LIVE/DEAD® Reduced Biohazard Cell Viability Kit #1	<ul style="list-style-type: none"> SYTO® 10 nucleic acid stain DEAD Red™ nucleic acid stain Detailed protocols 	100 microscopy assays or 100 flow cytometry assays	Membrane-permeant SYTO® 10 dye labels the nucleic acids of live cells with green fluorescence, and membrane-impermeant DEAD Red™ dye labels nucleic acids of membrane-compromised cells with red fluorescence. Subsequent fixation inactivates pathogens without distorting the staining pattern.
L23105 L34957 L34959 L34955 L23101 L23102 L10120 L10119 L34960 †	LIVE/DEAD® Fixable Dead Cell Stain Kits *	<ul style="list-style-type: none"> Fluorescent reactive dye DMSO Detailed protocols 	200 flow cytometry assays	Live cells react with the fluorescent reactive dye only on their surface to yield weakly fluorescent cells. Cells with compromised membranes react with the dye throughout their volume, yielding brightly stained cells. Subsequent fixation inactivates pathogens without distorting the staining pattern.
L7010	LIVE/DEAD® Cell-Mediated Cytotoxicity Kit	<ul style="list-style-type: none"> DiOC₁₈(3) Propidium iodide Detailed protocols 	2000 microscopy assays or 200 flow cytometry assays	Target cells are preincubated with the green-fluorescent membrane stain DiOC ₁₈ (3) and then mixed with effector cells in the presence of the red-fluorescent, membrane-impermeant propidium iodide. Live and dead target cells retain their green-fluorescent membrane stain; target and effector cells with compromised membranes exhibit red-fluorescent nucleic acid staining; live effector cells are nonfluorescent.
L7011	LIVE/DEAD® Sperm Viability Kit	<ul style="list-style-type: none"> SYBR® 14 nucleic acid stain Propidium iodide Detailed protocols 	1000 microscopy assays or 200 flow cytometry assays	Membrane-permeant SYBR® 14 nucleic acid stain labels live sperm with green fluorescence, and membrane-impermeant propidium iodide labels the nucleic acids of membrane-compromised sperm with red fluorescence.
L34951	LIVE/DEAD® Cell Vitality Assay Kit	<ul style="list-style-type: none"> Dodecylresazurin (C₁₂-resazurin) SYTOX® Green nucleic acid stain DMSO Phosphate-buffered saline Detailed protocols 	1000 flow cytometry assays	Metabolically active cells reduce C ₁₂ -resazurin to red-fluorescent C ₁₂ -resorufin, and cells with compromised membranes (usually late-apoptotic and necrotic cells) are labeled with the green-fluorescent SYTOX® Green nucleic acid stain.
L34958	LIVE/DEAD® Cell Vitality Assay Kit	<ul style="list-style-type: none"> CellTrace™ calcein violet AM Aqua-fluorescent reactive dye DMSO Detailed protocols 	200 flow cytometry assays	Live cells are labeled with CellTrace™ calcein violet AM, and dead cells with the aqua-fluorescent reactive dye. Both stains are compatible with the 405 nm violet laser diode.
V23110	Vybrant® Cell Metabolic Assay Kit	<ul style="list-style-type: none"> Dodecylresazurin (C₁₂-resazurin) DMSO Resorufin Detailed protocols 	200 flow cytometry assays or 1000 microplate assays	Nonfluorescent C ₁₂ -resazurin is reduced to fluorescent C ₁₂ -resorufin by viable cells; the resulting signal is proportional to the number of cells present.
V23111	Vybrant® Cytotoxicity Assay Kit	<ul style="list-style-type: none"> Resazurin DMSO Reaction mixture Reaction buffer Lysis buffer Detailed protocols 	1000 microplate assays	Damaged and dying cells release glucose 6-phosphate into the surrounding medium, which is detected by an enzymatic process that leads to the reduction of resazurin into red-fluorescent resorufin.
Assay Kits for Yeast				
L7009	LIVE/DEAD® Yeast Viability Kit	<ul style="list-style-type: none"> FUN® 1 cell stain Calcofluor White M2R Detailed protocols 	>1000 microscopy assays or 1000 microplate assays	Plasma membrane integrity and metabolic function of fungi are required to convert the yellow-green-fluorescent intracellular staining of FUN® 1 into red-orange-fluorescent intravacuolar structures; Calcofluor White M2R labels cell-wall chitin with blue fluorescence regardless of metabolic state.
L34952	LIVE/DEAD® FungaLight™ Yeast Viability Kit *for flow cytometry*	<ul style="list-style-type: none"> SYTO® 9 nucleic acid stain Propidium iodide Detailed protocols 	~200 flow cytometry assays	Membrane-permeant SYTO® 9 dye generally labels all yeast in a population—those with intact membranes and those with damaged membranes. In contrast, propidium iodide penetrates only yeast with damaged membranes, causing displacement of the SYTO® 9 stain.
F34953	FungaLight™ CFDA AM/Propidium Iodide Yeast Viability Kit *for flow cytometry*	<ul style="list-style-type: none"> 5-carboxyfluorescein diacetate, acetoxymethyl ester (CFDA AM) Propidium iodide Dimethylsulfoxide (DMSO), anhydrous Detailed protocols 	~200 flow cytometry assays	The cell-permeant CFDA AM is combined with the membrane integrity indicator propidium iodide to evaluate the vitality of yeast cells by flow cytometry or microscopy. With an appropriate stain mixture, esterase-active yeast with intact cell membranes stain fluorescent green, whereas yeast with damaged membranes stain fluorescent red.
* The LIVE/DEAD® Fixable Dead Cell Stain Kits are available in eight fluorescent colors (excitation/emission maxima): blue (350/450 nm, L23105), aqua (367/526 nm, L34957), yellow (400/575 nm, L34959), violet (416/451 nm, L34955), green (495/520 nm, L23101), red (595/615 nm, L23102), far red (650/665 nm, L10120) and near infrared (750/775 nm, L10119), as well as in the LIVE/DEAD® Fixable Dead Cell Stain Sampler Kit (L34960), which contains all eight fluorescent fixable dead cell stains. † 320 flow cytometry assays.				

Table 15.2 Molecular Probes® assay kits for cell viability, cell counting and bacterial gram staining—*continued*.

Cat. No.	Kit Name	Kit Components	# Assays	Assay Principle
Assay Kits for Bacteria				
L7012 L7007 L13152	LIVE/DEAD® <i>BacLight</i> ™ Bacterial Viability Kit	<ul style="list-style-type: none"> • SYTO® 9 nucleic acid stain • Propidium iodide • <i>BacLight</i>™ mounting oil • Detailed protocols 	For Kit L7007 and L7012: >1000 microscopy assays, 1000 microplate assays or 200 flow cytometry assays. For Kit L13152: each applicator set allows ~1000 microscopy assays, 50 microplate assays or 10 flow cytometry assays	Membrane-permeant SYTO® 9 dye labels live bacteria with green fluorescence; membrane-impermeant propidium iodide labels membrane-compromised bacteria with red fluorescence. In Kit L7007, the stains are supplied in a mixed, two-component formulation, whereas in Kit L7012 the stains are provided as separate solutions. In Kit L13152, the separate dyes are dry and premeasured into pairs of polyethylene transfer pipettes.
L34856	LIVE/DEAD® <i>BacLight</i> ™ Bacterial Viability and Counting Kit	<ul style="list-style-type: none"> • SYTO® 9 nucleic acid stain • Propidium iodide • Microsphere standard • Detailed protocols 	100 flow cytometry assays	Membrane-permeant SYTO® 9 dye labels live bacteria with green fluorescence; membrane-impermeant propidium iodide labels membrane-compromised bacteria with red fluorescence. The calibrated suspension of polystyrene microspheres serves as a standard for the volume of suspension analyzed and is clearly distinguishable from stained bacteria in a fluorescence versus side scatter cytogram.
B34954	<i>BacLight</i> ™ RedoxSensor™ Green Vitality Kit	<ul style="list-style-type: none"> • RedoxSensor™ Green reagent • Propidium iodide, an indicator of membrane integrity • Sodium azide • Carbonyl cyanide 3-chlorophenylhydrazone (CCCP) • Detailed protocols 	200 flow cytometry assays	The RedoxSensor™ Green reagent reports reductase activity in both gram-positive and gram-negative bacteria (although differences in signal intensity may be observed based upon cell wall characteristics), providing an accurate view of this important aspect of bacterial vitality. Following reduction, the RedoxSensor™ Green reagent will produce a stable green-fluorescent signal (excitation/emission maxima ~490/520 nm) in 10 minutes that is compatible with formaldehyde fixation techniques.
B34956	<i>BacLight</i> ™ RedoxSensor™ CTC Vitality Kit	<ul style="list-style-type: none"> • 5-cyano-2,3-ditoyl tetrazolium chloride (CTC) • SYTO® 24 green-fluorescent nucleic acid stain • 4',6'-diamidino-2-phenylindole, dihydrochloride (DAPI) • Detailed protocols 	50 tests by flow cytometry or microscopy	This kit contains 5-cyano-2,3-ditoyl tetrazolium chloride (CTC), for detection of respiration-linked dehydrogenase activity. SYTO® 24 and DAPI counterstains facilitate the differentiation of cells from debris and the calculation of total cell numbers.
B34950	<i>BacLight</i> ™ Bacterial Membrane Potential Kit	<ul style="list-style-type: none"> • DiOC₂(3) in DMSO • CCCP in DMSO • Phosphate-buffered saline (PBS) • Detailed protocols 	100 flow cytometry assays	At low concentrations, DiOC ₂ (3) exhibits green fluorescence in all bacterial cells, but it becomes more concentrated in healthy cells that are maintaining a membrane potential, causing the dye to self-associate and the fluorescence emission to shift to red. CCCP is included in the kit for use as a control because it eradicates the proton gradient, eliminating bacterial membrane potential.
V7023	ViaGram™ Red ⁺ Bacterial Gram Stain and Viability Kit	<ul style="list-style-type: none"> • DAPI • SYTOX® Green nucleic acid stain • Texas Red®-X conjugate of wheat germ agglutinin (WGA) • Sodium bicarbonate • <i>BacLight</i>™ mounting oil • Detailed protocols 	200 microscopy assays	Membrane-permeant DAPI labels live bacteria with blue fluorescence; membrane-impermeant SYTOX® Green nucleic acid stain labels bacteria with compromised membranes with green fluorescence. Simultaneous Texas Red®-X WGA staining produces red-fluorescent surface labeling of gram-positive bacteria.
L7005	LIVE <i>BacLight</i> ™ Bacterial Gram Stain Kit	<ul style="list-style-type: none"> • SYTO® 9 nucleic acid stain • Hexidium iodide • <i>BacLight</i>™ mounting oil • Detailed protocols 	>1000 microscopy assays, 1000 microplate assays or 200 flow cytometry assays	When gram-negative and gram-positive bacteria are simultaneously stained with the membrane-permeant SYTO® 9 dye and hexidium iodide, gram-negative bacteria fluoresce green and gram-positive bacteria fluoresce red.
B7277	Bacteria Counting Kit (Section 15.4)	<ul style="list-style-type: none"> • SYTO® BC bacteria stain • Suspended microsphere standard • Detailed protocols 	100 flow cytometry assays	The membrane-permeant SYTO® BC stain labels both gram-positive and gram-negative bacteria with green fluorescence; the calibrated suspension of polystyrene microspheres serves as a standard for the volume of suspension analyzed.
ATP Assay Kit for All Cell Types				
A22066	ATP Determination Kit	<ul style="list-style-type: none"> • Luciferin • Luciferase • ATP • Dithiothreitol (DTT) • Reaction buffer • Detailed protocols 	1000 microplate assays	Luciferase catalyzes the chemiluminescent reaction of luciferin, ATP and oxygen, producing a photon and other chemical by-products. Stores of ATP are higher in viable cells; therefore, the signal strength correlates with population viability.

* The LIVE/DEAD® Fixable Dead Cell Stain Kits are available in eight fluorescent colors (excitation/emission maxima): blue (350/450 nm, L23105), aqua (367/526 nm, L34957), yellow (400/575 nm, L34959), violet (416/451 nm, L34955), green (495/520 nm, L23101), red (595/615 nm, L23102), far red (650/665 nm, L10120) and near infrared (750/775 nm, L10119), as well as in the LIVE/DEAD® Fixable Dead Cell Stain Sampler Kit (L34960), which contains all eight fluorescent fixable dead cell stains. † 320 flow cytometry assays.

Several laboratories have established the validity of the LIVE/DEAD® viability/cytotoxicity assay for use with animal cells and tissues. Published applications have included measuring the toxic effects of tumor necrosis factor⁷ (TNF), β -amyloid protein,⁸ adenovirus E1A proteins,⁹ tetrodotoxin (TTX) binding to Na⁺ channels,¹⁰ methamphetamine,¹¹ mitogenic sphingolipids¹² and photodynamic therapy.¹³ This assay has also been adapted to quantitate lymphocyte-mediated cytotoxicity by flow cytometry,¹⁴ cell-mediated cytotoxicity by fluorescence microscopy¹⁵ and the viability of boar sperm by fluorescence microscopy.¹⁶

The LIVE/DEAD® Viability/Cytotoxicity Kit is intended for use with animal cells that can be analyzed within about an hour of adding

Figure 15.3.5 A mixture of live and dead goat lymphocytes stained with the LIVE/DEAD® Reduced Biohazard Viability/Cytotoxicity Kit (L7013) and subsequently fixed with 4% glutaraldehyde. This image was photographed in a single exposure through an Omega® Optical triple bandpass filter set.

Figure 15.3.6 Flow cytometric analysis of a mixed population of live and complement-treated goat lymphocytes stained using the reagents and protocols provided in our LIVE/DEAD® Reduced Biohazard Cell Viability Kit #1 (L7013) and monitored over a 24-hour period. The panels (left to right, top to bottom) represent the distribution of SYTO® 10 green fluorescence and DEAD Red™ red fluorescence in lymphocytes at 0, 5 and 24 hours after fixation. Data are on a logarithmic scale. The lower right panel is a plot of the separation between the live- and dead-population peaks as a function of time.

the dyes to the cells. The kit components, number of assays and assay principles are summarized in Table 15.2. This kit's two viability probes—calcein AM (C1430, C3099, C3100MP) and ethidium homodimer-1 (E1169)—are also available separately (see Section 15.2) and may be used in combination with other probes for discrimination of live and dead cells. When assays need to be conducted over longer periods or when hazardous samples are being analyzed, we recommend our LIVE/DEAD® Reduced Biohazard Cell Viability Kit #1 (L7013, see below).

LIVE/DEAD® Reduced Biohazard Cell Viability Kit

Rigorous precautions are necessary during analysis of biohazardous specimens.^{17,18} Therefore, fixation procedures that inactivate cells yet produce minimal distortion of their characteristics are highly advantageous.¹⁹ The LIVE/DEAD® Reduced Biohazard Cell Viability Kit #1 (L7013) provides a two-color fluorescence assay for animal cell viability that is designed to reduce the risk associated with handling potential biohazards such as viral, bacterial or protozoan pathogens.

Viability analysis with the LIVE/DEAD® Reduced Biohazard Cell Viability Kit #1 is provided by the cell-permeant, green-fluorescent SYTO® 10 and cell-impermeant, red-fluorescent DEAD Red™ (ethidium homodimer-2) nucleic acid stains. The dye concentrations and their relative affinities are balanced so that a cell population exposed simultaneously to both dyes becomes differentially stained—live cells fluoresce green and dead cells fluoresce red (Figure 15.3.5). This assay is simple, fast and can be carried out using a fluorescence microscope, flow cytometer or fluorescence microplate reader. Moreover, the staining pattern of a cell population is retained for several hours after fixation (Figure 15.3.6).

Our LIVE/DEAD® Reduced Biohazard Cell Viability Kit #1 has several unique features:

- **Reduced handling risks.** This kit allows viability staining to take place while the potentially pathogenic sample is well contained. Subsequent treatment with 4% glutaraldehyde (or less effectively with formaldehyde) permits safer handling during analysis, without disrupting the distinctive staining pattern. Glutaraldehyde is known to inactivate cells and viruses, while preserving their overall morphology.²⁰ In addition, the high sensitivity and specificity of the assay mean that sample sizes can be very small, further reducing potential biohazards.
- **Specificity and reliability.** Live cells initially fluoresce green, and dead cells fluoresce red. With time, this discrimination is reduced but can still be detected, even after 24 hours (Figure 15.3.6).
- **Independence from enzymatic activity.** Because it relies on two nucleic acid stains that differ in their membrane permeability, this assay equates loss of cell viability with loss of membrane integrity. Consequently, the assay is totally independent of variations in enzymatic activity or electrical potential of the cell.
- **Versatility.** The analysis is readily quantitated with a fluorescence microscope or flow cytometer (Figure 15.3.6). This kit's protocol includes methods for analyzing the viability of nonadherent cells, as well as adherent cells on coverslips.
- **Convenience.** Cells can be stained and fixed at various times during the experiment, and the results can be analyzed several hours later, without loss of the discrimination pattern.

The kit components, number of assays and assay principles are summarized in Table 15.2.

LIVE/DEAD® Fixable Dead Cell Stain Kits

The LIVE/DEAD® Fixable Dead Cell Stain Kits (three of which were formerly named LIVE/DEAD® Reduced Biohazard Cell Viability Kits #2, #3 and #4) employ an amine-reactive fluorescent dye to evaluate mammalian cell viability by flow cytometry (Figure 15.3.7).²⁰ The LIVE/DEAD® Fixable Dead Cell Stain Kits are identical except for the fluorescent color of the amine-reactive dye:

- LIVE/DEAD® Fixable Blue Dead Cell Stain Kit, for UV excitation (L23105, excitation/emission maxima ~350/450 nm)
- LIVE/DEAD® Fixable Aqua Dead Cell Stain Kit, for 405 nm excitation (L34957, excitation/emission maxima ~367/526 nm)
- LIVE/DEAD® Fixable Yellow Dead Cell Stain Kit, for 405 nm excitation (L34959, excitation/emission maxima ~400/575 nm)
- LIVE/DEAD® Fixable Violet Dead Cell Stain Kit, for 405 nm excitation (L34955, excitation/emission maxima ~416/451 nm)
- LIVE/DEAD® Fixable Green Dead Cell Stain Kit, for 488 nm excitation (L23101, excitation/emission maxima ~495/520 nm)
- LIVE/DEAD® Fixable Red Dead Cell Stain Kit, for 488 nm excitation (L23102, excitation/emission maxima ~595/615 nm)
- LIVE/DEAD® Fixable Far Red Dead Cell Stain Kit, for 633 or 635 nm excitation (L10120, excitation/emission maxima ~650/665 nm)
- LIVE/DEAD® Fixable Near-IR Dead Cell Stain Kit, for 633 or 635 nm excitation (L10119, excitation/emission maxima ~750/775 nm)
- LIVE/DEAD® Fixable Dead Cell Stain Sampler Kit, for flow cytometry (L34960), which contains one vial of each of the eight different fluorescent reactive dyes

In cells with compromised membranes, the dye reacts with free amines both in the cell interior and on the cell surface, yielding intense fluorescent staining. In viable cells, the dye's reactivity is restricted to the cell-surface amines, resulting in less intense fluorescence. The difference in intensity between the live and dead cell populations is typically greater than 50 fold (Figure 15.3.8), and this fluorescence intensity discrimination is preserved following formaldehyde fixation, using conditions that inactivate pathogens. These single-color assays use only one channel of a flow cytometer, making the reactive dyes in the LIVE/DEAD® Fixable Dead Cell Stain Kits compatible with multiparameter staining experiments; appropriate flow cytometer channels may vary depending on the instrument. The assays can also be used to detect dead cells by fluorescence microscopy; however, the difference in fluorescence intensity of the live and dead cells can be appreciable, making it relatively difficult to simultaneously photograph the two populations. The kit components, number of assays and assay principles are summarized in Table 15.2.

ArC™ Amine-Reactive Compensation Bead Kit

Optimized for use with the LIVE/DEAD® Fixable Dead Cell Stain Kits, the ArC™ Amine Reactive Compensation Bead Kit (A10346) is a tool designed to remove spectral overlap of the fixable dead-cell stains with other standard fluorophores. This kit provides two polystyrene microsphere samples: ArC™ Reactive Beads, which are reactive to all dyes in the Live/Dead Fixable Dead Cell Stain Kits, and Negative Control Beads, which have no reactivity. The two components provide negative and positive populations that can be used to help accurately set compensation when using the Live/Dead Fixable Dead Cell Stains.

LIVE/DEAD® Cell-Mediated Cytotoxicity Kit

Cytotoxicity triggered by a natural defense mechanism may be much slower than cell lysis triggered by a cytotoxic reagent. Our LIVE/DEAD® Cell-Mediated Cytotoxicity Kit (L7010) is intended for cytotoxicity assessments extending over time periods that are too long for effective use of cytoplasmic markers, such as calcein, which may leak out or become sequestered. This kit is based directly on procedures developed by Kroesen and colleagues for measuring natural killer (NK) cell-mediated, lymphokine-activated killer (LAK) cell-mediated and T cell-mediated cytotoxicity by fluorescence microscopy.²¹ The assay has also been adapted for rapid flow cytometric analysis of NK cell activity.^{22–24}

Figure 15.3.7 Principle of our LIVE/DEAD® Fixable Green Dead Cell Stain Kit (L23101). Live cells (A) react with the kit's green-fluorescent, amine-reactive dye only on their surface to yield weakly fluorescent cells. Cells with compromised membranes (B) react with the dye throughout their volume, yielding brightly stained cells. In both cases, the excess reactive dye is subsequently washed away.

Figure 15.3.8 Live and dead cells distinguished by flow cytometry using the LIVE/DEAD® Fixable Green Dead Cell Stain Kit (L23101). The LIVE/DEAD® Fixable Green Dead Cell Stain Kit was used to differentially stain live and dead Jurkat cells taken from a healthy culture (top panel), an aged culture (middle panel) and a heat-killed culture (bottom panel). Following the staining reaction, the cells were fixed in 3.7% formaldehyde and analyzed by flow cytometry. Nearly identical results were obtained using unfixed cells (data not shown).

Figure 15.3.10 Flow cytometric analysis of Jurkat cells using the LIVE/DEAD® Cell Vitality Assay Kit (L34951). Jurkat human T-cell leukemia cells were first exposed to 10 μ M camptothecin for 4 hours at 37°C, 5% CO₂. The cells were then treated with the reagents in the LIVE/DEAD® Cell Vitality Assay Kit as specified in the kit protocol and analyzed by flow cytometry. This dot plot of SYTOX® Green fluorescence versus resorufin fluorescence shows resolution of live-, injured- and dead-cell populations.

Analysis of cell-mediated cytotoxicity using this kit is easy. In order to distinguish target cells, cultures are labeled overnight with DiOC₁₈(3), a green-fluorescent membrane stain (Section 14.4). Target cells are then washed free of excess DiOC₁₈(3) and combined in various proportions with effector cells. After a suitable incubation period, propidium iodide, a red-fluorescent, membrane-impermeant nucleic acid stain, is added. Propidium iodide labels dead effector cells, as well as dead target cells once their plasma membranes are compromised. Because the target cells retain the green-fluorescent membrane stain, both live and dead effector cells and live and dead target cells can readily be discriminated with a fluorescence microscope. Dead target cells exhibit both green-fluorescent membrane staining and red-fluorescent nuclear staining, whereas dead effector cells show only red-fluorescent nuclear staining. Live target cells have only green-fluorescent membrane staining, and live effector cells are unstained. The kit components, number of assays and assay principles are summarized in Table 15.2.

LIVE/DEAD® Sperm Viability Kit

The LIVE/DEAD® Sperm Viability Kit (L7011), developed in collaboration with Duane L. Garner, provides a novel fluorescence-based method for analyzing the viability of sperm in different species.^{25–28} The LIVE/DEAD® Sperm Viability Kit contains the membrane-permeant SYBR® 14 nucleic acid stain, along with the conventional dead-cell stain, propidium iodide. Using this combination of dyes, researchers can rapidly distinguish live and dead cells with visible-light excitation (Figure 15.3.9), thus avoiding the harmful effects of UV exposure and allowing flow cytometric analysis of sperm viability to be performed using an argon-ion laser excitation source. When semen is incubated briefly with these two stains, live sperm with intact membranes fluoresce bright green, whereas sperm cells with damaged membranes fluoresce red. Garner and colleagues assessed bovine sperm viability with flow cytometry and with fluorescence microscopy; both techniques allowed live and dead cells to be visualized simultaneously.^{28,29} Furthermore, it was reported that neither the ability to fertilize oocytes nor the development of the embryos was affected by SYBR® 14 staining of porcine sperm.²⁵ The effect of two-photon illumination on the viability of human sperm stained with these reagents has also been analyzed.³⁰ This assay is particularly useful for evaluating the viability of cryopreserved sperm.^{31–35}

The dyes provided in the LIVE/DEAD® Sperm Viability Kit stain cells more rapidly than conventional stains (within 5–10 minutes), and both label DNA, thereby avoiding the ambiguity that may arise from targeting separate cellular components. The membrane-permeant SYBR® 14 stain provided in the LIVE/DEAD® Sperm Viability Kit should also serve as a valuable tool for labeling and tracking live sperm, thus facilitating analysis of their motility and abundance in

Figure 15.3.9 A mixture of live and dead bovine sperm cells stained with the dyes provided in our LIVE/DEAD® Sperm Viability Kit (L7011). Live sperm with intact membranes are labeled with our proprietary cell-permeant nucleic acid stain, SYBR® 14, and fluoresce green. Dead sperm, which have been killed by unprotected freeze-thawing, are labeled with propidium iodide (P1304MP, P3566, P21493) and fluoresce red-orange. The image was contributed by Duane L. Garner, School of Veterinary Medicine, University of Nevada, Reno, and Lawrence A. Johnson, USDA Agricultural Research Service.

semen samples. Reliable viability measurements with bovine,²⁸ porcine, ovine, murine,²⁶ goat, turkey²⁷ and human sperm^{26,30} have been published. The kit components, number of assays and assay principles are summarized in Table 15.2.

Conventional sperm viability assays have employed mixtures of two or three dyes, including fluorescein diacetate derivatives, rhodamine 123 and reduced nucleic acid stains such as dihydroethidium^{27,36–39} (hydroethidine, D1168, D11347, D23107; Section 15.2). Acridine orange (A1301, A3568), which fluoresces at different wavelengths when bound to DNA and RNA,^{40,41} and the UV light–excitable nucleic acid stains Hoechst 33258 (H1398, H3569, H21491) and Hoechst 33342^{42–44} (H1399, H3570, H21492) are frequently used to determine sperm viability and DNA content and to trace sperm–oocyte fusion.^{45,46} These nucleic acid stains are described in Section 8.1.

LIVE/DEAD® Violet Viability/Vitality Kit

The LIVE/DEAD® Violet Viability/Vitality Kit (L34958) provides a two-color cell viability and vitality assay that enables the simultaneous identification of live and dead cells. The assay employs two fluorescent probes—calcein violet AM and aqua-fluorescent reactive dye—to indicate recognized parameters of cell health (intracellular esterase activity and plasma membrane integrity, respectively). Both dyes utilize 405 nm violet diode laser excitation, allowing other laser lines to be used for conventional fluorophores. The kit components, number of assays and assay principles are summarized in Table 15.2.

LIVE/DEAD® Cell Vitality Assay Kit

The LIVE/DEAD® Cell Vitality Assay Kit (L34951) provides a simple two-color fluorescence assay that distinguishes metabolically active cells from injured cells and dead cells. The assay is based on the reduction of C₁₂-resazurin to red-fluorescent C₁₂-resorufin in metabolically active cells and the uptake of the cell-impermeant SYTOX® Green nucleic acid stain in cells with compromised plasma membranes (usually late apoptotic and necrotic cells). Dead cells emit mostly green fluorescence, whereas the healthy, metabolically active cells emit mostly red fluorescence (Figure 15.3.10). The injured cells have lower metabolic activity and, consequently, reduced red-fluorescent emission. Because they possess intact membranes, however, injured cells accumulate little SYTOX® Green dye and, therefore, emit very little green fluorescence.

Nonfluorescent resazurin, which can be reduced by viable cells to red-fluorescent resorufin, has been extensively used to detect the metabolic activity of many different cell types, from bacteria to higher eukaryotes.^{47–49} Resazurin is nontoxic and stable in culture media, allowing researchers to continuously monitor proliferating cells⁵⁰ and to investigate cytotoxicity in both conventional⁵¹ and high-throughput applications.⁵² The LIVE/DEAD® Cell Vitality Assay Kit includes a lipophilic version of resazurin, C₁₂-resazurin, which is more permeable to live cells and, after reduction to C₁₂-resorufin, is far better retained than the nonlipophilic resorufin. These characteristics result in brighter signals and better detection limits. The kit components, number of assays and assay principles are summarized in Table 15.2.

Vybrant® Cell Metabolic Assay Kit

One potential drawback in the use of resazurin as a substrate that can detect metabolic activity in live cells (R12204, Section 15.2) is the relatively poor uptake of the substrate and poor cellular retention of the reduced by-product, resorufin. We have found that the lipophilic dodecylresazurin (C₁₂-resazurin), included as a component in the Vybrant® Cell Metabolic Assay Kit (V23110), surpasses resazurin alone in cell permeability and its reduction product (C₁₂-resorufin) is very well retained, permitting single-cell analysis of the substrate's turnover by flow cytometry (Figure 15.3.11). This enhanced uptake, turnover and retention of C₁₂-resazurin by metabolically active cells translates into much brighter signals and far better detection limits when compared with assays using resazurin alone (Figure 15.3.12).

C₁₂-resazurin can be used in any viability/cytotoxicity assay that employs resazurin for both conventional and high-throughput applications. C₁₂-resorufin, which is the reduction product of C₁₂-resazurin, has the same absorption/emission maxima as unmodified resorufin (~571/ 585 nm, Figure 15.3.13); therefore, no changes in instrumentation are required in

Figure 15.3.11 Flow cytometric analysis of Jurkat cells stained with C₁₂-resazurin. Cells were loaded with 0.1 μM C₁₂-resazurin, a component of the Vybrant® Cell Metabolic Assay Kit (V23110), and 1 mM SYTOX® Green (S7020). After a 15-minute incubation, the cells were analyzed. Healthy (live) cells reduce C₁₂-resazurin into red-fluorescent C₁₂-resorufin and exclude the cell impermeant green-fluorescent SYTOX® Green. Dead cells show little reduction of the C₁₂-resazurin, but strong staining by SYTOX® Green. Cells indicated in the figure as dying are of indeterminate viability, showing both reduction of C₁₂-resazurin and compromised membrane integrity.

Figure 15.3.12 Detection limit of C₁₂-resazurin and linear response with increasing cell number using our Vybrant® Cell Metabolic Assay Kit (V23110). Jurkat cells were loaded with 5 μM C₁₂-resazurin for 15 minutes. The resulting signal was measured in a fluorescence microplate reader with excitation/emission at 530/590 nm. For comparison, the detection limit for resazurin in a similar experiment was ~8000 cells/well (data not shown).

Figure 15.3.13 Absorption and fluorescence emission spectra of resorufin in pH 9.0 buffer.

Figure 15.3.15 Detection of dead and dying cells using the Vybrant® Cytotoxicity Assay Kit (V23111). Jurkat cells were treated with 10 μM camptothecin for 6 hours, then assayed for glucose 6-phosphate dehydrogenase release. An untreated control sample is shown for comparison. The fluorescence was measured in a microplate reader (excitation/emission $\sim 530/590$ nm). A background of 55 fluorescence units was subtracted from each value.

Figure 15.3.16 10% bovine serum was assayed for the presence of lactate dehydrogenase (LDH, blue) and glucose 6-phosphate dehydrogenase (G6PD, red). G6PD was assayed using the Vybrant® Cytotoxicity Assay Kit (V23111); LDH was detected using a similar method, in which LDH reduces lactate to generate NADH. The result clearly shows that, over the time course of the experiment, the serum generates a much lower signal in the G6PD assay than in the LDH assay.

Figure 15.3.17 Fluorescence emission spectra of a *Saccharomyces cerevisiae* suspension that has been stained with the FUN® 1 cell stain, which is available separately (F7030) or in our LIVE/DEAD® Yeast Viability Kit (L7009). After the FUN® 1 reagent was added to the medium, the fluorescence emission spectrum (excited at 480 nm) was recorded in a spectrofluorometer at the indicated times during a 30-minute incubation period. The shift from green (G) to red (R) fluorescence reflects the processing of FUN® 1 by metabolically active yeast cells.

order to use the kit in place of a resazurin-based assay. The Vybrant® Cell Metabolic Assay Kit (V23110) contains:

- Dodecylresazurin (C_{12} -resazurin)
- DMSO
- Resorufin
- Detailed protocols for the assay

Each kit contains sufficient reagents for 500–1000 assays in a fluorescence microplate or about 10,000 flow cytometry assays.

Vybrant® Cytotoxicity Assay Kit

The LIVE/DEAD® kits generally assay cell death via probes that gain entry to the interior of the cell as a result of plasma membrane damage. In contrast, the Vybrant® Cytotoxicity Assay Kit (V23111) monitors the release of the cytosolic enzyme glucose 6-phosphate dehydrogenase (G6PD) from damaged cells into the surrounding medium. G6PD is a ubiquitous enzyme that is part of the pentose phosphate pathway, and is crucial for cellular antioxidant defenses via its production of NADPH.^{53,54} Detection of G6PD is by a two-step enzymatic process that leads to the reduction of resazurin into the red-fluorescent resorufin (Figure 15.3.14). The resulting signal is proportional to the amount of G6PD released into the cell medium, which correlates with the number of dead cells in the sample (Figure 15.3.15).

The Vybrant® Cytotoxicity Assay Kit contains all enzymes and substrates needed to detect the release of G6PD from damaged and dying cells. The assay can be completed in less than an hour and is effective with as few as 500 cells per sample. Resorufin, the end product of the G6PD cytotoxicity assay, has absorption and emission maxima at ~ 571 nm and 585 nm, respectively (Figure 15.3.13), placing the fluorescent signal beyond the autofluorescence of most biological samples. In addition, the levels of G6PD in serum commonly used for cell culture are lower than those of lactate dehydrogenase (LDH), an enzyme often used in similar assays, thus resulting in lower background signals (Figure 15.3.16). The Vybrant® Cytotoxicity Assay Kit (V23111) contains:

- Resazurin (5 vials)
- DMSO
- Reaction mixture (diaphorase, glucose 6-phosphate and NADP^+)
- Reaction buffer
- Cell-lysis buffer
- Detailed protocols for the assay

Sufficient reagents are provided for about 1000 assays in a fluorescence microplate reader.

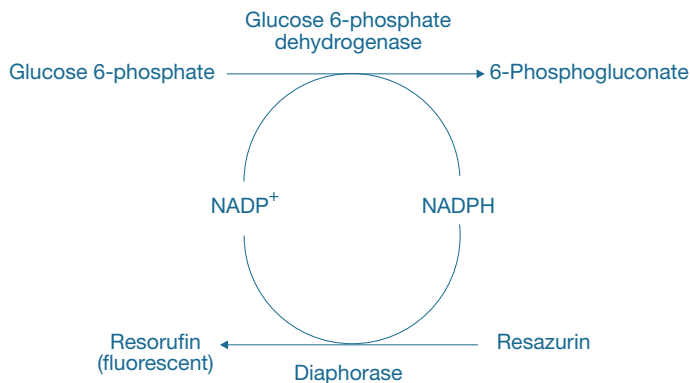

Figure 15.3.14 Principle of the coupled enzymatic assay for detection of glucose 6-phosphate dehydrogenase activity. Oxidation of glucose 6-phosphate by glucose 6-phosphate dehydrogenase results in the generation of NADPH, which in turn leads to the reduction of resazurin by diaphorase to yield fluorescent resorufin.

Viability Assay Kits for Yeast

LIVE/DEAD® Yeast Viability Kit

Our LIVE/DEAD® Yeast Viability Kit (L7009) provides an extremely simple and sensitive assay for discriminating viable yeast and fungi in complex mixtures or in pure cultures.^{55–57} This kit contains our unique two-color fluorescent viability probe, the FUN® 1 dye, which has low intrinsic fluorescence, moderate affinity for nucleic acids and exceptional membrane permeability. Also included is the UV light–excitable counterstain Calcofluor White M2R, which labels the cell walls of yeast and fungi fluorescent blue, regardless of the cell's metabolic state.^{58–60}

The FUN® 1 viability probe displays some extraordinary spectral properties when used to stain metabolically active yeast and fungal cells, exploiting normal endogenous biochemical processing mechanisms that appear to be well conserved among different fungal species. The FUN® 1 stain passively diffuses into a variety of cell types and initially stains the cytoplasm with a diffusely distributed green fluorescence. However, in several common species of yeast and fungi, subsequent processing of the dye by live cells results in the formation of distinct vacuolar structures with compact form that exhibit a striking red fluorescence, accompanied by a reduction in the green cytoplasmic fluorescence^{57,61} (Figure 15.3.17). Formation of the red-fluorescent intravacuolar structures requires both plasma membrane integrity and metabolic capability. Dead cells fluoresce bright yellow-green, with no discernable red structures.

FUN® 1 stain can be used alone or together with Calcofluor White M2R to determine the metabolic activity of single fungal cells by manual or automated fluorescence microscopy (Figure 15.3.18, Figure 15.3.19). Both live and dead cells may be viewed simultaneously by fluorescence microscopy using a standard fluorescein longpass optical filter set. FUN® 1 dye staining can also be used to assay the viability of suspensions of fungal cells using a fluorescence microplate reader or a fluorometer. The FUN® 1 reagent has been extensively used for flow cytometric analysis of yeast, including of their susceptibility to antifungal agents.^{62–66}

The LIVE/DEAD® Yeast Viability Kit has been tested on several fungal species, including *Candida albicans*, *Candida pseudotropicalis* and several strains of *Saccharomyces cerevisiae*, under a variety of experimental conditions. Formation of the red-fluorescent structures was observed not only in logarithmically growing cells but also in nonculturable cells with residual metabolic activity. The LIVE/DEAD® Yeast Viability Kit should be particularly useful for detecting very low numbers of live or dead fungal cells, even in complex mixtures such as blood. The kit components, number of assays and assay principles are summarized in Table 15.2. The FUN® 1 cell stain is also available separately (F7030, Section 15.2).

LIVE/DEAD® FungaLight™ Yeast Viability Kit

The LIVE/DEAD® FungaLight™ Yeast Viability Kit (L34952) allows researchers to easily, reliably and quantitatively distinguish live and dead yeast in minutes. The kit contains solutions of SYTO® 9 green-fluorescent nucleic acid stain and the red-fluorescent nucleic acid stain, propidium iodide. These stains differ both in their spectral characteristics and in their ability to penetrate healthy yeast cells. When used alone, the SYTO® 9 stain generally labels all yeast in a population—those with intact membranes and those with damaged membranes. In contrast, propidium iodide penetrates yeast with damaged membranes, displacing SYTO® 9 stain. Thus, with an appropriate mixture of the SYTO® 9 and propidium iodide stains, yeast with intact cell membranes stain fluorescent green, whereas yeast with damaged membranes stain fluorescent red. The background remains virtually nonfluorescent. Furthermore, this kit also accommodates fine-tuning of the dye combinations so that optimal staining of yeast can be achieved under a variety of experimental conditions. The kit components, number of assays and assay principles are summarized in Table 15.2.

FungaLight™ CFDA AM/Propidium Iodide Yeast Vitality Kit

The FungaLight™ CFDA AM/Propidium Iodide Yeast Vitality Kit (F34953) combines a cell-permeant esterase substrate with a membrane integrity indicator to evaluate the vitality of yeast cells by flow cytometry or microscopy. The acetoxymethyl ester (AM) of the esterase substrate 5-carboxy-fluorescein diacetate (CFDA) allows this reagent to permeate cell membranes. Once inside the cell, the lipophilic blocking and diacetate groups are cleaved by non-specific esterases, resulting in a fluorescent, charged form that leaks out of cells very slowly.

Figure 15.3.18 *Saccharomyces cerevisiae* stained with FUN® 1 cell stain, which generates red-fluorescent intravacuolar structures, and with Calcofluor White M2R, a blue-fluorescent cell wall stain. Both probes are provided in our LIVE/DEAD® Yeast Viability Kit (L7009); FUN® 1 cell stain is also available separately (F7030). A series of z-section images was acquired with a Deltavision wide-field optical sectioning microscope (Applied Precision, Inc.). A three-dimensional projection movie was generated from a deconvolved z-image stack.

Figure 15.3.19 *Saccharomyces cerevisiae* stained with the FUN® 1 dye, available separately (F7030) or in our LIVE/DEAD® Yeast Viability Kit (L7009). Metabolically active yeast process the FUN® 1 dye, forming numerous red fluorescent cylindrical structures within their vacuoles.

Figure 15.3.20 Use of our LIVE/DEAD® *BacLight*™ Bacterial Viability Kit (L7007, L7012, L13152) to identify individual live and dead bacteria along a chain of *Streptococcus pyogenes*. This image was photographed in a single exposure through an Omega® Optical triple bandpass filter set.

Figure 15.3.21 A mixed population of live and isopropyl alcohol-killed *Micrococcus luteus* and *Bacillus cereus* stained with the LIVE/DEAD® *BacLight*™ Bacterial Viability Kit (L7007, L7012). Bacteria with intact cell membranes exhibit green fluorescence, whereas bacteria with damaged membranes exhibit red fluorescence. Prior to imaging, the bacteria were placed onto a polycarbonate filter and immersed in *BacLight*™ mounting oil. This multiple exposure image was acquired with a triple-bandpass optical filter set appropriate for simultaneous imaging of DAPI, fluorescein and Texas Red® dyes.

Figure 15.3.22 Live and dead bacteria visualized on freshly isolated human cheek epithelial cells using our LIVE/DEAD® *BacLight*™ Bacterial Viability Kit (L7007, L7012, L13152). When incubated with the SYTO® 9 and propidium iodide nucleic acid stains provided in this kit, live bacteria with intact cell membranes fluoresce green and dead bacteria with compromised membranes fluoresce red. This image was photographed in a single exposure through an Omega® Optical triple bandpass filter set.

In contrast, the membrane integrity indicator, propidium iodide, penetrates yeast with damaged membranes. With an appropriate mixture of the CFDA AM and propidium iodide stains, esterase-active yeast with intact cell membranes stain fluorescent green, whereas yeast with damaged membranes stain fluorescent red. The excitation/emission maxima for these dyes are 492/517 nm for CFDA AM and 530/635 nm for propidium iodide. The kit components, number of assays and assay principles are summarized in Table 15.2.

Viability Assay and Gram Stain Kits for Bacteria

LIVE/DEAD® *BacLight*™ Bacterial Viability Kits

Molecular Probes® original LIVE/DEAD® Viability/Cytotoxicity Kit (L3224, see above) is a proven tool for assessing viability of animal cells but is generally not suitable for use with bacterial and yeast cells.⁶⁷ Consequently, we have developed the LIVE/DEAD® *BacLight*™ Bacterial Viability Kits (L7007, L7012, L13152), which provide two different nucleic acid stains—the SYTO® 9 dye and propidium iodide—to rapidly distinguish live bacteria with intact plasma membranes from dead bacteria with compromised membranes^{55,57,68} (Figure 15.3.20, Figure 15.3.21).

This assay has several significant features:

- **Ease of use.** The reagents are simultaneously added to the bacterial suspension, which is then incubated for 5–10 minutes. No wash steps are required before analysis.
- **Specificity.** Live bacteria fluoresce green and dead bacteria fluoresce red. Live and dead bacteria can be distinguished and quantitated in minutes, even in a mixed population of bacterial species (Figure 15.3.22).
- **Reliability.** The LIVE/DEAD® *BacLight*™ Bacterial Viability Kits yield consistent results in tests on a variety of eubacterial genera (Table 15.3). It can also be used to assess the viability of *Eurioplasma eurilytica* and *Mycoplasma hominus* mycoplasma as well as cysts of the protozoan parasite *Giardia muris*⁶⁹ (Figure 15.3.23).
- **Validity.** Viability measurements in fresh cultures of bacteria typically correlate well with enumeration techniques involving growth in liquid or solid media. However, variable results have been found using the LIVE/DEAD® *BacLight*™ reagents to assess viability in some marine bacteria from environmental samples.
- **Versatility.** Bacteria can be stained in suspension or immobilized on microscope slides or filter membranes. Protocols are provided for bacterial viability analysis using a fluorescence microscope, fluorometer (Figure 15.3.24) or fluorescence microplate reader.

The intensities of the fluorescence signals produced by the SYTO® 9 and propidium iodide nucleic acid stains can be adjusted by mixing different proportions of the dye solutions provided in the LIVE/DEAD® *BacLight*™ Kits. We have balanced the dye concentrations so that, for most bacteria, equal volumes of the two solutions provided give balanced staining of most species. The background remains virtually nonfluorescent, allowing live and dead cells to be easily differentiated in any fluorescence microscope equipped with

a longpass fluorescein or comparable optical filter set. Under certain conditions, bacteria with compromised membranes may recover and reproduce, even though such bacteria may be scored as dead in this assay. Conversely, some bacteria with intact membranes may be unable to reproduce in nutrient medium, yet be scored as live.⁷⁰ Combining several different measures of viability, such as membrane permeability, enzyme activity and redox potential, offers a more thorough assessment of bacterial viability and eliminates the inherent limitations of any single viability assay.

The LIVE/DEAD® BacLight™ viability assay has been used to estimate total and viable bacteria in drinking water,⁷¹ to quantitate total and viable concentrations of aerosolized *Pseudomonas fluorescens* by fluorescence microscopy⁷² and to measure the reliability of disinfection agents on reducing the viability of *Cryptosporidium parvum* and *Giardia muris* cysts.^{69,73,74} The number of live natural planktonic bacteria, as determined with the LIVE/DEAD® BacLight™ Bacterial Viability Kit, reportedly correlated well with the number of bacteria with high DNA content (HDNA), as determined with SYTO® 13 green-fluorescent nucleic acid stain (S7575), leading to the recommendation that %HDNA be used as an index of the percentage of actively growing bacterial cells in marine plankton samples.⁷⁵ The reagents in the LIVE/DEAD® BacLight™ Bacterial Viability Kit have been utilized in a high-throughput fluorescence-based screen for bacterial mechanosensitive ion-channel (MscL) activity that replaces otherwise tedious and difficult assays.⁷⁶

Our original packaging of the LIVE/DEAD® BacLight™ Bacterial Viability Kit (L7007), in which the dyes were mixed at different proportions in two solutions, is still available for customers who have already developed protocols using that formulation. However, we recommend use of the LIVE/DEAD® BacLight™ Bacterial Viability Kit (L7012), which is more flexible because it provides separate solutions of the SYTO® 9 and propidium iodide nucleic acid stains, thus facilitating calibration of bacterial fluorescence at each of the two emission wavelengths in quantitative assays. Kit L7007 was designed primarily for use in fluorescence microscopy; Kit L7012 is equally well suited for use in fluorescence microscopy and is better suited than Kit L7007 for use in quantitative analysis with a fluorometer (Figure 15.3.24), fluorescence microplate reader, flow cytometer or other instrumentation.

Figure 15.3.23 *Giardia muris* cysts stained with the reagents in the LIVE/DEAD® BacLight™ Bacterial Viability Kit (L7007, L7012). When incubated with the SYTO® 9 and propidium iodide nucleic acid stains provided in this kit, live bacteria with intact cell membranes fluoresce green and dead bacteria with compromised membranes fluoresce red.

Table 15.3 Some organisms that have been successfully stained with our LIVE/DEAD® BacLight™ Bacterial Viability Kits.

Bacteria	
Gram-Positive	Gram-Negative
• <i>Bacillus cereus</i>	• <i>Agrobacterium tumefaciens</i>
• <i>Bacillus subtilis</i>	• <i>Edwardsiella ictaluri</i>
• <i>Clostridium paerfringens</i>	• <i>Escherichia coli</i>
• <i>Lactobacillus</i> sp.	• <i>Deleya aquamarina</i>
• <i>Micrococcus luteus</i>	• <i>Helicobacter pylori</i>
• <i>Mycobacterium phlei</i>	• <i>Klebsiella pneumoniae</i>
• <i>Propionibacterium</i> sp.	• <i>Legionella pneumophila</i>
• <i>Staphylococcus aureus</i>	• <i>Pseudomonas aeruginosa</i>
• <i>Streptococcus pyogenes</i>	• <i>Pseudomonas syringae</i>
	• <i>Salmonella oranienburg</i>
	• <i>Serratia marcescens</i>
	• <i>Shigella sonnei</i>
	• <i>Zymomonas</i> sp.
Mycoplasma	
• <i>Eurioplasma eurilytica</i>	
• <i>Mycoplasma hominus</i>	
Protozoa	
• <i>Giardia muris</i> cysts	

Figure 15.3.24 Viability analysis of bacterial suspensions comprising various proportions of live and isopropyl alcohol-killed *Escherichia coli* using the reagents in the LIVE/DEAD® BacLight™ Bacterial Viability Kit (L7007, L7012, L13152). Live and dead bacteria are stained fluorescent green (G) by SYTO® 9 and fluorescent red (R) by propidium iodide, respectively. Bacterial suspensions that have been incubated in the two stains simultaneously and then excited at 470 nm exhibit a fluorescence spectral shift from red to green as the percentage of live bacteria in the sample is increased.

Figure 15.3.25 The convenient and versatile procedure for using the specially packaged LIVE/DEAD® *BacLight*™ Bacterial Viability Kit (L13152). Simply dissolve the pre-measured dyes in buffer, mix with the bacterial sample and observe the fluorescence.

For added convenience, our LIVE/DEAD® *BacLight*™ Bacterial Viability Kit (L13152) provides the separate stains dry and premeasured into pairs of polyethylene transfer pipettes (Figure 15.3.25). Kit L13152 has several advantages:

- The stains are dry, without DMSO or other potentially harmful solvents, allowing viability determination of solvent-sensitive microorganisms—just dissolve the dyes in virtually any aqueous medium and then add them to the cells.
- The stains are premeasured and supplied in sealed polyethylene transfer pipettes, eliminating the need for pipetting microliter volumes—perfect for educational settings, where there is a need to simplify handling and minimize equipment expenditures.
- This stain formulation does not require refrigeration and is chemically stable, even in poor conditions—storage at 37°C for more than six months produces no detectable changes, making the assay well suited to field testing and other situations where storage or use conditions are less than optimal.

Each of our LIVE/DEAD® *BacLight*™ Bacterial Viability Kits includes a procedure for mounting bacteria stained with the reagents in the LIVE/DEAD® *BacLight*™ Bacterial Viability Kit on filter membranes and a proprietary mounting oil that we have found to be useful for the direct epifluorescence filter technique⁷⁷ (DEFT). The kit components, number of assays and assay principles are summarized in Table 15.2. The SYTO® 9 nucleic acid stain is also available separately (S34854, Section 15.2).

LIVE/DEAD® *BacLight*™ Bacterial Viability and Counting Kit

Accurate detection and enumeration of the live and dead bacteria in a sample is an important aspect of many experimental procedures in biotechnology. Because of the marked differences in morphology, cytology and physiology among the many bacterial genera, a universally applicable direct-count viability assay has been very difficult to attain. Conventional direct-count assays of bacterial viability are based on metabolic characteristics or membrane integrity. However, methods relying on metabolic characteristics often only work for a limited subset of bacterial groups,⁷⁸ and methods for assessing bacterial membrane integrity commonly have high levels of background fluorescence.⁷⁹ Both types of determinations suffer from being very sensitive to growth and staining conditions.^{80,81} The LIVE/DEAD® *BacLight*™ Bacterial Counting and Viability Kit (L34856) allows researchers to reliably distinguish and quantitate live and dead bacteria with the aid of a flow cytometer, even in a mixed population containing a range of bacterial types.

This kit utilizes a mixture of two nucleic acid stains—the green-fluorescent SYTO® 9 dye and red-fluorescent propidium iodide—for viability determinations, as well as a calibrated suspension of beads for accurate sample volume measurements. The SYTO® 9 and propidium iodide stains differ both in their spectral characteristics and in their ability to penetrate healthy bacterial cells. When used alone, the SYTO® 9 stain generally labels all bacteria in a population—those with intact membranes and those with damaged membranes. In contrast, propidium iodide penetrates only bacteria with damaged membranes, causing a reduction in the SYTO® 9 stain fluorescence when both dyes are present. With an appropriate mixture of the SYTO® 9 and propidium iodide stains, bacteria with intact cell membranes fluoresce bright green, whereas bacteria with damaged membranes exhibit significantly less green fluorescence and they often also fluoresce red. The cell type and the gram character influence the amount of red-fluorescent staining exhibited by dead bacteria. Both the SYTO® 9 and propidium iodide stains are efficiently excited by the 488 nm spectral line of the argon-ion laser found in most flow cytometers, and their nucleic acid complexes can be detected in the green and red channels, respectively; the background remains virtually nonfluorescent.

The calibrated suspension of microspheres serves as a reference standard for sample volume. The size and fluorescence of the beads in this microsphere standard have been carefully chosen to ensure that they will be clearly distinguishable from any stained bacteria population in a fluorescence versus side scatter cytogram. A bacterial culture is simply stained with the optimal mixture of SYTO® 9 dye and propidium iodide, and then a fixed number of microspheres are added before analyzing the sample on a flow cytometer. Live and dead bacteria and the microspheres are all easily distinguished in a plot of fluorescence versus side scatter (Figure 15.3.26). The concentration of both the live bacteria and the dead bacteria can then be determined from the ratio of bacteria events to microsphere events in the cytogram (Figure 15.3.27).

The kit components, number of assays and assay principles are summarized in Table 15.2. The SYTO® 9 nucleic acid stain is also available separately (S34854, Section 15.2).

BacLight™ RedoxSensor™ Green Vitality Kit

Bacterial oxidation–reduction activity is an informative parameter for measuring cell vitality. Bacterial oxidases and reductases engage in important functions involving the electron transport chain, catabolic and anabolic pathways and xenobiotic compound metabolism.⁸² The RedoxSensor™ Green reagent, available in the BacLight™ RedoxSensor™ Green Vitality Kit (B34954), is an indicator of bacterial reductase activity; this reductase activity is, in turn, a reliable marker for changes in electron transport chain function and for changes in vitality that occur following antibiotic treatment. The RedoxSensor™ Green reagent penetrates both gram-positive and gram-negative bacteria, although differences in signal intensity may be observed based upon cell wall characteristics. Following reduction, the RedoxSensor™ Green reagent will produce a stable green-fluorescent signal (excitation/emission maxima ~490/520 nm) in about 10 minutes that is compatible with formaldehyde fixation techniques. The BacLight™ RedoxSensor™ Green Vitality Kit is useful for measuring the effects of antimicrobial agents and for monitoring cultures in fermenters.

The fluorescence intensity of cells stained with the RedoxSensor™ Green reagent is altered when cells are treated with reagents that disrupt electron transport, such as sodium azide or carbonyl cyanide 3-chlorophenylhydrazone (CCCP), which are both included in this kit. Species differences in responses may be observed. For example, sodium azide disrupts the fluorescence response in *Escherichia coli*, and CCCP disrupts fluorescence response in *Staphylococcus aureus*. The BacLight™ RedoxSensor™ Green Vitality Kit has been tested on logarithmically growing cultures of the following bacterial species: *Micrococcus luteus*, *Staphylococcus aureus*,

Figure 15.3.27 Best-fit linear regression analysis generated using the LIVE/DEAD® BacLight™ Bacterial Viability and Counting Kit (L34856). Suspensions of live (untreated, (—)) ($r^2=0.9982$) and dead (alcohol-treated, (- - -)) ($r^2=0.9974$) *Staphylococcus aureus* were mixed at various live:dead ratios. Mixtures were stained according to the kit protocol and analyzed in triplicate by flow cytometry. Values of bacteria/mL were calculated according to the equation provided in the kit protocol; the mean values are shown above. This experiment may be performed to determine optimal dye concentrations, to practice the cell-staining procedure or to generate a standard curve for unknown samples.

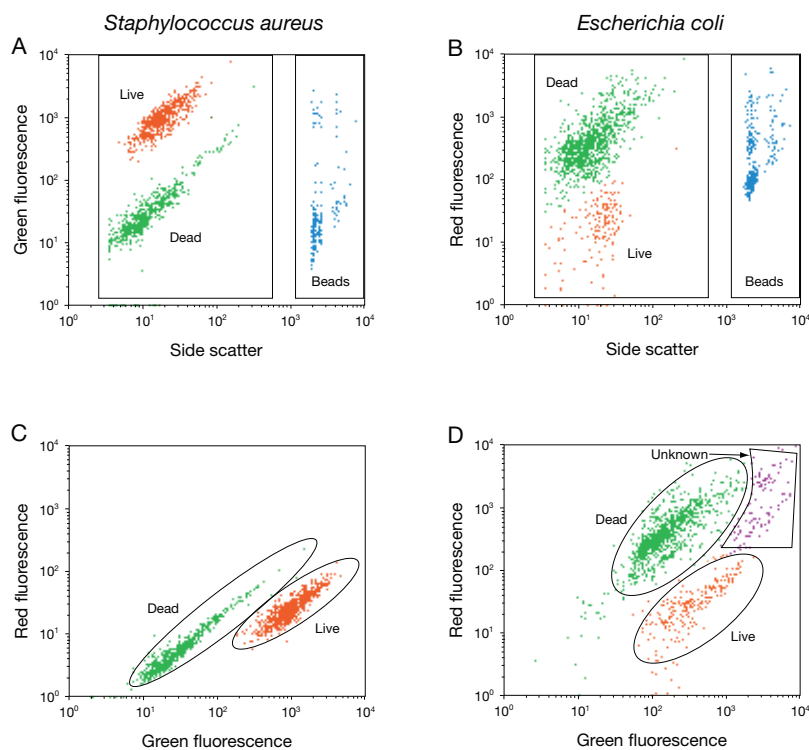

Figure 15.3.26 Analysis of bacterial cultures using the LIVE/DEAD® BacLight™ Bacterial Viability and Counting Kit (L34856). Suspensions of live (untreated) and dead (alcohol-treated) *Staphylococcus aureus* (A and C) and *Escherichia coli* (B and D) were stained with the SYTO® 9 nucleic acid stain and propidium iodide and then analyzed by flow cytometry according to the kit protocol. The green or red fluorescence versus side scatter cytogram (A or B) was used to gate the bacterial population and the bead population (left and right boxes, respectively). Events in the bacteria region of each cytogram are also displayed in red fluorescence versus green fluorescence cytograms (C and D). Live and dead bacteria/mL can be calculated from either the fluorescence versus side scatter cytogram or the green fluorescence versus red fluorescence cytogram, depending on which one shows the best separation of the live and dead populations. The position of the live and dead populations in these cytograms may be dependent on cell type and gram character. Some samples may exhibit events that fall outside the defined regions and should be evaluated appropriately (e.g., see panel D).

Figure 15.3.28 Detection of membrane potential in various bacteria with the *BacLight™* Bacterial Membrane Potential Kit (B34950). Red/green fluorescence ratios were calculated using population mean fluorescence intensities for gram-positive (*Micrococcus luteus*, *Staphylococcus aureus*, *Bacillus cereus* and *Staphylococcus warnerii*) and gram-negative (*Escherichia coli* and *Salmonella choleraesuis*) bacteria incubated with 30 μM DiOC₂(3) for 30 minutes in either the presence or absence of 5 μM CCCP, according to the kit protocol.

Figure 15.3.29 Response of *Staphylococcus aureus* to valinomycin and external potassium ions, as measured by flow cytometry using the *BacLight™* Bacterial Membrane Potential Kit (B34950). Samples containing *S. aureus* were treated with 5 μM valinomycin in different concentrations of potassium buffer, and then stained using 30 μM DiOC₂(3) for 30 minutes, according to the kit protocol. Data are expressed either using a ratiometric parameter based on the formula provided in the kit protocol (Δ , right axis) or as the ratio of population mean red-fluorescence intensity/mean green-fluorescence intensity (\bullet , left axis).

Bacillus cereus, *B. subtilis*, *Klebsiella pneumoniae*, *Escherichia coli* and *Salmonella choleraesuis*. Most gram-positive bacteria stain more efficiently than many gram-negative bacteria; and the response of each bacterial system should be investigated and optimized.

Each *BacLight™* RedoxSensor™ Green Vitality Kit contains:

- RedoxSensor™ Green reagent
- Propidium iodide, an indicator of membrane integrity
- Sodium azide
- Carbonyl cyanide 3-chlorophenylhydrazone (CCCP)
- Detailed protocols

At the recommended reagent dilutions and volumes, this kit contains sufficient material to perform ~200 tests by flow cytometry. Although the *BacLight™* RedoxSensor™ Green Vitality Kit has been developed for flow cytometric analysis, it may be appropriate for other analysis platforms.

BacLight™ RedoxSensor™ CTC Vitality Kit

The *BacLight™* RedoxSensor™ CTC Vitality Kit (B34956) provides effective reagents for evaluating bacterial health and vitality, and these staining reagents can withstand fixation procedures. This kit contains 5-cyano-2,3-ditoyl tetrazolium chloride (CTC), which has been used by researchers to evaluate the respiratory activity of many bacterial populations derived from environmental sources including food,^{83,84} soil,⁸⁵ stone⁸⁶ and marine and fresh water,^{87–90} as well as populations undergoing drug efficacy evaluations. Briefly, healthy cells respiring via the electron transport chain will absorb and reduce CTC into an insoluble, red-fluorescent formazan product. Cells not respiring or respiring at slower rates will reduce less CTC, and consequently produce less fluorescent product, giving a semiquantitative estimate of healthy versus unhealthy bacteria. SYTO® 24 green-fluorescent nucleic acid stain and DAPI are provided as counterstains to assist the researcher in differentiating cells from debris and in calculating total cell numbers. Bacteria labeled with CTC and either counterstain may be evaluated immediately or after storage, with or without fixation, using a flow cytometer equipped with appropriate excitation sources (CTC in combination with SYTO® 24 green-fluorescent nucleic acid stain: single 488 nm argon-ion laser; CTC in combination with DAPI: dual UV and 488 nm lasers). Bacteria stained using the *BacLight™* RedoxSensor™ CTC Vitality Kit may also be viewed using most standard epifluorescence microscopes equipped with the appropriate filters; for visualizing CTC, SYTO® 24 and DAPI staining, we recommend optical filters optimized for the Texas Red® dye, FITC and DAPI, respectively.

Each *BacLight™* RedoxSensor™ CTC Vitality Kit contains:

- 5-cyano-2,3-ditoyl tetrazolium chloride (CTC)
- SYTO® 24 green-fluorescent nucleic acid stain
- 4',6-diamidino-2-phenylindole, dihydrochloride (DAPI)
- Detailed protocols

At the recommended reagent dilutions and volumes, this kit contains sufficient material to perform at least 50 tests by flow cytometry or microscopy.

BacLight™ Bacterial Membrane Potential Kit

The *BacLight™* Bacterial Membrane Potential Kit (B34950) provides a fluorescent membrane-potential indicator dye, DiOC₂(3), along with a proton ionophore (CCCP) and premixed buffer. At low concentrations, DiOC₂(3) exhibits green fluorescence in all bacterial cells, but it becomes more concentrated in healthy cells that are maintaining a membrane potential, causing the dye to self-associate and the fluorescence emission to shift to red. The red- and green-fluorescent bacterial populations are easily distinguished using a flow cytometer. CCCP is included in the kit for use as a control because it eradicates the proton gradient, eliminating bacterial membrane potential.^{91,92}

Using the *BacLight™* Bacterial Membrane Potential Kit, we have detected membrane potentials in all bacteria tested (including logarithmically growing cultures of *Micrococcus luteus*,

Staphylococcus aureus, *Bacillus cereus*, *Staphylococcus warnerii*, *Escherichia coli* and *Salmonella choleraesuis*), although the magnitude varies with species (Figure 15.3.28). For many gram-positive species, such as *M. luteus* and *S. aureus*, the DiOC₂(3) red:green ratio has been shown to vary with the intensity of the proton gradient (Figure 15.3.29). In gram-negative bacteria, such as *E. coli* and *S. choleraesuis*, a DiOC₂(3) response is observed in the presence of a membrane potential but the response does not appear to be proportional to proton gradient intensity.

Each BacLight™ Bacterial Membrane Potential Kit contains:

- DiOC₂(3) in dimethylsulfoxide (DMSO)
- CCCP in DMSO
- Phosphate-buffered saline (PBS)
- Detailed protocols

Using the recommended reagent dilutions and volumes, this kit provides sufficient DiOC₂(3) to perform approximately 100 individual assays by flow cytometry; sufficient CCCP is provided for 30 depolarized control samples. The BacLight™ Bacterial Membrane Potential Kit is designed to assay bacterial concentrations between 10⁵ and 10⁷ organisms per mL. Note that DiOC₂(3) and CCCP are inhibitors of respiration, rendering the cells nonculturable beyond the brief time window required for staining and analysis.

LIVE BacLight™ Bacterial Gram Stain Kit

The LIVE BacLight™ Bacterial Gram Stain Kit (L7005) is based on differential nucleic acid staining of *live* gram-negative and gram-positive bacteria. The gram stain is one of the most important and widely used differential stains for the taxonomic classification of bacteria in both clinical and research settings. The original method involves several steps, including heat fixation of the bacteria, a two-step staining protocol, alcohol extraction and counterstaining. Over the years, several improved gram-staining techniques have been developed, but most still involve cell-fixation or cell-permeabilization steps that kill the bacteria being tested. Our single-step LIVE BacLight™ Bacterial Gram Stain Kits can overcome many of the problems inherent in these labor-intensive, fixation-dependent procedures.

Unlike conventional gram stain procedures, the LIVE BacLight™ Bacterial Gram Stain Kit allows researchers to rapidly classify bacteria as either gram-negative or gram-positive in minutes using a single staining solution, no fixatives and no wash steps. The LIVE BacLight™ Bacterial Gram Stain Kit contains our green-fluorescent SYTO® 9 and red-fluorescent hexidium iodide nucleic acid stains. These two dyes differ in both their spectral characteristics and in their ability to label live gram-negative and gram-positive bacteria. When a mixed population of live gram-negative and gram-positive bacteria is simultaneously stained with the membrane-permeant SYTO® 9 dye in combination with hexidium iodide, gram-negative bacteria fluoresce green, and the gram-positive bacteria fluoresce red-orange (Figure 15.3.30, Figure 15.3.31). Dead bacteria do not exhibit predictable staining patterns. Gram-negative and gram-positive organisms can be easily differentiated in any fluorescence microscope equipped with a standard fluorescein longpass optical filter set or by flow cytometry.⁹³ The assay provides a sensitive indicator system for analyzing low numbers of bacteria in the presence of background material because the unbound reagents exhibit low fluorescence when not bound to nucleic acids. The LIVE BacLight™ Bacterial Gram Stain Kit should be a useful tool for measuring dynamic changes in the composition of bacterial populations.

Our LIVE BacLight™ Bacterial Gram Stain Kit provides separate solutions of the SYTO® 9 and hexidium iodide nucleic acid stains, thus facilitating calibration of bacterial fluorescence at each of the two emission wavelengths in quantitative assays. The kit is well suited for use in fluorescence microscopy, as well as for use in quantitative analysis with a fluorometer (Figure 15.3.32), fluorescence microplate reader, flow cytometer⁹⁴ or other instrumentation. The kit includes a procedure for mounting bacteria stained with the LIVE BacLight™ Bacterial Gram Stain Kit on filter membranes, as well as the proprietary BacLight™ mounting oil that we have found to be useful for the direct epifluorescence filter technique⁷⁷ (DEFT). The kit components, number of assays and assay principles are summarized in Table 15.2. Hexidium iodide (H7593), the gram-positive bacteria-selective nucleic acid stain, and the SYTO® 9 nucleic acid stain (S34854) are both available separately (Section 15.2). The validity of using hexidium iodide in combination with the SYTO® 13 green-fluorescent nucleic acid stain to correctly predict the

Figure 15.3.30 Live *Micrococcus luteus* and *Salmonella oranienburg* bacteria stained with the LIVE BacLight™ Bacterial Gram Stain Kit (L7005). Gram-positive *M. luteus* cells fluoresce orange, whereas gram-negative *S. oranienburg* cells fluoresce green. This image was photographed in a single exposure through an Omega® Optical triple bandpass filter set.

Figure 15.3.31 A mixed population of *Bacillus cereus* and *Pseudomonas aeruginosa* stained with the dye mixture provided in our LIVE BacLight™ Gram Stain Kit (L7005). When live bacteria are incubated with this kit's cell-permeant nucleic acid stains, gram-positive organisms fluoresce orange and gram-negative organisms fluoresce green. The bacteria were photographed through an Omega® Optical triple bandpass filter set.

Figure 15.3.32 Analysis of the percentage of gram-negative *Escherichia coli* in mixed suspensions containing gram-positive *Staphylococcus aureus* using the reagents in the LIVE BacLight™ Bacterial Gram Stain Kit (L7005). Live gram-negative and gram-positive bacteria are stained fluorescent green (G) by SYTO® 9 and fluorescent red (R) by hexidium iodide, respectively. Bacterial suspensions that have been incubated in the two stains simultaneously and then excited at 470 nm exhibit a fluorescence spectral shift from red to green as the percentage of gram-negative bacteria in the sample is increased.

Figure 15.3.33 *Bifidobacterium* sp. bacteria stained with the ViaGram™ Red⁺ Bacterial Gram Stain and Viability Kit (V7023). While all cells exhibit a red-fluorescent surface stain (gram-positive), live cells exhibit blue-fluorescent internal staining and dead cells with compromised membranes exhibit yellow-green-fluorescent internal staining. This image was obtained by taking multiple exposures through bandpass optical filter sets appropriate for DAPI, fluorescein and Texas Red® dye.

gram sign of 45 clinically relevant organisms, including several known to be gram variable, has been demonstrated.⁹³

ViaGram™ Red⁺ Bacterial Gram Stain and Viability Kit

The ViaGram™ Red⁺ Bacterial Gram Stain and Viability Kit (V7023) provides an easy, three-color fluorescent staining protocol that differentially stains many gram-negative and gram-positive bacterial species and, at the same time, discriminates live from dead cells based on plasma membrane integrity. This kit contains three reagents: two nucleic acid stains for viability determination—the blue-fluorescent cell-permeant DAPI and the green-fluorescent cell-impermeant SYTOX® Green nucleic acid stain—as well as the red-fluorescent Texas Red®-X wheat germ agglutinin (WGA) for gram sign determination. Bacteria with intact cell membranes stain fluorescent blue with DAPI, whereas bacteria with damaged membranes stain fluorescent green with the SYTOX® Green nucleic acid stain. The background remains virtually nonfluorescent. The Texas Red®-X WGA component selectively binds to the surface of gram-positive bacteria, providing a red-fluorescent cell-surface stain that effectively distinguishes them from gram-negative bacteria, even in the presence of the viability stains. Thus, with three fluorescent colors, the four possible combinations of live or dead, gram-negative and gram-positive cells are discriminated with a fluorescence microscope (Figure 15.3.33, Figure 15.3.34). This kit also includes a procedure for mounting bacteria on filter membranes and the BacLight™ mounting oil, which we have found to be useful for the direct epifluorescence filter technique⁷⁷ (DEFT). The kit components, number of assays and assay principles are summarized in Table 15.2.

FilmTracer™ LIVE/DEAD® Biofilm Viability Kit

The FilmTracer™ LIVE/DEAD® Biofilm Viability Kit (L10316) provides a two-color fluorescence assay of bacterial viability based on membrane integrity, and has proven useful for a diverse array of bacterial genera, including those growing in biofilm communities. The kit utilizes a mixture of SYTO® 9 green-fluorescent nucleic acid stain and the red-fluorescent nucleic acid stain, propidium iodide, which differ both in their spectral characteristics and in their ability to penetrate healthy bacteria. SYTO® 9 stain generally labels all bacteria in a population—those with intact membranes and those with damaged membranes. In contrast, propidium iodide penetrates only bacteria with damaged membranes; SYTO® 9 stain fluorescence is thereby reduced in cells where both dyes are present. When treated with an appropriate mixture of these stains, bacteria with intact cell membranes display green fluorescence while those with damaged membranes display red fluorescence.

We offer several individual fluorescent FilmTracer™ biofilm stains, which are described in Section 15.2):

- FilmTracer™ calcein red-orange biofilm stain (F10319)
- FilmTracer™ calcein violet biofilm stain (F10320)

Figure 15.3.34 A mixed population of live and isopropyl alcohol-killed *Micrococcus luteus* and *Bacillus cereus* simultaneously stained with DAPI (D1306, D3571, D21490) and SYTOX® Green nucleic acid stain (S7020), the viability determination components of the ViaGram™ Red⁺ Bacterial Gram Stain and Viability Kit (V7023). Bacteria with intact cell membranes are stained exclusively with the cell-permeant DAPI nuclear stain and exhibit blue fluorescence, whereas cells with damaged membranes are stained with both fluorophores and exhibit green fluorescence. This image was acquired with a UV longpass optical filter set.

- FilmTracer™ calcein green biofilm stain (F10322)
- FilmTracer™ FM® 1-43 green biofilm cell stain (F10317)
- FilmTracer™ SYPRO® Ruby biofilm matrix stain (F10318)

Wheat Germ Agglutinin Sampler Kit

Fluorescent lectins have proven useful in microbiology applications. Fluorescent wheat germ agglutinin (WGA) conjugates selectively stain chitin in fungal cell walls,⁹⁵ as well as the surface of gram-positive but not of gram-negative bacteria. Fluorescent WGA has also been shown to bind to sheathed microfilariae and has been used to detect filarial infection in blood smears.⁹⁶ Our Wheat Germ Agglutinin Sampler Kit (W7024) provides 1 mg samples of four of our brightest fluorescent WGA conjugates, spanning the spectrum from blue to red. Included in this kit are conjugates of the blue-fluorescent Alexa Fluor® 350, green-fluorescent Oregon Green® 488, orange-fluorescent tetramethylrhodamine and red-fluorescent Texas Red®-X dyes (Table 7.10). See Section 7.7 for more information on lectins, including additional WGA and concanavalin A (Con A) conjugates.

Reverse Transcriptase Assay for Retrovirus Titering

The EnzChek® Reverse Transcriptase Assay Kit (E22064) is designed to provide a convenient and efficient method for measuring reverse transcriptase activity. This kit has been used to determine HIV-1 reverse transcriptase heterodimer activity,⁹⁷ to measure SARS-CoV viral titers in 293T host cultures⁹⁸ and to quantitate reverse transcriptase activity in Friend virus (FV) culture supernatants.⁹⁹

The key to this assay is our PicoGreen® dsDNA quantitation reagent, which preferentially detects dsDNA or RNA–DNA heteroduplexes over single-stranded nucleic acids or free nucleotides. In the assay, the sample to be measured is added to a mixture of a long poly(A) template, an oligo(dT) primer and dTTP. Reverse transcriptase activity in the sample results in the formation of long RNA–DNA heteroduplexes, which are detected by the PicoGreen® reagent at the end of the assay. In less than an hour, samples can be read in a fluorometer or microplate reader with filter sets appropriate for fluorescein (FITC). The assay is sensitive, detecting as little as 0.02 units of HIV reverse transcriptase and has about a 50-fold linear range.

The EnzChek® Reverse Transcriptase Assay Kit contains sufficient reagents for approximately 1000 assays using a fluorescence microplate reader:

- PicoGreen® dsDNA quantitation reagent
- Bacteriophage lambda DNA standard
- Poly(A) ribonucleotide template
- Oligo dT16 primer
- TE buffer, polymerization buffer and an EDTA solution
- Detailed protocols

ATP Determination

The luciferin–luciferase bioluminescence assay is extremely sensitive; most luminometers can detect as little as 1 picomole of pre-existing ATP or ATP as it is generated in kinetic systems. This sensitivity has led to its widespread use for detecting ATP in various enzymatic reactions, as well as for measuring viable cell number,¹⁰⁰ for monitoring ATP release from cells^{101–104} and for detecting low-level bacterial contamination in samples such as blood, milk, urine, soil and sludge.^{105–109} The luciferin–luciferase bioluminescence assay has also been used to determine cell proliferation and cytotoxicity in both bacterial^{110,111} and mammalian cells,^{112,113} and to distinguish cytostatic versus cytotoxic potential of anticancer drugs on malignant cell growth.¹¹⁴

We offer a convenient ATP Determination Kit (A22066) for the sensitive bioluminescence-based detection of ATP with recombinant firefly luciferase and its substrate luciferin. This assay is based on luciferase's absolute requirement for ATP to produce light. In the presence of Mg^{2+} , luciferase catalyzes the reaction of luciferin, ATP and O_2 to form oxyluciferin, AMP, CO_2 , pyrophosphate and ~560 nm light (Figure 15.3.35).

The ATP Determination Kit (A22066) contains:

- Luciferin (5 × 3 mg)
- Luciferase
- ATP
- Dithiothreitol (DTT)
- Concentrated reaction buffer
- Detailed protocols for ATP quantitation

Unlike most other commercially available ATP detection kits, our ATP Determination Kit provides the luciferase and luciferin packaged separately, which enables researchers to optimize the reaction conditions for their particular instruments and samples. The ATP Determination Kit provides sufficient reagents to perform 200 ATP assays using 0.5 mL sample volumes or 500 ATP assays using 0.2 mL sample volumes.

Figure 15.3.35 Reaction scheme for bioluminescence generation via luciferase-catalyzed conversion of luciferin to oxyluciferin.

L23101	LIVE/DEAD® Fixable Green Dead Cell Stain Kit *for 488 nm excitation* *200 assays*	1 kit
L10119	LIVE/DEAD® Fixable Near-IR Dead Cell Stain Kit *for 633 or 635 nm excitation* *200 assays*	1 kit
L23102	LIVE/DEAD® Fixable Red Dead Cell Stain Kit *for 488 nm excitation* *200 assays*	1 kit
L34955	LIVE/DEAD® Fixable Violet Dead Cell Stain Kit *for 405 nm excitation* *200 assays*	1 kit
L34959	LIVE/DEAD® Fixable Yellow Dead Cell Stain Kit *for 405 nm excitation* *200 assays*	1 kit
L34952	LIVE/DEAD® FungaLight™ Yeast Viability Kit *for flow cytometry*	1 kit
L7013	LIVE/DEAD® Reduced Biohazard Cell Viability Kit #1 *green and red fluorescence* *100 assays*	1 kit
L7011	LIVE/DEAD® Sperm Viability Kit *200–1000 assays*	1 kit
L3224	LIVE/DEAD® Viability/Cytotoxicity Kit *for mammalian cells*	1 kit
L34958	LIVE/DEAD® Violet Viability/Vitality Kit *for 405 nm excitation* *200 assays*	1 kit
L7009	LIVE/DEAD® Yeast Viability Kit *1000 assays*	1 kit
V7023	ViaGram™ Red+ Bacterial Gram Stain and Viability Kit *200 assays*	1 kit
V23110	Vybrant® Cell Metabolic Assay Kit *with C ₁₂ -resazurin* *500–1000 assays*	1 kit
V23111	Vybrant® Cytotoxicity Assay Kit *G6PD release assay* *1000 assays*	1 kit
W7024	Wheat Germ Agglutinin Sampler Kit *four fluorescent conjugates, 1 mg each*	1 kit

15.4 Assays for Cell Enumeration, Cell Proliferation and Cell Cycle

Cell proliferation and the characterization of agents that either promote or retard cell proliferation are extremely important areas of cell biology and drug-discovery research. We offer both traditional reagents for assessing cell proliferation and cell cycle—in particular the Hoechst nucleic acid stains and probes for 5-bromo-2'-deoxyuridine (BrdU) incorporation during cell division—as well as some exceptional tools developed in our laboratories, including the Click-iT® EdU cell proliferation assay. For simply detecting the presence or counting the number of cells, fluorescent stains that identify cells by their characteristic morphology or light-scattering properties may be sufficient.

Cell Enumeration and Cell Proliferation Assays for Animal Cells

Reagents for counting cells and quantitating cell proliferation are valuable research tools. Most cell proliferation assays estimate the number of cells either by incorporating a modified nucleotide into cells during proliferation or by measuring total nucleic acid or protein content of lysed cells.^{1,2} Several of our nucleic acid stains (Section 8.1) and nucleotides (Section 8.2) have proven useful in nucleic acid labeling protocols. Here we describe our Click-iT® EdU cell proliferation assay, which provides a superior alternative to bromodeoxyuridine (BrdU) or ³H-thymidine incorporation methods for measuring new DNA synthesis. Alternatively, our CyQUANT® Cell Proliferation Assay Kits use the CyQUANT® GR, CyQUANT® NF or CyQUANT® Direct nucleic acid stains to measure increases in nucleic acid content that accompany cell proliferation

Click-iT® Tools for Cell Proliferation Analysis

Click-iT® labeling technology employs a bioorthogonal reactive chemistry for the *in situ* labeling of specific molecular populations, such as newly synthesized nucleic acids, in an experimental time window of interest. The Click-iT® labeling reaction is based on a copper-catalyzed azide-alkyne cycloaddition^{3,4} and derives its high degree of specificity from the fact that the azide and alkyne reaction partners have no endogenous representation in biological molecules, cells, tissues or model organisms.⁵⁻⁷ Click-iT® labeling technology and the details of the click reaction are discussed in Section 3.1. For a complete list of azide and alkyne derivatives compatible with Click-iT® labeling technology, see Table 3.1. Here we highlight the Click-iT® EdU cell proliferation assay.

The Click-iT® EdU cell proliferation assay provides a superior alternative to bromodeoxyuridine (BrdU) or ³H-thymidine incorporation methods for measuring new DNA synthesis.^{8,9} The alkynyl nucleoside analog EdU (5-ethynyl-2'-deoxyuridine; A10044, E10187, E10415) is incorporated into DNA during the synthesis phase (S phase) of the cell cycle and is subsequently detected by copper (I)-catalyzed click coupling to an azide-derivatized fluorophore¹⁰ (Figure 15.4.1). The small size of the click-coupled fluorophore compared to that of antibodies required for immunodetection of BrdU enables efficient penetration of complex samples without the need for harsh cell treatment, simplifying the assay considerably. The Click-iT® EdU assay protocol is compatible with both adherent cells and cell suspensions. From start to finish, the EdU detection assay is complete in as little as 90 minutes, as compared with the antibody-based BrdU method, which takes 6–24 hours to complete. In addition, the Click-iT® EdU cell proliferation assay can be multiplexed with surface and intracellular marker detection using Alexa Fluor® dye-labeled secondary antibodies¹¹⁻¹⁴ (Section 7.2) (Figure 15.4.2).

Figure 15.4.2 Multicolor imaging with the Click-iT® EdU Imaging Kits. Muntjac cells were treated with 10 μ M EdU for 45 minutes. Cells were then fixed and permeabilized, and EdU that had been incorporated into newly synthesized DNA was detected by the far-red-fluorescent Click-iT® EdU Alexa Fluor® 647 HCS Assay (C10356, C10357). Tubulin was labeled with an anti-tubulin antibody and visualized with an Alexa Fluor® 350 goat anti-mouse IgG antibody (A21049). The Golgi complex was stained with the green-fluorescent Alexa Fluor® 488 conjugate of lectin HPA from *Helix pomatia* (edible snail) (L11271), and peroxisomes were labeled with an anti-peroxisome antibody and visualized with an orange-fluorescent Alexa Fluor® 555 donkey anti-rabbit IgG antibody (A31572).

Figure 15.4.1 Click-iT® copper-catalyzed azide-alkyne cycloaddition chemistry applied to detection of newly synthesized DNA. The reaction partners in this example are 5-ethynyl-2'-deoxyuridine (EdU), which can be enzymatically incorporated in DNA during S phase, and the green-fluorescent Alexa Fluor® 488 azide.

Although the majority of applications are in cultured mammalian cells, Click-iT® EdU reagents and methods have also been successfully applied to a wide range of model organisms including:

- *Escherichia coli*¹⁵
- *Caenorhabditis elegans*¹²
- *Drosophila*¹⁶
- Zebrafish¹⁷
- Mouse¹³
- Plants^{18,19} (alfalfa, *Arabidopsis*, grape, maize, rice and tobacco)

The Click-iT® EdU Flow Cytometry Assay Kits provide all the reagents needed to perform 50 assays using 0.5 mL reaction buffer per assay, including the nucleoside analog EdU and all components for fixation, permeabilization and labeling whole blood samples, adherent cells or suspension cells.^{9,20} Additionally, two cell-cycle stains compatible with the fluorescence excitation and emission characteristics of the fluorescent azide detection reagents are included. We offer three Click-iT® EdU Flow Cytometry Assay Kits:

- Click-iT® EdU Alexa Fluor® 488 Flow Cytometry Assay Kit (C35002)
- Click-iT® EdU Alexa Fluor® 647 Flow Cytometry Assay Kit (A10202)
- Click-iT® EdU Pacific Blue™ Flow Cytometry Assay Kit (A10034)

The Click-iT® EdU Imaging Kits contain all of the components needed to label and detect incorporated EdU on 50 coverslips using 0.5 mL reaction buffer per test, as well as the blue-fluorescent Hoechst 33342 nuclear stain for performing cell-cycle analysis on adherent cell samples. We offer four Click-iT® EdU Imaging Kits:

- Click-iT® EdU Alexa Fluor® 488 Imaging Kit (C10337)
- Click-iT® EdU Alexa Fluor® 555 Imaging Kit (C10338)
- Click-iT® EdU Alexa Fluor® 594 Imaging Kit (C10339)
- Click-iT® EdU Alexa Fluor® 647 Imaging Kit (C10340)

The Click-iT® EdU HCS Assay Kits contain all of the materials needed to label and detect incorporated EdU in adherent cells in 96-well microplates and 100 µL reaction buffer per assay. For cell

Figure 15.4.3 Detection of proliferation in W125 Lymphoma B cells. Cells were treated with 10 µM 5-bromo-2'-deoxyuridine (BrdU, B23151) in culture medium for 1 hour, then pelleted and fixed with cold 70% ethanol. After treatment with RNase and 4 M HCl (to denature the DNA), the cells were labeled with anti-BrdU antibody and detected using green-fluorescent Alexa Fluor® 488 goat anti-mouse IgG antibody (A11001). In addition, the cells were labeled with red-fluorescent propidium iodide (P1304MP, P3566, P21493) to assess the total cellular DNA content. The cells were analyzed by flow cytometry using 488 nm excitation; the fluorescent signals were collected at ~525 nm for the Alexa Fluor® 488 dye and at ~675 nm for propidium iodide. Increased BrdU incorporation is indicative of actively proliferating cells.

registration or DNA profiling, these kits also include the blue-fluorescent HCS NuclearMask™ Blue stain (H10325, Section 12.5). We offer four Click-iT® EdU HCS Assay Kits:

- Click-iT® EdU Alexa Fluor® 488 HCS Assay Kit (2-plate size, C10350; 10-plate size, C10351)
- Click-iT® EdU Alexa Fluor® 555 HCS Assay Kit (2-plate size, C10352; 10-plate size, C10353)
- Click-iT® EdU Alexa Fluor® 594 HCS Assay Kit (2-plate size, C10354; 10-plate size, C10355)
- Click-iT® EdU Alexa Fluor® 647 HCS Assay Kit (2-plate size, C10356; 10-plate size, C10357; Figure 15.4.2)

In addition to these kits, our Click-iT® EdU Microplate Assay Kit (C10214) provides a simple and rapid workflow with fewer wash steps resulting in a substantial time-savings advantage over traditional BrdU colorimetric or fluorescent cell proliferation assays. This assay uses Oregon Green® 488 azide for click coupling to synthetically incorporated EdU. The signal is amplified using immunodetection of the Oregon Green® 488 fluorophore by a rabbit anti-Oregon Green® horseradish peroxidase (HRP) conjugate followed by fluorogenic or chromogenic detection with our Amplex® UltraRed HRP substrate. The Click-iT® EdU microplate assay has been successfully tested in HeLa, A549, U2OS and A541 cells with a variety of reagents that modulate DNA synthesis, including the DNA synthesis inhibitor aphidicolin and the mitotic inhibitor paclitaxel. The Click-iT® EdU Microplate Assay Kit contains sufficient reagents for performing 400 individual assays in a 96-well plate format.

Proliferation Assays Using Bromodeoxyuridine Incorporation

Incorporation of 5-bromo-2'-deoxyuridine (BrdU, B23151) into newly synthesized DNA permits indirect detection of rapidly proliferating cells with fluorescently labeled anti-BrdU antibodies or certain nucleic acid stains, thereby facilitating the identification of cells that have progressed through the S phase of the cell cycle during the BrdU labeling period.^{2,21,22} We offer fluorescent conjugates of the mouse monoclonal anti-BrdU antibody clone MoBU-1 labeled with our brightest and most photostable dyes:

- Alexa Fluor® 488 anti-BrdU antibody (B35130, B35139)
- Alexa Fluor® 555 anti-BrdU antibody (B35131)
- Alexa Fluor® 594 anti-BrdU antibody (B35132)
- Alexa Fluor® 647 anti-BrdU antibody (B35133, B35140)
- Pacific Blue™ anti-BrdU antibody (B35129)

This anti-BrdU antibody is also available biotinylated (B35138), as well as unlabeled (B35128, B35141). The unlabeled mouse anti-BrdU can be detected with our anti-mouse secondary antibodies (Table 7.1) using either flow cytometry (Figure 15.4.3) or imaging.

Because fluorescence of the Hoechst 33258 (H1398, H3569, H21491) and Hoechst 33342 (H1399, H3570, H21492) dyes bound to DNA is quenched at sites where BrdU is incorporated, Hoechst dye fluorescence can also be used to detect BrdU incorporation in single cells.^{1,23-26} This technique has been employed to quantitate the noncycling cell fraction, as well as the fraction of cells that are in G₁ and G₂ of two subsequent cycles.²⁷ The addition of ethidium bromide as a counterstain that is insensitive to BrdU incorporation allows the resolution of G₁, S and G₂ compartments of up to three consecutive cell cycles.^{28,29}

Unlike the fluorescence of Hoechst dyes, the fluorescence of TO-PRO[®]-3 (T3605) and LDS 751 (L7595) is considerably *enhanced* by the presence of bromodeoxyuridine in DNA. In conjunction with propidium iodide (P1304MP, P3566, P21493; Section 8.1), these nucleic acid stains have been used to discriminate BrdU-labeled cells from nonproliferating cells by flow cytometry^{30,31} and with an imaging system for automated cell proliferation.³²

Proliferation Assays Using ChromaTide[®] Nucleotides

In the strand break induction by photolysis (SBIP) technique, proliferating cells that have incorporated BrdU into newly synthesized DNA are subjected to Hoechst 33258 staining, followed by UV photolysis to induce DNA strand breaks³³ (Figure 15.4.4). Once the cells are fixed, strand breaks can be detected *in situ* using mammalian terminal deoxynucleotidyl transferase (TdT), which covalently adds labeled nucleotides to the 3'-hydroxyl ends of these DNA fragments.^{34–37} Break sites have traditionally been labeled with biotinylated or haptenylated dUTP conjugates (Section 8.2) in conjunction with antibodies to the hapten (Section 7.4) or conjugates of streptavidin^{37,38} (Section 7.6). However, a single-step procedure has been described that uses our ChromaTide[®] BODIPY[®] FL-14-dUTP (C7614, Figure 15.4.5) as a TdT substrate for directly detecting DNA strand breaks both in BrdU-labeled cells following SBIP and in apoptotic cells^{33,39–42} (Section 15.5; Figure 15.4.6, Figure 15.4.7).

The single-step BODIPY[®] FL dye-based assay has several advantages over indirect detection of biotinylated or haptenylated nucleotides. With direct detection procedures, no secondary detection reagents are required; fewer protocol steps translate into less chance for error and more immediate results. Moreover, the yield of cells with direct detection procedures is reported to be about three times greater than that of multistep procedures employing biotin- or digoxigenin-conjugated dUTP. Although both BODIPY[®] FL dye- and fluorescein-labeled nucleotides can be detected with fluorescence microscopy or flow cytometry, the BODIPY[®] FL dye-labeled nucleotides provide ~40% stronger signal than fluorescein-labeled nucleotides when assaying strand breaks in apoptotic versus nonapoptotic cells. In addition, fading of the fluorescence of the incorporated BODIPY[®] FL dUTP is less than that of the corresponding fluorescein dUTP analog.³⁹ Unlike traditional proliferation assays based on BrdU incorporation, no DNA

Figure 15.4.7 HL-60 cells treated with camptothecin for 3 hours. The DNA strand nicks characteristic of apoptosis were detected with the TUNEL (terminal deoxynucleotidyl transferase-mediated dUTP nick end-labeling) assay using the fluorescently labeled nucleotide ChromaTide[®] BODIPY[®] FL-14-dUTP (C7614). Image contributed by Zbigniew Darzynkiewicz, Cancer Research Institute, New York Medical College.

Figure 15.4.4 Schematic diagram showing the sequence of events in the strand break induction by photolysis (SBIP) technique. A) Proliferating cells that have incorporated BrdU (*) into newly synthesized DNA are B) exposed to UV light in order to induce DNA strand breaks. If the cells are stained with Hoechst 33258 prior to UV illumination, the photolysis efficiency is increased. C) Once the cells are fixed, the 3'-hydroxyl ends exposed at these strand breaks can be directly labeled *in situ* using mammalian terminal deoxynucleotidyl transferase (TdT) and our ChromaTide[®] BODIPY[®] FL-14-dUTP (C7614).

Figure 15.4.5 ChromaTide[®] BODIPY[®] FL-14-dUTP (C7614).

Figure 15.4.6 Detection of BrdU-incorporating cells using the SBIP (Strand Breaks Induced by Photolysis) technique. Exponentially growing human promyelocytic leukemia (HL60) cells were incubated with 20 μ M BrdU (B23151) for 40 minutes and then with 20 μ g/mL Hoechst 33258 (H1398, H3569, H21491) in the presence of 2% DMSO for an additional 20 minutes. After this incubation, the cells were exposed to 300 nm UV light for 5 minutes to selectively photolyze DNA that contained the incorporated BrdU, and then fixed in 70% ethanol. Subsequent incubation of the permeabilized cells with the ChromaTide[®] BODIPY[®] FL-14-dUTP (C7614) in the presence of exogenous terminal deoxynucleotidyl transferase resulted in incorporation of the fluorophore into DNA strand breaks, thereby labeling the S-phase cells. The DNA was counterstained with the red-fluorescent nucleic acid stain propidium iodide (P1304MP, P3566, P21493); therefore, the BODIPY[®] FL dye-labeled DNA appears yellow. The image was contributed by Zbigniew Darzynkiewicz, Cancer Research Institute, New York Medical College.

Figure 15.4.8 Tracking of asynchronous cell division using 5-(and 6)-carboxyfluorescein diacetate, succinimidyl ester (5(6)-CFDA SE or CFSE; C1157; V12883) labeling and flow cytometry. Cell division results in sequential halving of the initial fluorescence, resulting in a cellular fluorescence histogram. The peaks labeled 0, 1, 2, 3, 4 and 5 represent successive generations.

Figure 15.4.9 Following cell proliferation in human peripheral blood lymphocytes using the CellTrace™ CFSE Cell Proliferation Kit (C34554). Human peripheral blood lymphocytes were harvested and stained with CellTrace™ CFSE (carboxyfluorescein diacetate, succinimidyl ester; 5(6)-CFDA, SE) on day 0. A portion of the population was arrested at the parent generation using mitomycin C (red peak). The remainder of the sample was stimulated with phytohemagglutinin and allowed to proliferate for 5 days. Solid green peaks represent successive generations.

heat- or acid-denaturation steps are required with SBIP in order to visualize the labeled strand breaks, allowing simultaneous detection of the morphology of nuclear proteins and other cellular constituents by immunocytochemical analysis. The narrow emission spectrum of the BODIPY® FL dye-labeled nucleotides is especially useful for multicolor labeling experiments.

An elegant technique has been described that permits tracking of labeled chromosomes through mitosis by metabolic incorporation of microinjected fluorescent nucleotides, including our fluorescein-12-dUTP (C7604, Section 8.2), into DNA using endogenous cellular enzymes.^{43–45} The procedure does not interfere with subsequent progress through the cell cycle, and fluorescent strands of DNA can be followed as they assemble into chromosomes and segregate into daughters and granddaughters.^{43–45} Presumably, injection of 5'-bromo-2'-deoxyuridine triphosphate (BrdUTP, B21550), followed by detection of the incorporated BrdU with one of our Alexa Fluor® conjugates of anti-BrdU would also be suitable for studying mitosis. The corresponding ribonucleotide (BrUTP, B21551) that has been microinjected into cells is incorporated into RNA of a nucleolar compartment,^{46,47} a process that should also be detectable with fluorescent anti-BrdU conjugates.

Proliferation Assay Using the Succinimidyl Ester of Carboxyfluorescein Diacetate and Related Probes

The succinimidyl ester of carboxyfluorescein diacetate (5(6)-CFDA, SE or CFSE, C1157) is currently the most widely used probe for generation analysis of cells, although our succinimidyl ester of Oregon Green® 488 carboxylic acid diacetate (O34550, C34555; see below) offers several important advantages over this fluorescein derivative. CFDA SE spontaneously and irreversibly couples to both intracellular and cell-surface proteins by reaction with lysine side chains and other available amine groups. When cells divide, CFDA SE labeling is distributed equally between the daughter cells, which are therefore half as fluorescent as the parents. As a result, each successive generation in a population of proliferating cells is marked by a halving of cellular fluorescence intensity (excitation/emission maxima ~495/525 nm) that is readily detected by a flow cytometer (Figure 15.4.8), fluorescence microscope or fluorescence microplate reader. CFDA SE is available as a single vial containing 25 mg (C1157). CFDA SE is also available conveniently packaged for cell tracing applications in our Vybrant® CFDA SE Cell Tracer Kit (V12883, Figure 15.4.8) and for cell proliferation studies in our CellTrace™ CFSE Cell Proliferation Kit (C34554, Figure 15.4.9). The fluorescent CFDA SE product has excitation/emission maxima of ~492/517 nm and can be detected using a fluorescence microscope, flow cytometer or fluorescence microplate reader. Each kit includes 10 single-use vials of CFDA SE (500 µg each in Kit V12883, 50 µg each in Kit C34554), as well as high-quality anhydrous DMSO and a complete protocol.

CFDA SE produces more homogeneous cellular labeling and, consequently, much better intergenerational resolution than other cell-tracking dyes, such as the membrane marker PKH26. Using flow cytometric analysis of CFDA SE labeling, researchers can resolve 8 to 10 successive generations of lymphocytes.^{48,49} In transplanted cells the signal of CFDA SE can be traced *in vivo* for weeks.^{50,51} The feasibility of using cell-permeant fluorescent tracers to follow cell division of natural killer (NK) cells, B cells, T cells, thymocytes, lymphocytes, fibroblasts and hematopoietic cells has been demonstrated with CFDA SE.^{49,52–62} For instance, researchers have used CFDA SE labeling to show that transplantable hematopoietic cells proliferate *in vitro* in response to stimulation by a growth factor cocktail.⁶³ These studies helped provide direct evidence that the hematopoietic potential of cultured stem cells is limited by homing activity and not by proliferative capacity. Because the first division results in the largest change in fluorescence intensity, this method is particularly useful for detecting subsets of cells within a population that are resistant to cell division. The method is not limited to mammalian cells; it has also been applied to determine the number of cell divisions in stained *Lactobacillus plantarum*.⁶⁴

Like CFDA SE, the succinimidyl ester of Oregon Green® 488 carboxylic acid diacetate (carboxy-DFFDA SE) should be a useful tool for following proliferating cells. This Oregon Green® 488 probe passively diffuses into cells, where it is colorless and nonfluorescent until its acetate groups are removed by intracellular esterases to yield a highly green-fluorescent, amine-reactive dye. Upon reaction with intracellular amines, the probe forms Oregon Green® 488 conjugates that are well-retained by cells. Unlike fluorescein derivatives, however, Oregon Green® 488

derivatives exhibit bright green fluorescence that is not pH dependent at typical cellular pH values. Moreover, Oregon Green® 488 probes are usually brighter and more photostable than fluorescein probes. We offer carboxy-DFFDA SE in a 1 mg unit size (O34550) and specially packaged in a set of 20 vials, each containing 50 µg (CellTrace™ Oregon Green® 488 carboxylic acid diacetate succinimidyl ester, C34555).

The intracellular conjugates of 5-(and 6-)carboxyeosin diacetate succinimidyl ester (C22803) have absorption and emission spectra at longer wavelengths than CFDA SE, which may make this probe useful in combination with CFDA SE for studies of proliferation of mixed-cell populations. Eosin conjugates are more effective singlet-oxygen generators than are simple fluorescein derivatives, potentially resulting in their utility for photoablation of cells.

The succinimidyl ester of SNARF®-1 carboxylic acid, acetate (S22801) is also designed to serve as a cell tracer and indicator of cell division. However, unlike the green-fluorescent CFDA SE-labeled cells, cells labeled with the succinimidyl ester of SNARF®-1 carboxylic acid, acetate exhibit red fluorescence when excited near 488 nm. Although the fluorescence intensity of this SNARF® derivative in cells may be weaker than that of cells labeled with CFDA SE, its red fluorescence is easily distinguished from the green fluorescence of CFDA SE-labeled cells. The SNARF® dyes have been predominantly used as indicators of intracellular pH (Chapter 20).

CellTrace™ Violet Cell Proliferation Kit

CellTrace™ Violet stain is an esterase-activated phenolic fluorophore with a succinimidyl ester substituent for coupling to cell surface and intracellular amines. It is functionally analogous to CFSE, equally partitioning between daughter cells during division resulting in successive 2-fold reductions in cell-associated fluorescence intensity. When analyzed by flow cytometry, this progressive label partitioning provides a direct indication of cell proliferation status (Figure 15.4.10). In contrast to CFSE, CellTrace™ Violet stain is optimally excited by 405 nm violet diode lasers and generates blue fluorescence (emission peak ~455 nm). Consequently, it can be used in combination with CFSE to track cells from different origins after mixing or to analyze proliferation of GFP-expressing cells. The CellTrace™ Violet Cell Proliferation Kit (C34557) includes the CellTrace™ Violet stain together with dimethylsulfoxide (DMSO) for preparation of a stock solution.

CyQUANT® Cell Proliferation Assay Kit

Because cellular DNA content is highly regulated, it is closely proportional to cell number. Therefore, changes in nucleic acid content can serve as a sensitive indicator of overall cell proliferation, as well as of cytotoxic events or pathological abnormalities that affect cell proliferation. Our CyQUANT® Cell Proliferation Assay Kit (C7026) provides an excellent method both for enumerating cells in a population and for measuring their proliferative activity. This assay is an important development for the rapid and quantitative screening of agents that affect cell proliferation. The CyQUANT® assay is based on the use of our green-fluorescent CyQUANT® GR dye, which exhibits strong fluorescence enhancement when bound to cellular nucleic acids.⁶⁵ The assay protocol is simple: the culture medium is removed (nonadherent cells require brief centrifugation); the cells are frozen, thawed and lysed by addition of the CyQUANT® cell buffer containing detergent and the CyQUANT® GR dye; and fluorescence is then measured directly in a fluorometer or fluorescence microplate reader (Figure 15.4.11). No washing steps, growth medium changes or long incubations are required.

Figure 15.4.11 The simple procedure for using the CyQUANT® Cell Proliferation Assay Kit (C7026).

Figure 15.4.10 Human peripheral blood lymphocytes were harvested and stained with CellTrace™ Violet stain (C34557). The violet peaks represent successive generations of cells stimulated with mouse anti-human CD3 and Interleukin-2 and grown in culture for 7 days. The peak outlined in black represents cells that were grown in culture for 7 days with no stimulus.

The CyQUANT® cell proliferation assay has a number of significant advantages over other proliferation assays:

- **Sensitivity and linearity.** The CyQUANT® assay is linear from 50 or fewer cells to at least 50,000 cells in 200 μL volumes (Figure 15.4.12); increasing the dye concentration extends the linear range to at least 250,000 cells. Methods that employ Hoechst 33258⁶⁶ (H1398, H3569, H21491) or Hoechst 33342⁶⁷ (H1399, H3570, H21492) to measure cell number and proliferation are much less sensitive—detection limits of 500 cells for Hoechst 33258⁶⁶ or 2500 cells for Hoechst 33342⁶⁷—and have much smaller effective ranges.
- **No radioactivity.** Unlike assays that measure ³H-thymidine incorporation, the CyQUANT® assay does not require radioisotopes and thus does not have the hazards or the expense associated with use, storage and disposal of radioisotopes.
- **Quick and easy protocol.** The CyQUANT® assay is a single-step procedure that requires no lengthy incubation steps and can be completed within an hour (Figure 15.4.11).
- **Specificity and reliability.** The assay is specific for total nucleic acids, with essentially no interference from other cell components. No wash steps are required because cellular growth media do not significantly interfere with CyQUANT® GR fluorescence. The CyQUANT® assay is reliable for cell quantitation, even without treatment to eliminate cellular RNA. However, addition of RNase or DNase permits the easy quantitation of DNA or RNA, respectively, in the sample.
- **Convenience.** Unlike assays that use tetrazolium salts, ³H-thymidine, BrdU, neutral red or methylene blue,^{67–70} the CyQUANT® procedure is not dependent on cellular metabolism. Thus, cells can be frozen and stored prior to assaying, with no reduction in signal, or they can be assayed immediately after collection. Time-course assays are simplified because data obtained from stored samples taken at widely different time intervals can be assayed together with a single standard curve determination.

We have found the CyQUANT® Cell Proliferation Assay Kit to be useful for assaying widely disparate cell types, including:

- Human neonatal fibroblasts, keratinocytes, melanocytes, umbilical vein endothelial cells (HUVEC) and dermal microvascular endothelial cells (DMVEC)

Figure 15.4.12 Quantitation of NIH 3T3 fibroblasts using the CyQUANT® Cell Proliferation Assay Kit (C7026). Fluorescence measurements were made using a microplate reader with excitation at 485 nm and emission detection at 530 nm. The linear range of the assay under these conditions is from 50 to 50,000 cells per 200 μL sample. The inset shows the linearity that can be obtained at very low numbers of cells.

- Murine fibroblasts (NIH 3T3 and CRE BAG 2 cells) and myeloma (P3X63A68) cells
- Madin–Darby canine kidney (MDCK) cells
- Chinook salmon embryo (CHSE) cells
- Rat basophilic leukemia (RBL) and glioma (C6) cells

Determination of total cell number using the CyQUANT® GR reagent is potentially useful for quantitating cell adhesion (see “Cell Adhesion” in Section 15.6) and for determining the total number of cells in a tissue. Each CyQUANT® Cell Proliferation Assay Kit (C7026) includes:

- CyQUANT® GR reagent
- Cell-lysis buffer
- DNA standard for calibration
- Detailed protocols

The kit supplies sufficient materials for performing 1000 assays based on a 200 μL sample volume or a proportionately lower number of assays with a larger sample volume. The CyQUANT® cell-lysis buffer (a 20X concentrate, C7027) is also available separately and has been formulated to produce efficient lysis, to protect nucleic acids from nuclease activity and to dissociate proteins that may interfere with dye binding to nucleic acids. It may prove generally useful in the development of other assays that require cell lysis.

CyQUANT® NF Cell Proliferation Assay Kit

The CyQUANT® NF Cell Proliferation Assay Kit provides a fast and sensitive method for counting cells in a population and measuring proliferation in microplate format.⁷¹ This assay can be completed in 1 hour, with no washes, cell lysis, long incubations or radioactivity required, and it is not dependent on physiological activities that may exhibit cell number-independent variability. The CyQUANT® NF assay eliminates the freeze-thaw cell lysis step of the original CyQUANT® cell proliferation assay by using a cell-permeant DNA-binding dye in combination with a plasma membrane-permeabilization reagent. The CyQUANT® NF assay protocol requires only aspiration of growth medium (for adherent cells), replacement with dye binding solution, incubation for 30–60 minutes and then measurement of fluorescence in a microplate reader. The CyQUANT® NF assay has a linear detection range from at least 100 to 20,000 cells per well in most cell lines using a 96-well microplate format and a 100 μL assay volume.

The CyQUANT® NF Cell Proliferation Assay Kit can be used with either a 96-well or 384-well microplate format and is available in two configurations: a 200-assay kit (C35007) and a 1000-assay kit (C35006) for high-throughput applications.

Each kit contains:

- CyQUANT® NF dye reagent
- Dye delivery reagent
- Concentrated Hank’s balanced salt solution (HBSS)
- Detailed protocols

CyQUANT® Direct Cell Proliferation Assay Kit

CyQUANT® Direct Cell Proliferation Assay is a fluorescence-based proliferation and cytotoxicity assay for microplate readers. The no-wash, homogeneous format and fast add-mix-read protocol makes the CyQUANT® Direct assay ideal for high-throughput screening (HTS) applications. The assay can be completed in 1 hour, with no washes, cell

lysis, temperature equilibrations or radioactivity required, and the signal is stable for several hours to provide work-flow convenience. With a dynamic range from less than 50 to more than 20,000 cells of most adherent and suspension cell types, the CyQUANT® Direct assay can be used in 96-, 384- or 1,536-well microplate formats, and is compatible with most HTS and high-content screening (HCS) readers. Because the experimental protocol does not include a lysis step, the assay can conveniently be multiplexed using a spectrally distinct fluorescent or a luminescent readout.

The CyQUANT® Direct Cell Proliferation Assay Kit is available in two configurations: a 10-plate assay kit (C35011) and a 100-plate assay kit (C35012) for high-throughput applications. Each kit contains:

- CyQUANT® Direct nucleic acid stain
- CyQUANT® Direct background suppressor
- Detailed protocols

FluoReporter® Blue Fluorometric Nucleic Acid Assay Kit

The FluoReporter® Blue Fluorometric dsDNA Quantitation Kit (F2962) provides the protocols developed by Rago and colleagues⁷² for analyzing cellular DNA with the blue-fluorescent Hoechst 33258 nucleic acid stain. The kit enables researchers to detect ~10 ng of isolated calf thymus DNA or ~1000 mouse NIH 3T3 cells in a 200 µL sample (substantially lower levels are detectable using our CyQUANT® Cell Proliferation Assay Kit described above).

With this kit, quantitation of cellular DNA is rapid, and all manipulations can be carried out in microplate wells. The cells are lysed by freezing them in distilled water, which circumvents the requirement for extraction procedures used in other Hoechst 33258 dye-based protocols.^{69,73–76} The diluted dye solution is then added to the lysed cells, and fluorescence is measured. Kit components include:

- Hoechst 33258 in DMSO/H₂O
- TNE buffer
- Detailed protocol

Each kit provides sufficient reagents for assaying approximately 2000 samples using a fluorescence microplate reader.

Vybrant® MTT Cell Proliferation Assay Kit

The convenient Molecular Probes® Vybrant® MTT Cell Proliferation Assay Kit (V13154) simplifies the task of counting cells with a microplate absorbance reader. The colorimetric MTT assay, developed by Mossman, is based on the conversion of the water-soluble MTT to an insoluble purple formazan.^{77,78} This formazan is then solubilized, and its concentration determined by optical density at 570 nm. The Vybrant® MTT Cell Proliferation Assay Kit provides a sensitive assay with excellent linearity up to approximately 10⁶ cells per well. Each kit includes:

- MTT
- Sodium dodecyl sulfate (SDS)
- Detailed protocol

This kit provides sufficient materials for ~1000 assays using standard 96-well microplates. Numerous variations and modifications of the MTT assay have been published.^{79–81} In addition to dehydrogenases, MTT is reduced by glutathione S-transferase⁸² (GST). Therefore, MTT

may not always be a reliable cell viability probe in cells treated with compounds that affect GST activity.

Vybrant® DiI Cell-Labeling Solution

Analysis by mass spectrometry and HPLC indicates that the dye we use in our Vybrant® DiI cell-labeling solution (V22885) is structurally identical to the dye called PKH 26. DiI is a red-fluorescent lipophilic tracer that, in addition to being extensively used for cell tracing (Section 14.4), has been utilized for generational analysis of cells undergoing division.^{52,83–86} Unlike the PKH 26 dye, which requires a special cell-labeling medium and low ionic strength for successful cell loading, our Vybrant® DiI cell-labeling solution is simply added to cells in normal growth medium. Dividing cells distribute the lipophilic tracer approximately equally between daughter cells. It is usually possible to follow at least three or four generations of cells by flow cytometry, although asynchronous division times can quickly complicate the measurements. The dyes in our Vybrant® DiO, Vybrant® DiD and Vybrant® CM-DiI Labeling solutions (V22886, V22887, V22888) may have similar utility for tracing cells through cell division. CM-DiI contains a thiol-reactive chloromethyl that allows the dye to covalently bind to cellular thiols. Thus, unlike other membrane stains, this label is well retained in some cells throughout fixation and permeabilization steps; see Section 14.4 for more information.

CountBright™ Absolute Counting Beads

Flow cytometry provides a rapid method for quantitating cell characteristics, however most flow cytometers cannot directly provide the cell concentration or absolute count of cells in a sample. Absolute cell counts have been widely used in quantitating cell populations and disease progression^{87–89} and are generally obtained either by combining a separate cell concentration determination from a hematology analyzer with flow cytometry population data (multiple-platform testing) or by adding an internal microsphere counting standard to the flow cytometry sample (single-platform testing). The single-platform method is preferred as it is technically less complicated and more accurate than multiple-platform testing.⁹⁰

CountBright™ absolute counting beads (C36950) are a calibrated suspension of microspheres that are brightly fluorescent across a wide range of excitation and emission wavelengths and contain a known concentration of microspheres. For absolute counts, a specific volume of the microsphere suspension is added to a specific volume of sample, such that the ratio of sample volume to microsphere volume is known. The volume of sample analyzed can be calculated from the number of microsphere events and then used with cell events to determine cell concentration. In general, at least 1000 bead events should be acquired to assure a statistically significant determination of sample volume. Sufficient reagents are provided for 100 flow cytometry assays, each using 50 µL of counting beads per test.

CountBright™ absolute counting beads are broadly fluorescent and can be used with either a fluorescence or scatter threshold. Fluorescence can be excited by wavelengths from UV to 635 nm; fluorescence emission can be read between 385 nm and 800 nm. The fluorescence intensity of the microspheres has been adjusted to be about 5–50 times brighter than the anticipated intensities of typically stained cells. When using a scatter threshold, the microsphere signal should be above the threshold. The microspheres can be gated by a single parameter, but a combination of parameters can be used to resolve microspheres from cells and other events.

Figure 15.4.13 Adherent cells from human peripheral blood stained with the SYTO[®] 13 dye (S7575), one of the six visible light–excitable cell-permeant nucleic acid stains in our SYTO[®] Green Fluorescent Nucleic Acid Stain Sampler Kit #1 (S7572). The multilobed nuclei of these polymorphonuclear leukocytes are particularly striking in this field of view.

Figure 15.4.14 A mixture of live and heat-killed *Bacillus cereus* cells simultaneously stained with the cell-permeant SYTO[®] 59 red-fluorescent nucleic acid stain (S11341) and the cell-impermeant SYTOX[®] Green nucleic acid stain (S7020), each at a concentration of 5 μ M. Bacteria with intact cell membranes stain fluorescent red, whereas bacteria with damaged membranes stain fluorescent green. This maximum-projection image was generated from a series of 10 images taken at 0.2 μ m increments through the specimen with a Leica confocal laser-scanning microscope.

Figure 15.4.15 Pseudocolored photomicrograph of the synaptic region of fluorescently labeled living muscle fibers from the lumbricalis muscle of the adult frog *Rana pipiens*. Six hours after isolation of the muscle fibers, acetylcholine receptors were stained with red-fluorescent tetramethylrhodamine α -bungarotoxin (T1175) and myonuclei were stained with the green-fluorescent SYTO[®] 13 live-cell nucleic acid stain (S7575). Photo contributed by Christian Brösamle, Brain Research Institute, University of Zurich, and Damien Kuffler, Institute of Neurobiology, University of Puerto Rico.

CountBright[™] absolute counting beads can be used with any sample type, including no-wash/lysed whole blood. The microspheres in the reagents are approximately 7 μ m in diameter and have settling properties similar to lymphocytes. The accuracy of cell counts based on CountBright[™] absolute counting beads depends on sample handling and the precise delivery of the volume of beads. The CountBright[™] absolute counting beads must be mixed well to assure a uniform suspension of microspheres. After vortexing for 30 seconds, the microsphere suspension can be pipetted by standard techniques; however, more viscous solutions such as blood require reverse pipetting to facilitate accurate volume delivery. Cell suspensions may be diluted but should be assayed without wash steps. Other sample preparation steps that can lead to cell or microsphere loss should also be avoided. For antibody protocols, CountBright[™] absolute counting beads should be used with reagents titered for no-wash staining.

Detection and Enumeration Assays for Microorganisms and Viruses

Detecting Bacteria, Yeast and Plankton Using Nucleic Acid Stains

We recommend our SYTO[®] nucleic acid stains (see the complete list in Table 8.3) for simple detection of the presence of bacteria, yeast and other microbial cells^{91–95} (Figure 15.4.13, Figure 15.4.14, Figure 15.4.15). The SYTO[®] dyes are essentially nonfluorescent except when bound to nucleic acids, where they become highly fluorescent, often with quantum yields exceeding 0.5. Consequently, it is usually not necessary to remove unbound stains before analysis. SYTO[®] dyes are available with blue, green, orange or red fluorescence. The SYTO[®] dyes rapidly penetrate the membranes of almost all cells, including bacteria and yeast. The various cell types can often be identified by their characteristic morphology or, in the case of flow cytometric applications, by their light-scattering properties.

The SYTO[®] 11 and SYTO[®] 13 green-fluorescent nucleic acid stains show exceptional ability to penetrate tissues for at least 100 μ m, including untreated, unfixed human brain tissue, where they were used to enumerate cells by confocal laser-scanning microscopy.⁹⁶ Simultaneous labeling with a green-fluorescent SYTO[®] dye and a red-fluorescent nucleic acid stain—most often propidium iodide, ethidium homodimer-1 or -2, TOTO[®]-3 or TO-PRO[®]-3 (Table 8.2, Table 8.4)—is frequently used to assess cell viability (Section 15.2). Although some of the SYTO[®] dyes show higher quantum yields on DNA or RNA, they should not be considered specific stains for either of these nucleic acids. We offer four different SYTO[®] Nucleic Acid Stain Sampler Kits (S11350, S7572, S11360, S11340; Section 8.1).

In addition to its use for cell-cycle analysis (see below) and nuclear staining, DAPI (D1306, D3571, D21490) is frequently employed for DNA content–based counting of bacterial cells^{97–99} and for detecting malarial infections by fluorescence microscopy.¹⁰⁰

BacLight[™] Bacterial Stains

The BacLight[™] Green and BacLight[™] Red bacterial stains (B35000, B35001) are fluorescent, non–nucleic acid labeling reagents for detecting and monitoring bacteria. Bacteria stained with the BacLight[™] Green and BacLight[™] Red bacterial stains exhibit bright green (excitation/emission maxima ~480/516 nm) and red (excitation/emission maxima ~480/516 nm) fluorescence, respectively, and can be resolved simultaneously using the appropriate flow cytometry channels. Although these dyes were specifically chosen for flow cytometry applications, bacteria stained with these BacLight[™] reagents can also be visualized by fluorescence microscopy with only minor, if any, adjustments in the staining concentrations. Furthermore, the BacLight[™] bacterial staining patterns are compatible with formaldehyde or alcohol fixation methods.

These BacLight[™] bacterial stains efficiently label a variety of different bacteria species. The intensity of the staining appears to depend on several factors, including gram character, outer membrane composition and overall membrane integrity. In the species we tested, gram-positive bacteria generally exhibited brighter fluorescence than gram-negative bacteria, and cells with compromised membranes accumulated more dye than intact cells (Figure 15.4.16).

Bacteria Counting Kit

Accurate enumeration of low numbers of bacteria in samples must be performed daily in many quality-control laboratories.

To facilitate this determination by flow cytometry (Figure 15.4.17), we have developed the Bacteria Counting Kit (B7277), which provides:

- Cell-permeant, green-fluorescent SYTO® BC nucleic acid stain to label bacteria
- Fluorescent polystyrene microspheres to calibrate the volume of bacterial suspension analyzed
- Detailed protocols

SYTO® BC dye, which is also available separately (S34855, Section 8.1), is a high-affinity nucleic acid stain that easily penetrates both gram-negative and gram-positive bacteria, producing an exceptionally bright green-fluorescent signal. The calibrated suspension of polystyrene microspheres contains beads that exhibit a uniform density, low-level fluorescence and optimal size to clearly separate the light scattering of the microspheres from that of most bacteria.

The Bacteria Counting Kit is particularly valuable for monitoring antibiotic sensitivity because it provides a convenient and accurate means for assessing changes in a bacterial population over time. A sample of the population is simply diluted, stained briefly with the SYTO® BC dye, mixed with a fixed number of microspheres and analyzed on a flow cytometer. Signals from both the stained bacteria and the beads are easily detected in the green-fluorescence channel of most

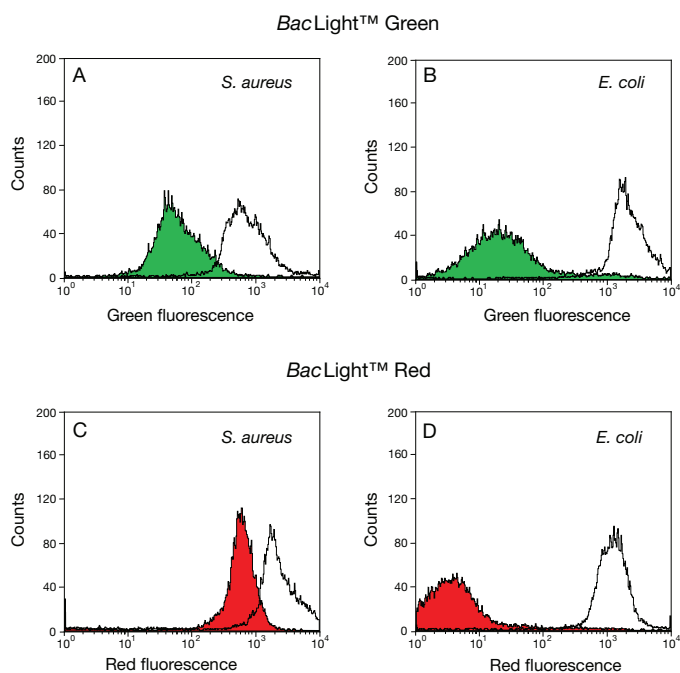

Figure 15.4.16 Flow cytometry histograms showing fluorescence of live and dead gram-positive and gram-negative bacteria stained with the BacLight™ bacterial stains. Untreated and alcohol-treated gram-positive (*Staphylococcus aureus*, (A and C)) and gram-negative (*Escherichia coli*, (B and D)) bacteria were each stained separately with 100 nM of either the BacLight™ Green (A and B) or the BacLight™ Red (C and D) bacterial stains (B35000, B35001) in 0.85% NaCl buffer and then analyzed by flow cytometry. The histograms for the untreated (colored histogram curve) and alcohol-treated (uncolored histogram curve) bacteria samples were overlaid for each species and BacLight™ bacterial stain.

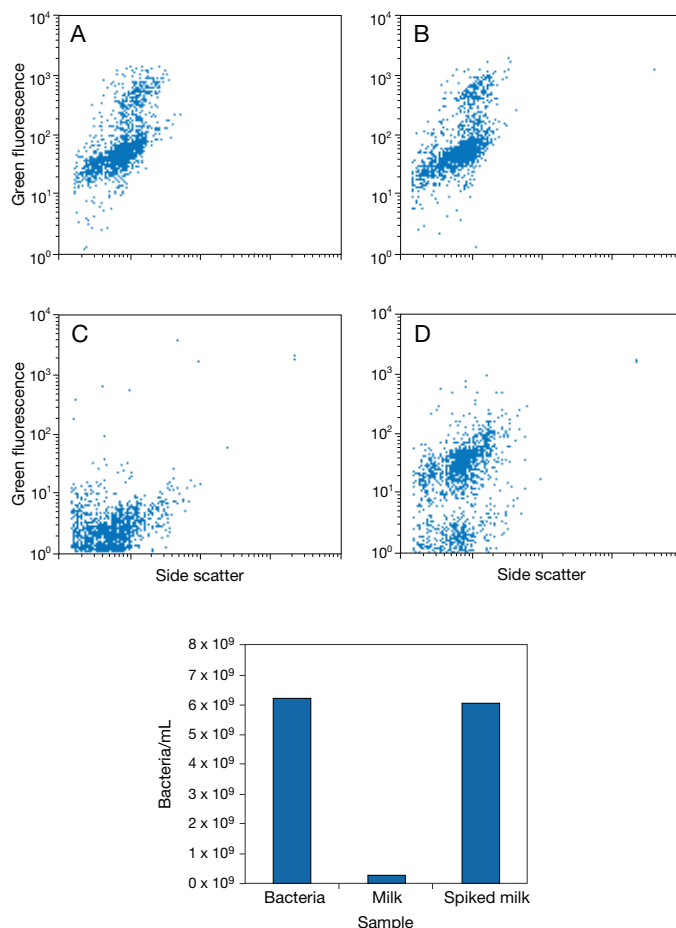

Figure 15.4.17 Detection and counting of bacteria in milk using the Bacteria Counting Kit (B7277). Equal numbers of bacteria were suspended in 150 mM NaCl or a mixture of milk and 150 mM NaCl and assayed using the protocol provided with the kit. As shown in the lower bar chart, the presence of milk does not affect the outcome of the assay. The upper panels plot green fluorescence versus side scatter for: A) bacteria alone, B) bacteria alone and D) bacteria mixed with milk (spiked milk). Panels B–D also contain reference beads, which appear in the upper right corner of the respective plots.

Figure 15.4.18 Flow cytometric enumeration of *Bacillus cereus* using the Bacteria Counting Kit (B7277). In this plot of forward scatter versus fluorescence, signals in the upper left-hand frame represent bacteria stained with SYTO® BC bacteria stain; signals in the lower right-hand frame represent microsphere particles, which serve as a standard used to indicate sample volume.

Figure 15.4.19 A mycoplasma-contaminated African green monkey fibroblast cell line was stained with cell-permeant, blue-fluorescent Hoechst 33342 nucleic acid stain (H1399, H3570, H21492), simultaneously illustrating both cell nuclei and mycoplasma. The image was acquired using filters appropriate for DAPI. Image contributed by Heiti Paves, Laboratory of Molecular Genetics, National Institute of Chemical Physics and Biophysics, Estonia.

flow cytometers and can be distinguished on a plot of forward scatter versus fluorescence (Figure 15.4.18). The density of the bacteria in the sample can be determined from the ratio of bacterial signals to microsphere signals in the cytogram. The Bacteria Counting Kit can be used with a variety of gram-negative and gram-positive species of bacteria and provides sufficient reagents for approximately 100 flow cytometry assays.

The fluorescent microspheres in our Bacteria Counting Kit have also been recommended for the enumeration of yeast.¹⁰¹ We offer a wide selection of labeled beads (Section 6.5, Section 23.1, Section 23.2) that may also prove useful for yeast quantitation and viability assays by flow cytometry.¹⁰²

Cell Culture Contamination Detection Kit

Molecular Probes® Cell Culture Contamination Detection Kit (C7028) uses a simple and effective procedure for visually screening cell cultures for contamination by yeast (and other fungi) or by gram-negative or gram-positive bacteria. This kit not only serves to detect the contaminants, but also identifies the contaminant type, enabling the researcher to choose an appropriate course of action.

A sample of the suspected culture is subjected to two slide-staining protocols. One sample slide is stained with Calcofluor White M2R, a UV light–excitable, blue-fluorescent stain specific for fungal cell walls. A second slide is stained with SYTO® 9 nucleic acid stain to identify all bacteria irrespective of gram signature, and also with the Texas Red®-X conjugate of wheat germ agglutinin (WGA), which selectively stains gram-positive bacteria.^{103,104} Gram-positive bacteria on the second slide typically exhibit a green-fluorescent interior with red-fluorescent cell-surface staining, whereas gram-negative bacteria show only green-fluorescent interior staining. Staining and examination of the slides under a fluorescence microscope can be typically performed in less than one hour. Each Cell Culture Contamination Detection Kit contains:

- Green-fluorescent SYTO® 9 nucleic acid stain
- Blue-fluorescent Calcofluor White M2R fungal cell wall stain
- Red-fluorescent Texas Red®-X WGA, for positive identification of gram-positive bacteria
- Buffer for reconstituting Texas Red®-X WGA
- Detailed protocols

This kit provides sufficient material for approximately 200 contamination detection assays. The SYTO® 9 nucleic acid stain, which is also available separately (S34854, Section 15.2), has been used to detect lactic acid–producing bacteria in wine.¹⁰⁵

Mycofluor™ Mycoplasma Detection Kit

Mycoplasma infections are generally difficult or impossible to detect during routine work with cultured cells because these intracellular pathogens cannot be observed by standard light microscopy. However, mycoplasma infections can be detected with the Hoechst dyes^{106,107} (Figure 15.4.19) or with DAPI^{108,109} (Section 8.1). Hoechst 33258, either alone¹¹⁰ or in combination with merocyanine 540¹¹¹ (M24571, Section 18.2), has been utilized to eradicate mycoplasma infections from cell cultures. Mycoplasma infections are relatively common. Estimates of contaminated cultures in the United States range from 5% to 35%, whereas the contamination rate is postulated to be much higher in those countries where systematic detection and elimination are not practiced.¹¹² Not only do mycoplasma cause physiological and morphological distortions that can affect experimental results, but contamination can quickly spread to other cell lines.

The MycoFluor™ Mycoplasma Detection Kit (M7006) provides an extremely rapid and sensitive fluorescence microscopy–based assay for the visual identification of mycoplasma infection in laboratory cell cultures and media. In order to detect mycoplasma, the fluorescent MycoFluor™ reagent is added directly to the culture medium, with or without cells present, and the stained sample is then examined under a fluorescence microscope. The test for the presence of mycoplasma in live or fixed cell cultures takes about 15 minutes from when the reagent is added until when the sample is viewed with a fluorescence microscope equipped with DAPI optical filters. The detection of mycoplasma in cell media requires about 30 minutes, depending on the amount of centrifugation required to concentrate potential contaminants.

Also provided with this kit are mycoplasma MORFS (Microscopic Optical Replicas for Fluorescence assays), which serve as inert positive controls that mimic the size, shape and fluorescence intensity of mycoplasma stained with the blue-fluorescent MycoFluor™ reagent and viewed by fluorescence microscopy. The optical properties of the mycoplasma MORFS enable the researcher to discriminate between stained mycoplasma and other fluorescent material without introducing infectious biological agents into the laboratory environment. No previous experience with mycoplasma testing is required.

Each MycoFluor™ Mycoplasma Detection Kit supplies sufficient materials for at least 100 tests of live cells, fixed cells or culture media. Kit contents include:

- Concentrated MycoFluor™ reagent
- Suspension of mycoplasma MORFS
- Coverslip sealant
- Cotton swab
- Reference micrographs
- Detailed protocols

Alternatively, the LIVE/DEAD® BacLight™ Bacterial Viability Kits (L7007, L7012, L13152; Section 15.3) are useful for detecting mycoplasma infections.¹¹³ Researchers have determined that the reagents in our LIVE/DEAD® BacLight™ Kits can be used for viability determinations in *Eurioplasma eurilytica* and *Mycoplasma hominus* mycoplasma and in the cysts of the protozoan parasite *Giardia muris* (Figure 15.4.20).

Detecting Viruses Using Nucleic Acid Stains

Because of their small size, direct detection of viruses by fluorescence requires highly sensitive reagents or, much more commonly, an amplification scheme. However, direct enumeration of marine viral abundance in seawater using SYBR® Green I nucleic acid gel stain^{114–116} (S7563, S7567, S7585; Section 8.3; Figure 15.4.21), YO-PRO®-1 (Y3603, Section 8.1) and DAPI¹¹⁷ (D1306, D3571, D21490) has been reported.

The slow off-rate of our dimeric nucleic acid stains, such as TOTO®-1 and YOYO®-1 (T3600, Y3601), has permitted their use for labeling nucleic acids, including viral RNA,¹¹⁸ prior to microinjection into live cells to follow their trafficking. Similar staining techniques may permit tracing of viral uptake and transport by live cells.

Countess® Automated Cell Counter

The Countess® automated cell counter (C10227, C10310, C10311; Figure 15.4.22) uses Trypan Blue staining combined with a sophisticated image analysis algorithm to count all cells in a sample—even mildly clumpy samples—as well as assess viability and measure average cell size. The Countess® instrument allows for accurate cell and viability counts and completes all calculations in about 30 seconds, using as little as 5 µL of your sample; a cell viability percentage value is calculated automatically.

The measurement range of the Countess® automated cell counter extends from 1×10^4 to 1×10^7 cells/mL, with an optimal range from 1×10^5 to 4×10^6 cells/mL, which is broader than that of a hemocytometer. Furthermore, the Countess® instrument counts cell size from 5 to 60 µm and counts beads from 4.5 to 60 µm. Countess® Test Beads (C10284) are designed to provide a reliable and rapid calibration standard for users who choose to operate the instrument outside its default parameters. The Countess® instrument has been validated for use with more than 20 common cell types, including primary cells, blood cells, yeast cells (without viability assessment), insect cells and fish cells.

The Countess® automated cell counter does not require a computer. Disposable chamber slides (C10228, C10312, C10313, C10314, C10315) provide rapid setup, with no cleaning, buffers or maintenance required other than battery replacement after approximately 5 years of use. Trypan Blue stain is also available as a stand-alone reagent (T10282). More information is available at www.invitrogen.com/handbook/countess.

Figure 15.4.20 *Giardia muris* cysts stained with the reagents in the LIVE/DEAD® BacLight™ Bacterial Viability Kit (L7007, L7012). When incubated with the SYTO® 9 and propidium iodide nucleic acid stains provided in this kit, live bacteria with intact cell membranes fluoresce green and dead bacteria with compromised membranes fluoresce red.

Figure 15.4.21 An environmental sample containing marine viruses (smallest dots), bacteria (larger, brighter dots), and a diatom (long thin cell with prominent nucleus) stained with SYBR® Green I nucleic acid stain (S7563, S7567, S7585). Image contributed by Jed Fuhrman, University of Southern California.

Premo™ FUCCI Cell Cycle Sensor

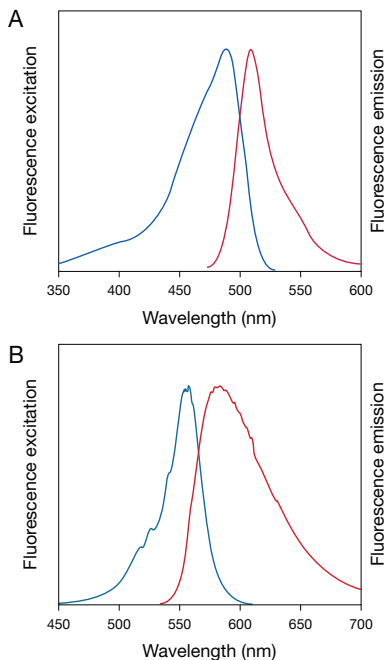

Figure 15.4.24 Fluorescence excitation and emission spectra for A) Premo™ geminin-GFP and B) Premo™ Cdt1-RFP.

In 2008, Miyawaki and colleagues developed the Fluorescence Ubiquitination Cell Cycle Indicator (FUCCI), a fluorescent protein (FP)-based sensor that employs a Red Fluorescent Protein (RFP) and a Green Fluorescent Protein (GFP), each of which is fused to one of two different regulators of the cell cycle: Cdt1 and geminin.¹¹⁹ Ubiquitin E3 ligases add ubiquitin to the Cdt1-GFP and geminin-RFP fusions, thereby targeting these proteins for proteasomal degradation. Temporal regulation of E3 ligase activity results in the biphasic cycling of the geminin and Cdt1 fusions through the cell cycle.

In the G₁ phase, the geminin-GFP fusion is degraded, leaving only the Cdt1-RFP fusion and resulting in red-fluorescent nuclei. During the G₁/S transition, Cdt1 levels decrease and geminin levels increase. Because both proteins are present in the cells, both GFP and RFP fluorescence is visible and the cell nuclei appear yellow when the green and red images are overlaid. In the S, G₂ and M phases, the Cdt1-RFP fusion is degraded, leaving only the geminin-GFP fusion and resulting in green-fluorescent nuclei. This dynamic color change from red to yellow to green serves as an indicator of the progression through cell cycle and division (Figure 15.4.23).

The Premo™ FUCCI Cell Cycle Sensor (P36232) combines the Cdt1 and geminin FP constructs with the powerful BacMam gene delivery and expression system (BacMam Gene Delivery and Expression Technology—Note 11.1). The genetically encoded and pre-packaged reagents are ready for immediate use, eliminating the need to purify plasmid. The BacMam reagent is simply added to cells for 1–2 hours, after which the cells are treated with an enhancer reagent for another 1–2 hours, washed, incubated overnight and then visualized using fluorescence microscopy or high-throughput imaging platforms (Figure 15.4.23). BacMam transduction is efficient and reproducible in most cell types, including primary and stem cells, without apparent cytotoxic effects.

The Premo™ FUCCI Cell Cycle Sensor is designed for live-cell imaging of cell cycle progression and can be used to assess the effect of drugs, siRNA or other factors on the transition of cells through the cell cycle. The fluorescence signals from geminin-GFP and Cdt1-RFP (Figure 15.4.24) have been demonstrated to be resistant to fixation with 4% formaldehyde and permeabilization with 0.1% Triton X-100, thereby enabling processing of labeled cells with antibodies to other cellular targets. Each kit contains all of the components needed to label cells with the Premo™ FUCCI Cell Cycle Sensor using a transduction volume of 2 mL; however, the protocol can easily be adjusted for larger or smaller volumes.

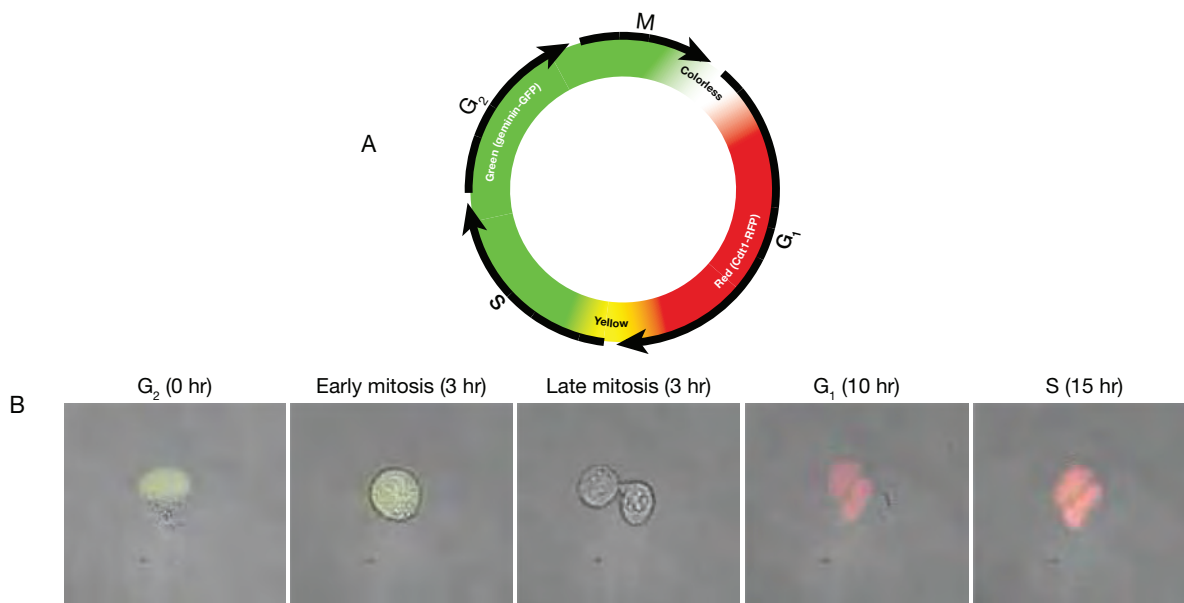

Figure 15.4.23 Imaging cell-cycle progression in live cells with Premo™ FUCCI Cell Cycle Sensor. A) Schematic of cell-cycle progression with nuclear fluorescence changes. B) U2OS cells were transduced with Premo™ FUCCI Cell Cycle Sensor, and images were collected over 15 hours.

Nucleic Acid Probes for Cell-Cycle Analysis

Live-cell studies of cellular DNA content and cell-cycle distribution are useful for investigating tumor behavior and suppressor gene mechanisms, for monitoring apoptosis and for detecting variations in growth patterns arising from a variety of physical, chemical and biological means. In a given population, cells will be distributed among three major phases of the cell cycle: G₀/G₁ phase (one set of paired chromosomes per cell), S phase (DNA synthesis with variable amount of DNA) and G₂/M phase (two sets of paired chromosomes per cell, prior to cell division).^{120–123} DNA content can be measured using fluorescent, DNA-selective stains that exhibit emission signals proportional to DNA mass. Flow cytometric analysis of these stained populations is then used to produce a frequency histogram that reveals the various phases of the cell cycle. This analysis is typically performed on permeabilized or fixed cells using a cell-impermeant nucleic acid stain,^{23,124–126} but is also possible using live cells and a cell-permeant nucleic acid stain.^{127,128} While the choices for fixed cell staining are varied, there are only a few examples of useful cell-permeant nucleic acid stains.

Vybrant® DyeCycle™ Stains

All Vybrant® DyeCycle™ stains are DNA-selective, cell membrane-permeant and nonfluorescent until bound to double-stranded DNA. Once bound to DNA, these dyes emit a fluorescence signal that is proportional to DNA mass. Staining cells with the Vybrant® DyeCycle™ stains is simple: suspended cells are incubated in the presence of a Vybrant® DyeCycle™ stain, and fluorescence is measured directly—no additional treatment or centrifugation is required. Fluorescence data can then be used to generate a frequency histogram that reveals the various phases of the cell cycle.

We offer four Vybrant® DyeCycle™ stains for flow cytometry analysis of DNA content in live cells:

- Vybrant® DyeCycle™ Violet stain¹²⁹ (V35003)
- Vybrant® DyeCycle™ Green stain (V35004)
- Vybrant® DyeCycle™ Orange stain (V35005)
- Vybrant® DyeCycle™ Ruby stain (V10273, V10309)

The Vybrant® DyeCycle™ stains spectrally match commonly available excitation sources, placing cell-cycle studies within reach of all flow cytometrists and allowing simultaneous staining of the cell population for other parameters. Vybrant® DyeCycle™ Violet stain (excitation/emission maxima ~396/437 nm) is well suited for the 405 nm laser line (Figure 15.4.25) but can also be used with UV excitation. Vybrant® DyeCycle™ Green stain (excitation/emission maxima ~506/534 nm) is efficiently excited with the 488 nm spectral line of the argon-ion laser (Figure 15.4.26). Vybrant® DyeCycle™ Orange stain (excitation/emission maxima ~519/563 nm) can be excited using either the 488 nm or 532 nm laser lines (Figure 15.4.27). Vybrant® DyeCycle™ Ruby stain (excitation/emission maxima ~638/686 nm) can be excited using the 635 nm red diode laser (Figure 15.4.28).

Figure 15.4.28 Fluorescence excitation and emission spectra of Vybrant® DyeCycle™ Ruby stain bound to DNA.

Figure 15.4.25 Fluorescence excitation and emission spectra of Vybrant® DyeCycle™ Violet stain bound to DNA.

Figure 15.4.26 Fluorescence excitation and emission spectra of Vybrant® DyeCycle™ Green stain bound to DNA.

Figure 15.4.27 Fluorescence excitation and emission spectra of Vybrant® DyeCycle™ Orange stain bound to DNA.

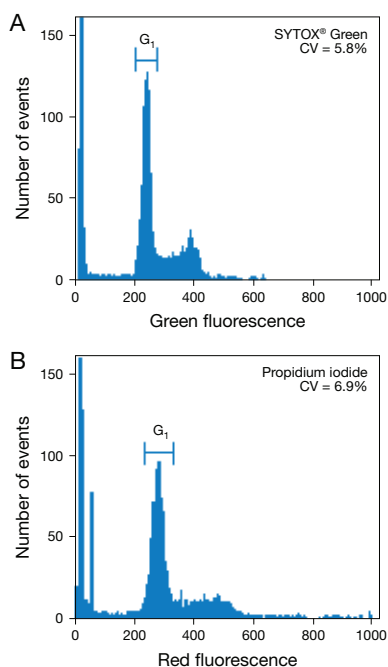

Figure 15.4.31 Comparison of DNA content histograms obtained with A) SYTOX® Green nucleic acid stain (S7020) and B) propidium iodide (P1304MP, P3566, P21493). Human B cells were suspended in permeabilizing buffer (100 mM Tris, pH 7.4, 154 mM NaCl, 1 mM CaCl₂, 0.5 mM MgCl₂, 0.1% Nonidet™ P-40) and then stained for 15 minutes with 0.5 μM SYTOX® Green or 5 μM propidium iodide. Flow cytometric analysis of the stained cells was carried out with excitation at 488 nm. SYTOX® Green staining produces a significantly narrower G₁ phase peak, indicated by the smaller coefficient of variation (CV).

Figure 15.4.32 DNA content histogram for WIL2S cells. The cells were fixed in ethanol, treated with RNase and stained with 2 μg/mL Hoechst 33342 (H1399, H3570, H21492). Flow cytometric analysis of the stained cells was carried out using excitation at 350 nm.

FxCycle™ Stains for Cell-Cycle Analysis

FxCycle™ Violet stain (F10347) is a violet laser-excited dye used for cell-cycle analysis in fixed cells. FxCycle™ Violet stain (4',6-diamidino-2-phenylindole, dihydrochloride or DAPI) preferentially stains dsDNA, exhibiting a ~20-fold fluorescence enhancement upon binding. Using FxCycle™ Violet for cell cycle analysis increases the ability to multiplex by freeing up the 488 nm and 633 nm lasers for other cellular analyses, such as immunophenotyping, apoptosis analysis and dead cell discrimination. As compared with several commonly used dyes (propidium iodide and 7-AAD), FxCycle™ Violet stain overlaps less with other fluorescence detection channels, resulting in minimal compensation requirements and more accurate data (Figure 15.4.29).

FxCycle™ Far Red stain (F10348) is useful for flow cytometric analysis of DNA content in fixed cells. Because FxCycle™ Far Red stain binds to both RNA as well as DNA, the addition of RNase A is required for DNA content analysis. This dye takes advantage of the commonly available 633/635 nm excitation sources, with emission around 660 nm (Figure 15.4.30), and is a good choice for DNA content analysis in multicolor cell-cycle studies.

SYTOX® Green Nucleic Acid Stain

SYTOX® Green nucleic acid stain (S7020) is particularly useful for cell-cycle analysis on RNase-treated fixed cells (Figure 15.4.31). In particular, the SYTOX® Green dye produces lower coefficients of variation than propidium iodide (P1304MP, P3566, P21493; Section 8.1), leading to improved resolution of cell phase. Figure 15.4.31 shows a comparison of DNA content histograms obtained with SYTOX® Green nucleic acid stain and propidium iodide after flow cytometric analysis.

Hoechst 33258, Hoechst 33342 and DAPI

The nucleic acid stains most frequently used for cell-cycle analysis—Hoechst 33258 (H1398, H3569, H21491), Hoechst 33342 (H1399, H3570, H21492) and DAPI (D1306, D3571, D21490)—bind to the minor groove of DNA at AT-rich sequences. Hoechst 33342, which more rapidly permeates cells than Hoechst 33258, is commonly used for determining the DNA content of viable cells without detergent treatment or fixation^{127,128} (Figure 15.4.32). The Hoechst dyes and DAPI can be excited with a mercury-arc lamp, the UV spectral lines of the argon-ion laser or the 325 nm spectral line of the He-Cd laser. These blue-fluorescent nucleic acid stains preferentially bind to AT-rich sequences and also exhibit higher quantum yields when bound to AT-rich nucleic acids, thus introducing a strong bias into the measurements of nuclear DNA content.^{130,131} As a consequence, data obtained with Hoechst 33342 and DAPI correlate very well with each other but less well with data obtained with propidium iodide, a red-fluorescent, cell-impermeant nucleic acid stain¹³² (P1304MP, P3566, P21493; Section 8.1). Hoechst 33342 is used in the high-speed sorting of X chromosome- and Y chromosome-bearing sperm based on their DNA content.^{133,134}

HCS Mitotic Index Kit

Histones are core proteins of DNA in eukaryotic cells. These histones are organized as octamers, around which the DNA is wrapped. The phosphorylation of histone 3 (H3) is involved in condensation of chromatin during mitosis and reaches a peak during mitosis. Mitotic H3 phosphorylation occurs at Ser10 of the amino terminus, and there is a tight correlation between H3 (Ser10) phosphorylation, chromosome condensation and segregation during mitosis. This event can serve as an indication of mitotic progression or inhibition within the context of drug profiling.

The HCS Mitotic Index Kit (H10293) was developed to measure mitotic cells using automated imaging and analysis and can be combined with other measurements such as DNA profiling, general cytotoxicity or immunocytochemical detection of choice targets. This kit includes sufficient reagents for two 96-well plate assays, including:

- Polyclonal rabbit anti-phospho-H3 antibody
- Alexa Fluor® 488 goat anti-rabbit IgG antibody
- DAPI
- HCS NuclearMask™ Deep Red stain
- Detailed protocols

The primary antibody against phosphorylated histone H3 (Ser10) serves as a sensitive index of mitosis and is detected using the green-fluorescent Alexa Fluor® 488 secondary antibody. The blue-fluorescent DAPI and near-infrared-fluorescent HCS NuclearMask™ Deep Red stain provide two choices for DNA profiling and cell demarcation during image analysis. The HCS Mitotic Index Kit represents a powerful image-based assay for the identification of compounds that affect mitotic progression (Figure 15.4.33).

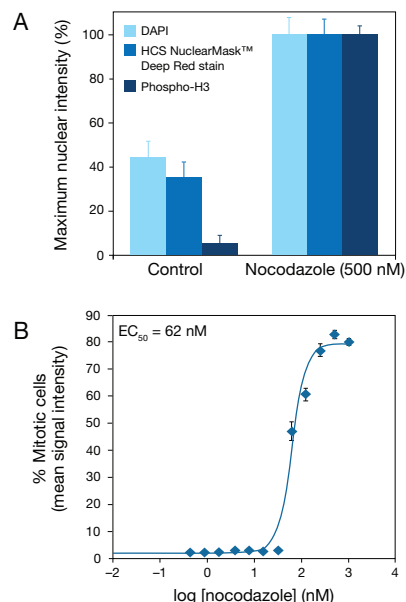

Figure 15.4.33 Imaging of nocodazole-induced mitotic arrest in A549 cells using the HCS Mitotic Index Kit (H10293). **A**) Quantitation of cells treated with 500 nM nocodazole for 24 hr. Nuclear segmentation and DNA content were measured using DAPI or HCS NuclearMask™ Deep Red stain. The strong increase in both phosphohistone 3 and DNA staining is indicative of mitotic cells. **B**) Dose response to 0–1,000 nM nocodazole after 24 hr incubation. The curve generated by nonlinear regression was used to determine the EC₅₀ value for nocodazole.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
2. Acetate hydrolysis of this compound yields a fluorescent product with similar pH-dependent spectral characteristics to C1904.
3. The molecular weight (MW) of this product is approximate because the degree of hydration and/or salt form has not been conclusively established.
4. Acetate hydrolysis of C22803 yields a fluorescent product with spectra similar to 5-carboxy eosin, Abs = 519 nm (EC = 100,000 cm⁻¹M⁻¹), Em = 542 nm in pH 9 buffer.
5. Acetate hydrolysis of this compound yields a fluorescent product with similar spectral characteristics to O6146.
6. Spectra represent aqueous solutions of nucleic acid-bound dye. EC values are derived by comparing the absorbance of the nucleic acid-bound dye with that of free dye in a reference solvent (H₂O or MeOH).
7. DAPI in H₂O: Abs = 342 nm (EC = 28,000 cm⁻¹M⁻¹), Em = 450 nm. The fluorescence quantum yield of DAPI bound to dsDNA is 0.34, representing an ~20-fold increase relative to the free dye in H₂O. (Photochem Photobiol (2001) 73:585)
8. This product is specified to equal or exceed 98% analytical purity by HPLC.
9. MW is for the hydrated form of this product.
10. The fluorescence quantum yield of Hoechst 33258 bound to dsDNA is 0.42, representing an ~30-fold increase relative to the free dye in H₂O. (Photochem Photobiol (2001) 73:585)
11. The fluorescence quantum yield of Hoechst 33342 bound to dsDNA is 0.38, representing an ~10-fold increase relative to the free dye in H₂O. (Photochem Photobiol (2001) 73:585)
12. This product is essentially nonfluorescent except when bound to DNA or RNA.
13. MW: The preceding ~ symbol indicates an approximate value, not including counterions.
14. S22801 is converted to a fluorescent product with spectra similar to C1270 after acetate hydrolysis.
15. Although this compound is soluble in water, preparation of stock solutions in water is not recommended because of possible adsorption onto glass or plastic.
16. This product is supplied as a ready-made staining solution.

PRODUCT LIST 15.4 ASSAYS FOR CELL ENUMERATION, CELL PROLIFERATION AND CELL CYCLE

Cat. No.	Product	Quantity
B35000	BacLight™ Green bacterial stain *special packaging*	20 x 50 µg
B35001	BacLight™ Red bacterial stain *special packaging*	20 x 50 µg
B7277	Bacteria Counting Kit *for flow cytometry*	1 kit
B35130	BrdU, mouse monoclonal antibody (Clone MoBU-1), Alexa Fluor® 488 conjugate *0.2 mg/mL*	350 µL
B35139	BrdU, mouse monoclonal antibody (Clone MoBU-1), Alexa Fluor® 488 conjugate *for flow cytometry* *100 tests*	1 each
B35131	BrdU, mouse monoclonal antibody (Clone MoBU-1), Alexa Fluor® 555 conjugate *0.2 mg/mL*	350 µL
B35132	BrdU, mouse monoclonal antibody (Clone MoBU-1), Alexa Fluor® 594 conjugate *0.2 mg/mL*	350 µL
B35133	BrdU, mouse monoclonal antibody (Clone MoBU-1), Alexa Fluor® 647 conjugate *0.2 mg/mL*	350 µL
B35140	BrdU, mouse monoclonal antibody (Clone MoBU-1), Alexa Fluor® 647 conjugate *for flow cytometry* *100 tests*	1 each
B35138	BrdU, mouse monoclonal antibody (Clone MoBU-1), biotin conjugate *0.2 mg/mL*	350 µL
B35129	BrdU, mouse monoclonal antibody (Clone MoBU-1), Pacific Blue™ conjugate *for flow cytometry* *100 tests*	1 each
B35128	BrdU, mouse monoclonal antibody (Clone MoBU-1), unconjugated *0.1 mg/mL*	350 µL
B35141	BrdU, mouse monoclonal antibody (Clone MoBU-1), unconjugated *for flow cytometry* *100 tests*	1 each
B23151	5-bromo-2'-deoxyuridine (BrdU)	100 mg
B21550	5-bromo-2'-deoxyuridine 5'-triphosphate (BrdUTP) *10 mM in TE buffer*	25 µL
B21551	5-bromouridine 5'-triphosphate (BrUTP) *10 mM in TE buffer*	25 µL
C22803	CEDA, SE (5-(and-6)-carboxy eosin diacetate, succinimidyl ester) *mixed isomers*	5 mg

PRODUCT LIST 15.4 ASSAYS FOR CELL ENUMERATION, CELL PROLIFERATION AND CELL CYCLE—continued

Cat. No.	Product	Quantity
C7028	Cell Culture Contamination Detection Kit *200 assays*	1 kit
C34554	CellTrace™ CFSE Cell Proliferation Kit *for flow cytometry*	1 kit
C34555	CellTrace™ Oregon Green® 488 carboxylic acid diacetate, succinimidyl ester (carboxy-DFFDA, SE) *cell permeant* *mixed isomers*	20 x 50 µg
C34557	CellTrace™ Violet Cell Proliferation Kit *for flow cytometry*	1 kit
C1157	5(6)-CFDA, SE; CFSE (5-(and-6)-carboxyfluorescein diacetate, succinimidyl ester) *mixed isomers*	25 mg
C7614	ChromaTide® BODIPY® FL-14-dUTP *1 mM in TE buffer*	25 µL
C35002	Click-iT® EdU Alexa Fluor® 488 Flow Cytometry Assay Kit *50 assays*	1 kit
A10202	Click-iT® EdU Alexa Fluor® 647 Flow Cytometry Assay Kit *50 assays*	1 kit
A10034	Click-iT® EdU Pacific Blue™ Flow Cytometry Assay Kit *50 assays*	1 kit
C10350	Click-iT® EdU Alexa Fluor® 488 HCS Assay *2-plate size*	1 kit
C10351	Click-iT® EdU Alexa Fluor® 488 HCS Assay *10-plate size*	1 kit
C10352	Click-iT® EdU Alexa Fluor® 555 HCS Assay *2-plate size*	1 kit
C10353	Click-iT® EdU Alexa Fluor® 555 HCS Assay *10-plate size*	1 kit
C10354	Click-iT® EdU Alexa Fluor® 594 HCS Assay *2-plate size*	1 kit
C10355	Click-iT® EdU Alexa Fluor® 594 HCS Assay *10-plate size*	1 kit
C10356	Click-iT® EdU Alexa Fluor® 647 HCS Assay *2-plate size*	1 kit
C10357	Click-iT® EdU Alexa Fluor® 647 HCS Assay *10-plate size*	1 kit
C10337	Click-iT® EdU Alexa Fluor® 488 Imaging Kit *for 50 coverslips*	1 kit
C10338	Click-iT® EdU Alexa Fluor® 555 Imaging Kit *for 50 coverslips*	1 kit
C10339	Click-iT® EdU Alexa Fluor® 594 Imaging Kit *for 50 coverslips*	1 kit
C10340	Click-iT® EdU Alexa Fluor® 647 Imaging Kit *for 50 coverslips*	1 kit
C10214	Click-iT® EdU Microplate Assay *400 assays*	1 kit
C36950	CountBright™ absolute counting beads *for flow cytometry* *100 tests*	5 mL
C10227	Countess® automated cell counter *with box of 50 cell counting chambers and Trypan Blue*	1 kit
C10311	Countess® Automated Cell Counter Lab Starter Kit *with 101 boxes of 50 cell counting chamber slides and Trypan Blue*	1 kit
C10310	Countess® Automated Cell Counter Starter Kit *with 11 boxes of 50 cell counting chamber slides and Trypan Blue*	1 kit
C10228	Countess® cell counting chamber slides *for use with Countess® automated cell counter* *box of 50 with Trypan Blue*	1 kit
C10312	Countess® Cell Counting Chamber Slides, 500 Slides (1000 Counts) *for use with Countess® automated cell counter* *10 boxes of 50 slides* *with Trypan Blue*	1 kit
C10313	Countess® Cell Counting Chamber Slides, 1250 Slides (2500 Counts) *for use with Countess® automated cell counter* *25 boxes of 50 slides* *with Trypan Blue*	1 kit
C10314	Countess® Cell Counting Chamber Slides, 2500 Slides (5000 Counts) *for use with Countess® automated cell counter* *50 boxes of 50 slides* *with Trypan Blue*	1 kit
C10315	Countess® Cell Counting Chamber Slides, 5000 Slides (10,000 Counts) *for use with Countess® automated cell counter* *100 boxes of 50 slides* *with Trypan Blue*	1 kit
C10285	Countess® power cord with four adapter cords *for use with Countess® automated cell counter*	1 set
C10284	Countess® test beads *for use with Countess® automated cell counter* *1 x 10 ⁶ beads/mL ±10%*	1 mL
C10286	Countess® USB drive *for use with Countess® automated cell counter* *1 Gbyte*	each
C7027	CyQUANT® cell lysis buffer *20X concentrate*	50 mL
C7026	CyQUANT® Cell Proliferation Assay Kit *for cells in culture* *1000 assays*	1 kit
C35011	CyQUANT® Direct Cell Proliferation Assay *for 10 microplates*	1 kit
C35012	CyQUANT® Direct Cell Proliferation Assay *for 100 microplates*	1 kit
C35006	CyQUANT® NF Cell Proliferation Assay Kit *1000 assays*	1 kit
C35007	CyQUANT® NF Cell Proliferation Assay Kit *200 assays*	1 kit
D1306	4',6-diamidino-2-phenylindole, dihydrochloride (DAPI)	10 mg
D21490	4',6-diamidino-2-phenylindole, dihydrochloride (DAPI) *FluoroPure™ grade*	10 mg
D3571	4',6-diamidino-2-phenylindole, dilactate (DAPI, dilactate)	10 mg
A10044	EdU (5-ethynyl-2'-deoxyuridine)	50 mg
E10187	EdU (5-ethynyl-2'-deoxyuridine)	500 mg
E10415	EdU (5-ethynyl-2'-deoxyuridine)	5 g
F2962	FluoReporter® Blue Fluorometric dsDNA Quantitation Kit *200–2000 assays*	1 kit
F10348	FxCycle™ Far Red stain *for flow cytometry* *500 assays*	1 set
F10347	FxCycle™ Violet stain *for flow cytometry* *500 assays* *DAPI*	1 set
H10293	HCS Mitotic Index Kit *2-plate size*	1 kit
H1398	Hoechst 33258, pentahydrate (bis-benzimide)	100 mg
H3569	Hoechst 33258, pentahydrate (bis-benzimide) *10 mg/mL solution in water*	10 mL
H21491	Hoechst 33258, pentahydrate (bis-benzimide) *FluoroPure™ grade*	100 mg
H1399	Hoechst 33342, trihydrochloride, trihydrate	100 mg
H3570	Hoechst 33342, trihydrochloride, trihydrate *10 mg/mL solution in water*	10 mL
H21492	Hoechst 33342, trihydrochloride, trihydrate *FluoroPure™ grade*	100 mg
L7595	LDS 751	100 mg
M7006	Mycobacterium Mycoplasma Detection Kit	1 kit
O34550	Oregon Green® 488 carboxylic acid diacetate, succinimidyl ester (carboxy-DFFDA, SE) *mixed isomers*	1 mg

PRODUCT LIST 15.4 ASSAYS FOR CELL ENUMERATION, CELL PROLIFERATION AND CELL CYCLE—continued

Cat. No.	Product	Quantity
P36232	Premo™ FUCCI Cell Cycle Sensor	1 kit
S22801	SNARF®-1 carboxylic acid, acetate, succinimidyl ester *special packaging*	10 x 50 µg
S7020	SYTOX® Green nucleic acid stain *5 mM solution in DMSO*	250 µL
T3605	TO-PRO®-3 iodide (642/661) *1 mM solution in DMSO*	1 mL
T3600	TOTO®-1 iodide (514/533) *1 mM solution in DMSO*	200 µL
T10282	Trypan Blue stain 0.4% *for use with Countess® automated cell counter*	2 x 1 mL
V12883	Vybrant® CFDA SE Cell Tracer Kit	1 kit
V22888	Vybrant® CM-Dil cell-labeling solution	1 mL
V22887	Vybrant® DiD cell-labeling solution	1 mL
V22885	Vybrant® Dil cell-labeling solution	1 mL
V22886	Vybrant® DiO cell-labeling solution	1 mL
V35004	Vybrant® DyeCycle™ Green stain *5 mM solution in DMSO* *200 assays*	400 µL
V35005	Vybrant® DyeCycle™ Orange stain *5 mM solution in DMSO* *200 assays*	400 µL
V10309	Vybrant® DyeCycle™ Ruby stain *2.5 mM solution in DMSO* *100 assays*	100 µL
V10273	Vybrant® DyeCycle™ Ruby stain *2.5 mM solution in DMSO* *400 assays*	400 µL
V35003	Vybrant® DyeCycle™ Violet stain *5 mM in water* *200 assays*	200 µL
V13154	Vybrant® MTT Cell Proliferation Assay Kit *1000 assays*	1 kit
Y3601	YOYO®-1 iodide (491/509) *1 mM solution in DMSO*	200 µL

15.5 Assays for Apoptosis and Autophagy

Apoptosis (programmed cell death) is the genetically controlled ablation of cells during normal development. Inappropriately regulated apoptosis is implicated in disease states such as Alzheimer disease, stroke and cancer.^{1,2} Apoptosis is distinct from necrosis in both the biochemical and the morphological changes that occur. In contrast to necrotic cells, apoptotic cells are characterized morphologically by compaction of the nuclear chromatin, shrinkage of the cytoplasm and production of membrane-bound apoptotic bodies. Biochemically, apoptosis is distinguished by fragmentation of the genome and cleavage or degradation of several cellular proteins.

As with cell viability, no single parameter fully defines cell death in all systems; therefore, it is often advantageous to use several different approaches when studying apoptosis. Several methods have been developed to distinguish live cells from early and late apoptotic cells and from necrotic cells; these are described below and in a number of review articles.^{3–5} Anti-cancer drug candidates failing to induce apoptosis are likely to have decreased clinical efficacy, making apoptosis assays important tools for high-throughput drug screening.^{6–9}

Apoptosis Assays Using Nucleic Acid Stains

DNA Stains for Detecting Apoptotic Cells

The characteristic breakdown of the nucleus during apoptosis comprises collapse and fragmentation of the chromatin, degradation of the nuclear envelope and nuclear blebbing, resulting in the formation of micronuclei. Therefore, nucleic acid stains can be useful tools for identifying even low numbers of apoptotic cells in cell populations. Several nucleic acid stains, all of which are listed in Section 8.1, have been used to detect apoptotic cells by fluorescence imaging or flow cytometry.^{10–13}

DNA fragmentation can also be detected *in vitro* using electrophoresis. DNA extracted from apoptotic cells and then separated by gel electrophoresis reveals a characteristic ladder pattern of low molecular weight DNA fragments.¹⁴ Our ultrasensitive SYBR® Green I nucleic acid stain (S7567, Section 8.4) allows the detection of even fewer apoptotic cells in these applications (Figure 15.5.1).

Membrane Permeability/Dead Cell Apoptosis Kit

Our Membrane Permeability/Dead Cell Apoptosis Kit (V13243) detects apoptosis based on changes that occur in the permeability of cell membranes. This kit contains ready-to-use solutions of both the YO-PRO®-1 and propidium iodide nucleic acid stains. Our YO-PRO®-1 nucleic acid stain (also available as a stand-alone reagent, Y3603) selectively passes through the plasma membranes of apoptotic cells and labels them with moderate green fluorescence.^{15–19}

Figure 15.5.1 DNA extracts from camptothecin-treated HL-60 cells separated on an agarose gel and stained with SYBR® Green I nucleic acid gel stain (S7563, S7567, S7585). The 200 to 5000 bp DNA fragments characteristic of apoptotic cells (which appear as "ladders") are clearly visualized with this sensitive nucleic acid stain. Cell preparations were gifts of Zbigniew Darzynkiewicz, Cancer Research Institute, New York Medical College.

The dyes included in this kit are effectively excited by the 488 nm spectral line of the argon-ion laser and are useful for both flow cytometry (Figure 15.5.2) and fluorescence microscopy (Figure 15.5.3). The kit components, number of assays and assay principles are summarized in Table 15.4.

Chromatin Condensation/Dead Cell Apoptosis Kit

The Chromatin Condensation/Dead Cell Apoptosis Kit (V13244) provides a rapid and convenient assay for apoptosis based upon fluorescence detection of the compacted state of the chromatin in apoptotic cells. This kit contains ready-to-use solutions of the blue-fluorescent Hoechst 33342 dye (excitation/emission maxima ~350/461 nm when bound to DNA), which stains the condensed chromatin of apoptotic cells more brightly than the chromatin of nonapoptotic cells, and the red-fluorescent propidium iodide (excitation/emission maxima ~535/617 nm when bound to DNA), which is permeant only to dead cells with compromised membranes. The staining pattern resulting from the simultaneous use of these dyes makes it possible to distinguish normal, apoptotic and dead cell populations by flow cytometry or fluorescence microscopy.²⁰ The 351 nm spectral line of an argon-ion laser or other suitable UV source is required for excitation of the Hoechst 33342 dye, whereas propidium iodide can be excited with the 488 nm spectral line of an argon-ion laser. The kit components, number of assays and assay principles are summarized in Table 15.4.

Figure 15.5.3 Apoptosis induced in Jurkat cells with 10 μ M camptothecin. The cells were then treated with the reagents in the Membrane Permeability/Dead Cell Apoptosis Kit (V13243). Apoptotic cell nuclei were labeled with YO-PRO[®]-1 dye (green) (Y3603). Necrotic cells were detected with propidium iodide (red) (P1304MP, P3566, P21493).

Figure 15.5.2 Flow cytometric analysis of Jurkat cells using the Membrane Permeability/Dead Cell Apoptosis Kit (V13243). Jurkat human T-cell leukemia cells were first exposed to 10 μ M camptothecin for 4 hours (A) or left untreated (as control, B). Cells were then treated with the reagents in the kit and analyzed by flow cytometry. Note that the camptothecin-treated cells (A) have a significantly higher percentage of apoptotic cells (indicated by an "A") than the basal level of apoptosis seen in the control cells (B). V = viable cells, D = dead cells.

Table 15.4 Molecular Probes[®] apoptosis assay kits.

Cat. No.	Kit Name	Probe(s) for Apoptotic Cells (Abs/Em) *	Probe for Necrotic or Live Cells (Abs/Em) *	Number of Assays	Kit Features
V13240	Single Channel Annexin V/Dead Cell Apoptosis Kit	Alexa Fluor [®] 488 annexin V (495/519)	SYTOX [®] Green nucleic acid stain (504/523)	50 flow cytometry assays, each containing 2×10^5 to 1×10^6 cells in a 1 mL volume	Because this Alexa Fluor [®] 488 annexin V-based assay uses only the green fluorescence channel on the flow cytometer, other parameters can be measured simultaneously using fluorescent probes that have different emission spectra.
V13241 V13245	Alexa Fluor [®] 488 Annexin V/Dead Cell Apoptosis Kit	Alexa Fluor [®] 488 annexin V (495/519)	Propidium iodide (535/617)	50 flow cytometry assays, each containing 2×10^5 to 1×10^6 cells in a 1 mL volume	Apoptotic cells are labeled with annexin V conjugated to our exceptionally bright and photostable green-fluorescent Alexa Fluor [®] 488 dye. Necrotic cells are labeled with red-fluorescent propidium iodide.
V13242	FITC Annexin V/Dead Cell Apoptosis Kit	FITC annexin V (494/519)	Propidium iodide (535/617)	50 flow cytometry assays, each containing 2×10^5 to 1×10^6 cells in a 1 mL volume	Similar to Kit V13241 except that it contains the fluorescein conjugate of annexin V.
V13243	Membrane Permeability/Dead Cell Apoptosis Kit	YO-PRO [®] -1 dye (491/509)	Propidium iodide (535/617)	200 flow cytometry assays, each containing 2×10^5 to 1×10^6 cells in a 1 mL volume	This assay detects changes in cell membrane permeability with YO-PRO [®] -1 dye, a green-fluorescent nucleic acid stain that is permeant to apoptotic cells but not to live cells. Necrotic cells are labeled with red-fluorescent propidium iodide.

* Approximate absorption and emission maxima, in nm.

Table 15.4 Molecular Probes® apoptosis assay kits—continued.

Cat. No.	Kit Name	Probe(s) for Apoptotic Cells (Abs/Em) *	Probe for Necrotic or Live Cells (Abs/Em) *	Number of Assays	Kit Features
V13244	Chromatin Condensation/Dead Cell Apoptosis Kit	Hoechst 33342 (346/460)	Propidium iodide (535/617)	200 flow cytometry assays, each containing 2×10^5 to 1×10^6 cells in a 1 mL volume	This assay uses Hoechst 33342 in combination with propidium iodide to distinguish between the condensed chromatin of apoptotic cells and the looser chromatin structure in live cells.
V23200	Vybrant® Apoptosis Assay Kit #6	Biotin-X annexin V and Alexa Fluor® 350 streptavidin (345/442)	Propidium iodide (535/617)	50 flow cytometry assays, each containing 2×10^5 to 1×10^6 cells in a 1 mL volume	Apoptotic cells are labeled with the biotin-X conjugate of annexin V in conjunction with blue-fluorescent Alexa Fluor® 350 streptavidin. Necrotic cells are labeled with red-fluorescent propidium iodide.
V23201	Chromatin Condensation/Membrane Permeability/Dead Cell Apoptosis Kit	Hoechst 33342 (346/460) and YO-PRO®-1 dye (491/509)	Propidium iodide (535/617)	200 flow cytometry assays, each containing 2×10^5 to 1×10^6 cells in a 1 mL volume	This kit is a combination of Kits V13243 and V13244. All three dyes can be excited by a UV laser, or by a combination of UV and 488 nm excitation.
V35112	PE Annexin V/Dead Cell Apoptosis Kit	R-phycoerythrin (R-PE) annexin V (496/578)	SYTOX® Green nucleic acid stain (504/523)	50 flow cytometry assays, each containing 2×10^5 to 1×10^6 cells in a 1 mL volume	Apoptotic cells are labeled with annexin V conjugated to the intensely orange-fluorescent R-phycoerythrin (R-PE). Necrotic cells are labeled with the green-fluorescent SYTOX® Green nucleic acid stain. Both probes can be excited by the 488 nm spectral line of the argon-ion laser.
V35113	APC Annexin V/Dead Cell Apoptosis Kit	Allophycocyanin annexin V (650/660)	SYTOX® Green nucleic acid stain (504/523)	50 flow cytometry assays, each containing 2×10^5 to 1×10^6 cells in a 1 mL volume	This kit is similar to Kit V35112 except that it contains the allophycocyanin conjugate of annexin V. Apoptotic cells are labeled with the intensely far-red-fluorescent allophycocyanin annexin V. Necrotic cells are labeled with green-fluorescent SYTOX® Green nucleic acid stain. These populations can easily be distinguished using a flow cytometer equipped with both the 488 nm spectral line of the argon-ion laser and the 633 nm spectral line of the He-Ne laser for excitation.
V35114	Metabolic Activity/Annexin V/Dead Cell Apoptosis Kit	Allophycocyanin annexin V (650/660)	SYTOX® Green nucleic acid stain (504/523)	50 flow cytometry assays, each containing 2×10^5 to 1×10^6 cells in a 1 mL volume	This kit is identical to Kit V35113 except that it also contains C_{12} -resazurin, which is reduced by viable cells to the orange-fluorescent C_{12} -resorufin (Abs/Em = 571/585 nm). Apoptotic, necrotic and live cell populations can easily be distinguished using a flow cytometer equipped with both the 488 nm spectral line of the argon-ion laser and the 633 nm spectral line of the He-Ne laser for excitation.
V35116	Mitochondrial Membrane Potential/Annexin V Apoptosis Kit	Alexa Fluor® 488 annexin V (495/519)	MitoTracker® Red CMXRos (578/599)	50 flow cytometry assays, each containing 2×10^5 to 1×10^6 cells in a 1 mL volume	Apoptotic cells are labeled with annexin V conjugated to our exceptionally bright and photostable green-fluorescent Alexa Fluor® 488 dye. Live cells are labeled with MitoTracker® Red CMXRos, which exhibits bright red fluorescence in the presence of a mitochondrial transmembrane potential. Apoptotic and live cell populations can easily be distinguished using a flow cytometer and the 488 nm spectral line of the argon-ion laser.
V35123	Violet Membrane Permeability/Dead Cell Apoptosis Kit	PO-PRO™-1 dye (435/455)	7-Aminoactinomycin D (7-AAD) (546/650)	200 flow cytometry assays, each containing 1×10^6 cells in a 1 mL volume	This assay detects changes in cell membrane permeability with PO-PRO™-1 dye, a violet-fluorescent nucleic acid stain that is permeant to apoptotic cells but not to live cells. Necrotic cells are labeled with red-fluorescent 7-AAD. Apoptotic and necrotic cell populations can easily be distinguished using a flow cytometer equipped with a violet laser and an argon-ion laser.
A35135	Violet Chromatin Condensation/Dead Cell Apoptosis Kit	Vybrant® DyeCycle™ Violet dye (370/440)	SYTOX® AADvanced™ dead cell stain (546/647)	200 flow cytometry assays, each containing 1×10^6 cells in a 1 mL volume	This assay uses Vybrant® DyeCycle™ Violet stain to stain the condensed chromatin of apoptotic cells more brightly than the chromatin of normal cells. The SYTOX® AADvanced™ stain labels only necrotic cells, based on membrane integrity. The staining pattern resulting from the simultaneous use of these stains makes it possible to distinguish normal, apoptotic and necrotic cell populations by flow cytometry.
A35136	Violet Annexin V/Dead Cell Apoptosis Kit	Pacific Blue™ annexin V conjugate (415/455)	SYTOX® AADvanced™ dead cell stain (546/647)	50 flow cytometry assays, each containing 1×10^6 cells in a 1 mL volume	The violet-excitable Pacific Blue™ annexin V conjugate stains phosphatidylserine in the exposed cell membrane surface. The SYTOX® AADvanced™ stain labels only necrotic cells, based on membrane integrity. With this assay, apoptotic cells show bright violet fluorescence, dead cells show red fluorescence, and live cells show dim violet fluorescence, allowing users to rapidly and reliably distinguish these populations.
A35137	Violet Ratiometric Membrane Asymmetry Probe/Dead Cell Apoptosis Kit	F2N12S (405/530 for apoptotic and dead cells, 405/585 for live cells)	SYTOX® AADvanced™ dead cell stain (546/647)	100 flow cytometry assays, each containing 1×10^6 cells in a 1 mL volume	This assay detects changes in cell membrane asymmetry using the ratiometric 405 nm-excitable F2N12S dye and SYTOX® AADvanced™ stain for dead cell detection. Apoptotic and necrotic cell populations can easily be distinguished using a flow cytometer equipped with a violet laser and an argon-ion laser.

* Approximate absorption and emission maxima, in nm.

Chromatin Condensation/Membrane Permeability/Dead Cell Apoptosis Kit

The Chromatin Condensation/Membrane Permeability/Dead Cell Apoptosis Kit (V23201) combines the detection principles used in the two related kits described above. Three nucleic acid stains—Hoechst 33342, YO-PRO®-1 and propidium iodide—are utilized to identify the blue-fluorescent live-cell population, the green-fluorescent apoptotic population and the red-fluorescent dead-cell population by flow cytometry. The stains are provided as separate solutions to facilitate optimization of the assay for the cell line under study and the equipment available. Once optimized, however, the assay can be completed using simultaneous staining with a mixture of the three nucleic acid stains and either UV excitation of all three dyes or with a combination of UV excitation for the Hoechst 33342 dye and excitation by the 488 nm spectral line of the argon-ion laser. The kit components, number of assays and assay principles are summarized in Table 15.4.

Violet Membrane Permeability/Dead Cell Apoptosis Kit

Like the Membrane Permeability/Dead Cell Apoptosis Kit, our Violet Membrane Permeability/Dead Cell Apoptosis Kit (V35123) detects apoptosis based on changes that occur in the permeability of cell membranes (Table 15.4). This kit contains ready-to-use solutions of both PO-PRO™-1 and 7-aminoactinomycin (7-AAD) nucleic acid stains. Our PO-PRO™-1 nucleic acid stain (also available as a stand-alone reagent, P3581) selectively passes through the plasma membranes of apoptotic cells and labels them with violet fluorescence. Furthermore, annexin V labeling of apoptosis yields poor results with trypsinized cells, whereas PO-PRO™-1 dye provides the same efficiency for detecting apoptosis with trypsinized cells as it does with suspension cells. Necrotic cells are stained with the red-fluorescent 7-AAD, a DNA-selective dye that is membrane impermeant but that easily passes through the compromised plasma membranes of necrotic cells. Live cells are not appreciably stained by either PO-PRO™-1 or 7-AAD. The dyes included in this kit are effectively excited by a flow cytometer that uses both the 405 nm spectral line of the violet laser and the 488 nm spectral line of the argon-ion laser for excitation. The kit components, number of assays and assay principles are summarized in Table 15.4.

Comet (Single-Cell Gel Electrophoresis) Assay to Detect Damaged DNA

The Comet assay, or single-cell gel electrophoresis assay, is used for rapid detection and quantitation of DNA damage from single cells.^{21,22} The Comet assay is based on the alkaline lysis of labile DNA at sites of damage. Cells are immobilized in a thin agarose matrix on slides and gently lysed. When subjected to electrophoresis, the unwound, relaxed DNA migrates out of the cells. After staining with a nucleic acid stain, cells that have accumulated DNA damage appear as fluorescent comets, with tails of DNA fragmentation or unwinding (Figure 15.5.4). In contrast, cells with normal, undamaged DNA appear as round dots, because their intact DNA does not migrate out of the cell. The ease and sensitivity of the Comet assay has provided a fast and convenient way to measure damage to human sperm DNA,²³ evaluate DNA replicative integrity,²⁴ monitor the sensitivity of tumor cells to radiation damage²⁵ and assess the sensitivity of molluscan cells to toxins in the environment.²⁶ The Comet assay can also be used in combination with FISH to identify specific sequences with damaged DNA.²⁵ Comet assays have traditionally been performed using ethidium bromide to stain the DNA;²¹ however, use of the SYBR® Gold and SYBR® Green I stains^{27,28} improves the sensitivity of this assay (Figure 15.5.4).

Figure 15.5.4 Comet assay with SYBR® Green I nucleic acid gel stain (S7563, S7567, S7585). DNA fragmentation associated with oxidative DNA damage was visualized using Trevigen's CometAssay® kit. HL-60 cells were treated with H₂O₂ and immobilized onto a Trevigen CometSlide™ for analysis. The cells were gently lysed, washed and treated with endonuclease. Slides were subjected to electrophoresis in alkaline electrophoresis buffer and stained with SYBR® Green I stain.

Figure 15.5.5 The EdUTP nucleotide, provided in the Click-iT® TUNEL Imaging Assay Kits.

Apoptosis Assays that Detect DNA Strand Breaks

Click-iT® TUNEL Alexa Fluor® Imaging Assays

The terminal deoxynucleotidyl transferase-dUTP nick end labeling (TUNEL) assay—based on the incorporation of modified dUTPs by terminal deoxynucleotidyl transferase (TdT) at the 3'-OH ends of fragmented DNA—is probably the most widely used *in situ* test for studying apoptotic DNA fragmentation.^{29,30} For a sensitive and reliable TUNEL imaging assay, it is vital that the modified nucleotide is an efficient substrate for TdT. We have developed a Click-iT® TUNEL imaging assay that incorporates an alkyne-modified dUTP (Figure 15.5.5) at the 3'-OH ends of fragmented DNA using TdT and then detects the enzymatically

Figure 15.5.7 TUNEL assay comparison—percentage positives detected. HeLa cells were treated with 0.5 μ M staurosporine for 4 hours. Following fixation and permeabilization, TUNEL imaging assays were performed according to the manufacturer's instructions. The percent positives were calculated based upon the corresponding negative control. Imaging and analysis was performed using a Thermo Fisher Scientific Cellomics® ArrayScan® II.

Figure 15.5.8 Human lymphoma cells treated with camptothecin for 4 hours and stained using the APO-BrdU™ TUNEL Assay Kit (A23210). Cells containing DNA strand nicks characteristic of apoptosis are detected by TUNEL and fluoresce green, while necrotic cells are stained with red-fluorescent propidium iodide.

incorporated nucleotide using a copper (I)-catalyzed click reaction with an azide-derivatized fluorophore (Figure 15.5.6).

The Click-iT® labeling reaction is based on a copper-catalyzed azide-alkyne cycloaddition^{31,32} and derives its high degree of specificity from the fact that the azide and alkyne reaction partners have no endogenous representation in biological molecules, cells, tissues or model organisms.^{33–35} The minimally modified EdUTP nucleotide (Figure 15.5.5) used in the Click-iT® TUNEL imaging assay is rapidly incorporated by TdT, allowing samples to be rapidly fixed in order to preserve late-stage apoptotic cells, thereby lessening the possibility of false-negative results due to cell detachment and subsequent loss. Compared with assays that use one-step incorporation of dye-modified nucleotides, the fast and reliable Click-iT® TUNEL imaging assay can detect a higher percentage of apoptotic cells under identical conditions in two hours or less (Figure 15.5.7). The Click-iT® TUNEL Imaging Assay Kits are available with a choice of azide-derivatized Alexa Fluor® dyes, providing flexibility for combination with other apoptosis detection reagents. They include:

- Click-iT® TUNEL Alexa Fluor® 488 Imaging Assay (C10245)
- Click-iT® TUNEL Alexa Fluor® 594 Imaging Assay (C10246)
- Click-iT® TUNEL Alexa Fluor® 647 Imaging Assay (C10247)

The Click-iT® TUNEL assays have been tested in HeLa, A549 and CHO K1 cells with a variety of reagents that induce apoptosis, including staurosporine, and multiplexed with antibody-based detection of other apoptosis biomarkers such as cleaved poly(ADP-ribose) polymerase (PARP), cleaved caspase-3 and phosphohistone 2B. It has also proven effective for detection of apoptosis induced by siRNA knockdown of the DEC2 transcription factor in human MCF-7 breast cancer cells.³⁶ Click-iT® labeling technology and the details of the click reaction are discussed in Section 3.1. For a complete list azide and alkyne derivatives compatible with Click-iT® labeling technology, see Table 3.1.

APO-BrdU™ TUNEL Assay Kit

Because DNA fragmentation is one of the most reliable methods for detecting apoptosis, we have collaborated with Phoenix Flow Systems to offer the APO-BrdU™ TUNEL Assay Kit (A23210), which provides all the materials necessary to label and detect the DNA strand breaks of apoptotic cells.³⁰ When DNA strands are cleaved or nicked by nucleases, a large number of 3'-hydroxyl ends are exposed. In the APO-BrdU™ assay, these ends are labeled with BrdUTP and terminal deoxynucleotidyl transferase (TdT) using the TUNEL technique described above. Once incorporated into the DNA, BrdU is detected using an Alexa Fluor® 488 dye-labeled anti-BrdU monoclonal antibody (Figure 15.5.8). This kit also provides propidium iodide for determining total cellular DNA content, as well as fixed control cells for assessing assay performance.

Figure 15.5.6 Detection of apoptosis with the Click-iT® TUNEL imaging assay.

The APO-BrdU™ TUNEL Assay Kit includes complete protocols for use in flow cytometry applications, though it may also be adapted for use with fluorescence microscopy. Each kit contains:

- Terminal deoxynucleotidyl transferase (TdT), for catalyzing the addition of BrdUTP at the break sites
- 5-Bromo-2'-deoxyuridine 5'-triphosphate (BrdUTP)
- Alexa Fluor® 488 dye-labeled anti-BrdU mouse monoclonal antibody PRB-1, for detecting BrdU labels
- Propidium iodide/RNase staining buffer, for quantitating total cellular DNA
- Reaction, wash and rinse buffers
- Positive control cells (a fixed human lymphoma cell line)
- Negative control cells (a fixed human lymphoma cell line)
- Detailed protocols

Sufficient reagents are provided for approximately 60 assays of 1 mL samples, each containing approximately 1×10^6 cells/mL.

Detecting DNA Strand Breaks with ChromaTide® Nucleotides

Break sites have traditionally been labeled with biotinylated dUTP, followed by subsequent detection with an avidin or streptavidin conjugate³⁷⁻⁴⁰ (Section 7.6, Table 7.9). However, a more direct approach for detecting DNA strand breaks in apoptotic cells is possible via the use of our ChromaTide® BODIPY® FL-14-dUTP (C7614) as a TdT substrate^{41,42} (Figure 15.5.9). The single-step BODIPY® FL dye-based assay has several advantages over indirect detection of biotinylated or haptenylated nucleotides, including fewer protocol steps and increased cell yields. BODIPY® FL dye-labeled nucleotides have also proven superior to fluorescein-labeled nucleotides for detection of DNA strand breaks in apoptotic cells because they provide stronger signals, a narrower emission spectrum and less photobleaching⁴¹ (Figure 15.5.9).

In situ DNA modifications by labeled nucleotides have been used to detect DNA fragmentation in what may be apoptotic cells in autopsy brains of Huntingtons and Alzheimer disease patients.⁴³⁻⁴⁶ DNA fragmentation is also associated with amyotrophic lateral sclerosis.⁴⁷

Analogous to TdT's ability to label double-strand breaks, the *E. coli* repair enzyme DNA polymerase I can be used to detect single-strand nicks,^{48,49} which appear as a relatively early step in some apoptotic processes.⁵⁰⁻⁵² Because our ChromaTide® BODIPY® FL-14-dUTP (C7614) and ChromaTide® fluorescein-12-dUTP^{53,54} (C7604) are incorporated into DNA by *E. coli* DNA polymerase I, they are also effective for *in situ* labeling with the nick translation method.⁵⁵

High-Content Analysis of Genotoxicity and Cytotoxicity

In mammalian cells, a double-strand break (DSB) in genomic DNA is a potentially lethal lesion. One of the earliest known responses to DSB formation is phosphorylation of H2A histones. Specifically, DNA damaging agents induce phosphorylation of histone variant H2AX at Ser139, leading to the formation of DNA foci at the site of DNA DSBs.⁵⁶⁻⁵⁸

The HCS DNA Damage Kit (H10292) was developed to enable simultaneous quantitation of two cell health parameters, genotoxicity and cytotoxicity, by high-content analysis in the same cell (Figure 15.5.10). DNA damage is measured as an indication of genotoxicity and accomplished by specific antibody-based detection of phosphorylated H2AX (Ser139) in the nucleus. Cytotoxicity is measured with the Image-iT® DEAD Green™ viability stain (also available as a stand-alone reagent, I10291),

Figure 15.5.9 HL-60 cells treated with camptothecin for 3 hours. The DNA strand nicks characteristic of apoptosis were detected with the TUNEL (terminal deoxynucleotidyl transferase-mediated dUTP nick end-labeling) assay using the fluorescently labeled nucleotide ChromaTide® BODIPY® FL-14-dUTP (C7614). Image contributed by Zbigniew Darzynkiewicz, Cancer Research Institute, New York Medical College.

Figure 15.5.10 Detection of genotoxicity and cytotoxicity in valinomycin-treated A549 cells using the HCS DNA Damage Kit (H10292). A549 cells were treated with 30 μM or 120 μM valinomycin for 24 hr before performing the assay. With increasing concentrations of valinomycin, cells showed genotoxic effects as indicated by detection with a pH2AX antibody in conjunction with Alexa Fluor® 555 goat anti-mouse IgG antibody (orange fluorescence), and cytotoxic effects as indicated by staining with the Image-iT® DEAD Green™ viability stain (green fluorescence). Blue-fluorescent Hoechst 33342 was used as a nuclear segmentation tool, and Alexa Fluor® 647 phalloidin was used to visualize F-actin (pseudocolored magenta). The image on the left shows untreated cells with intact F-actin cytoskeletons and no evidence of cytotoxicity or genotoxicity. The image on the right shows cells treated with 120 μM valinomycin, which completely disrupted the actin cytoskeletons, increased levels of DNA damage and compromised plasma membrane integrity.

a cell-impermeant, nonfluorescent, high-affinity DNA stain that forms highly fluorescent and stable dye–nucleic acid complexes when bound to DNA. Thus, staining of nuclear DNA by the Image-iT® DEAD Green™ viability stain cannot occur in live cells due to the impermeability of the plasma membrane to the stain. Drugs and test compounds that lead to serious cell injuries, including plasma membrane permeability, allow entry of the Image-iT® DEAD Green™ viability stain, enabling discrimination of dead cells. Hoechst 33342, which stains nuclear DNA in live and dead cells, is included in the kit as a segmentation tool for automated image analysis.

The HCS DNA Damage Kit contains sufficient material to perform the DNA damage assay on two 96-well plates when used as described in the protocol provided:

- Image-iT® Dead Green viability stain
- pH2AX mouse monoclonal antibody
- Alexa Fluor® 555 goat anti–mouse IgG antibody
- Hoechst 33342 nucleic acid stain
- Detailed protocols

Because no single parameter fully defines cell viability in all systems, it is often useful to use multiple approaches to study cytotoxicity. In addition to the HCS DNA Damage Kit, we offer the HCS LIVE/DEAD® Green Kit (H10290) and the HCS Mitochondrial Health Kit (H10295), both of which employ the Image-iT® DEAD™ Green viability stain. Additionally, the HCS LIVE/DEAD® Kit provides a choice of two nucleic acid stains—the far-red–fluorescent HCS NuclearMask™ Deep Red stain (H10294, Section 12.5) and the blue–fluorescent Hoechst 33342 (H1399, H3570, H21492; Section 12.5)—for use as cell-permeant nuclear segmentation tools. The HCS Mitochondrial Health Kit provides Image-iT® DEAD Green viability stain and Hoechst 33342 stain,

Figure 15.5.11 F2N12S, a component of the Violet Ratiometric Membrane Asymmetry Probe/Dead Cell Apoptosis Kit (A35137).

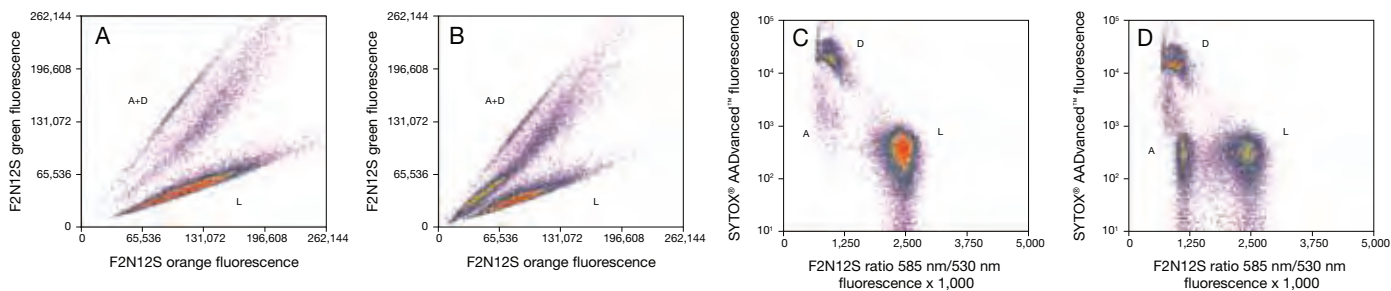

Figure 15.5.12 Jurkat cells (T-cell leukemia, human) treated with 10 μM camptothecin for 4 hours (B and D) or untreated (A and C), control. Cells were stained according to the protocol. Samples were analyzed on a flow cytometer with 405 nm excitation using 585 nm and 530 nm bandpass filters for F2N12S and 488 nm excitation for SYTOX® AADvanced™ dead cell stain using a 695 nm bandpass filter. In panels A and B, live cells can be discriminated from apoptotic and dead cells by the relative intensities of the two emission bands from F2N12S. In C and D, SYTOX® AADvanced™ dead cell stain fluorescence is plotted against a derived ratio parameter from the two emission bands (585/530 nm) of F2N12S. A = apoptotic cells, L = live cells, D = dead cells.

as well as the MitoHealth stain, which accumulates in the mitochondria of live cells in proportion to the mitochondrial membrane potential. Both of these kits provide sufficient reagents to perform the assays on two 96-well plates, using the protocol provided.

Apoptosis Assays that Detect Membrane Asymmetry

Violet Ratiometric Membrane Asymmetry Probe/Dead Cell Apoptosis Kit

The Violet Ratiometric Membrane Asymmetry Probe/Dead Cell Apoptosis Kit (A35137) provides a simple and fast method for detecting apoptosis with dead-cell discrimination by flow cytometry. The violet ratiometric membrane asymmetry probe, F2N12S (4'-N,N-diethylamino-6-(N-dodecyl-N-methyl-N-(3-sulfopropyl))ammonio-methyl-3-hydroxyflavone, Figure 15.5.11), is a novel violet diode-excitable dye for the detection of membrane phospholipid asymmetry changes during apoptosis. This dye exhibits an excited-state intramolecular proton transfer (ESIPT) reaction, resulting in a dual fluorescence with two emission bands corresponding to 530 nm and 585 nm and producing a two-color ratiometric response to variations in surface charge.⁵⁹ This ratiometric probe is therefore a self-calibrating indicator of apoptotic transformation, which is independent of probe concentration, cell size and instrument variation, such as fluctuations of laser intensity or sensitivity of the detectors.

Given that apoptosis modifies the surface charge of the outer leaflet of the plasma membrane, F2N12S can be used to monitor changes in membrane asymmetry that occur during apoptosis through a change in the relative intensity of the two emission bands of the dye⁵⁹ (Figure 15.5.12). The F2N12S-based apoptosis assay allows samples to be analyzed after a 5-minute incubation at room temperature and does not require special buffers or wash steps. This kit can be paired with other reagents such as MitoProbe™ DiIC₁(5) or annexin V for multiparametric analysis of apoptosis and viability. The kit components, number of assays and assay principles are summarized in Table 15.4.

Annexin V Conjugates

The human vascular anticoagulant annexin V is a 35–36 kilodalton, Ca²⁺-dependent phospholipid-binding protein that has a high affinity for the anionic phospholipid phosphatidylserine (PS). In normal

viable cells, PS is located on the cytoplasmic surface of the cell membrane. In apoptotic cells, however, PS is translocated from the inner to the outer leaflet of the plasma membrane, exposing PS to the external cellular environment where it can be detected by annexin V conjugates.⁶⁰ In leukocyte apoptosis, PS on the outer surface of the cell marks the cell for recognition and phagocytosis by macrophages.^{61,62}

Highly fluorescent annexin V conjugates provide quick and reliable detection methods for studying the externalization of phosphatidylserine,^{63–65} an indicator of intermediate stages of apoptosis. Nuclear fragmentation, mitochondrial membrane potential flux and caspase-3 activation apparently precede phosphatidylserine "flipping" during apoptosis, whereas permeability to propidium iodide and cytoskeletal collapse occur later. The difference in fluorescence intensity between apoptotic and nonapoptotic cells stained by our fluorescent annexin V conjugates, as measured by flow cytometry, is typically about 100-fold (Figure 15.5.13). Our annexin V conjugates are available as stand-alone reagents, each suitable for 50–100 flow cytometry assays or many more imaging assays, or in several variations of our apoptosis assay kits (Table 15.4). Our annexin V conjugates include:

- Alexa Fluor® 488 annexin V⁶⁶ (A13201, Figure 15.5.14)
- Fluorescein (FITC) annexin V (A13199)
- Oregon Green® 488 annexin V (A13200)
- Alexa Fluor® 555 annexin V (A35108)
- R-phycoerythrin (R-PE) annexin V (A35111)
- Alexa Fluor® 568 annexin V (A13202)
- Alexa Fluor® 594 annexin V^{67,68} (A13203)
- Alexa Fluor® 647 annexin V⁶⁴ (A23204)
- Allophycocyanin (APC) annexin V (A35110)
- Alexa Fluor® 680 annexin V⁶⁹ (A35109)
- Alexa Fluor® 350 annexin V (A23202)
- Pacific Blue™ annexin V (A35122)
- Biotin-X annexin V⁶⁵ (A13204)

Single Channel Annexin V/Dead Cell Apoptosis Kit

With the Single Channel Annexin V/Dead Cell Apoptosis Kit (V13240), apoptotic cells are detected based on the externalization of phosphatidylserine. This kit contains recombinant annexin V conjugated to the Alexa Fluor® 488 dye, our brightest and most photostable green fluorophore, to permit maximum sensitivity. In addition, the kit includes a ready-to-use solution of the SYTOX® Green nucleic acid stain. The SYTOX® Green dye is impermeant to live cells and apoptotic cells but stains necrotic cells with intense green fluorescence by binding to cellular nucleic acids. After staining a cell population with Alexa Fluor® 488 annexin V and SYTOX® Green dye in the provided binding buffer, apoptotic cells show green fluorescence, dead cells show a higher level of green fluorescence and live cells show little or no fluorescence (Figure 15.5.15). These populations can easily be distinguished using a flow cytometer with the 488 nm spectral line of

Figure 15.5.14 Jurkat human T-cell leukemia cells treated with 1 μM camptothecin. The externalized phosphatidylserine, a characteristic of early-stage apoptotic cells, was detected with Alexa Fluor® 488 annexin V (A13201). The late-stage apoptotic and necrotic cells were stained with propidium iodide (P1304MP, P3566, P21493). The image was acquired using bandpass filters appropriate for fluorescein.

Figure 15.5.15 Flow cytometric analysis of Jurkat cells using the Single Channel Annexin V/Dead Cell Apoptosis Kit (V13240). Jurkat human T-cell leukemia cells were first exposed to 10 μM camptothecin for four hours (green line) or left untreated (as control, blue line). Cells were then treated with the reagents in the kit and analyzed by flow cytometry. Note that the camptothecin-treated cells (intermediate green fluorescence) have a significantly higher percentage of apoptotic cells than the basal level of apoptosis seen in the control cells (blue line).

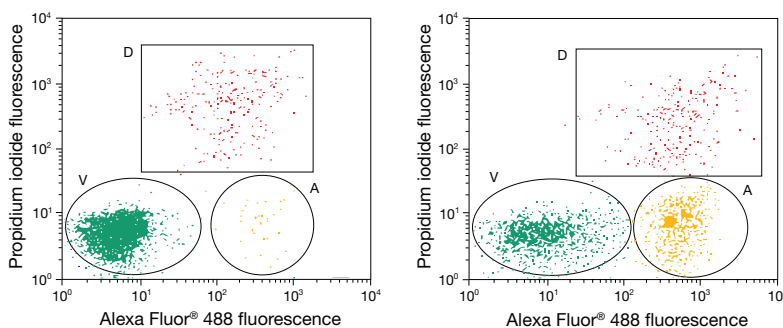

Figure 15.5.13 Flow cytometric analysis of Jurkat cells using the Alexa Fluor® 488 Annexin V/Dead Cell Apoptosis Kit (V13241). Jurkat human T-cell leukemia cells were first exposed to 10 μM camptothecin for 4 hours (right) or left untreated (as control, left). Cells were then treated with the reagents in the kit and analyzed by flow cytometry. Note that the camptothecin-treated cells have a significantly higher percentage of apoptotic cells (indicated by an "A") than the basal level of apoptosis seen in the control cells. V = viable cells, D = dead cells.

an argon-ion laser for excitation. Both Alexa Fluor® 488 annexin and the SYTOX® Green dye emit a green fluorescence that can be detected in the green channel, freeing the other channels for the detection of additional probes in multicolor labeling experiments. The kit components, number of assays and assay principles are summarized in Table 15.4.

Alexa Fluor® 488 Annexin V/Dead Cell Apoptosis Kit

Like the Single Channel Annexin V/Dead Cell Apoptosis Kit, our Alexa Fluor® 488 Annexin V/Dead Cell Apoptosis Kit (V13241) detects the externalization of phosphatidylserine in apoptotic cells.⁷⁰ This kit provides a sensitive two-color assay that employs our green-fluorescent Alexa Fluor® 488 annexin and a ready-to-use solution of the red-fluorescent propidium iodide nucleic acid stain. Propidium iodide is impermeant to live cells and apoptotic cells but stains necrotic cells with red fluorescence, binding tightly to the nucleic acids in the cell. After staining a cell population with Alexa Fluor® 488 annexin V and propidium iodide in the provided binding buffer, apoptotic cells show green fluorescence, dead cells show red and green fluorescence, and live cells show little or no fluorescence (Figure 15.5.13). These populations can easily be distinguished using a flow cytometer with the 488 nm spectral line of an argon-ion laser for excitation. The kit components, number of assays and assay principles are summarized in Table 15.4.

FITC Annexin V/Dead Cell Apoptosis Kit

The FITC Annexin V/Dead Cell Apoptosis Kit (V13242) is similar to the Alexa Fluor® 488 Annexin V/Dead Cell Apoptosis Kit, except that it contains fluorescein (FITC) annexin V in place of the Alexa Fluor®

Figure 15.5.16 Flow cytometric analysis of Jurkat cells using the APC Annexin V/Dead Cell Apoptosis Kit (V35113). Jurkat human T-cell leukemia cells were first exposed to 10 μ M camptothecin at 37°C, 5% CO₂. The cells were then treated with the reagents in the kit and analyzed by flow cytometry. The SYTOX® Green fluorescence versus allophycocyanin (APC) annexin fluorescence dot plot shows resolution of live, apoptotic and dead cell populations.

488 conjugate. The kit components, number of assays and assay principles are summarized in Table 15.4.

Vybrant Apoptosis Assay Kit

The Vybrant Apoptosis Assay Kit #6 (V23200) is similar to the Alexa Fluor® 488 Annexin V/Dead Cell Apoptosis Kit, except that it contains biotin-X annexin V and Alexa Fluor® 350 streptavidin in place of the Alexa Fluor® 488 conjugate. After staining a cell population with biotin-X annexin V in the provided binding buffer, Alexa Fluor® 350 streptavidin is added to fluorescently label the bound annexin V. Finally, propidium iodide is added to detect necrotic cells. Apoptotic cells show blue fluorescence, dead cells show red and blue fluorescence and live cells show little or no fluorescence. These populations can easily be distinguished using a flow cytometer with UV excitation for the Alexa Fluor® 350 fluorophore and 488 nm excitation for the propidium iodide. With this kit, fluorescence in the green channel is minimal. In the same experiment for apoptosis detection, the researcher can apply a green-fluorescent probe, for example an antibody labeled with the Alexa Fluor® 488 dye or with fluorescein. The kit components, number of assays and assay principles are summarized in Table 15.4.

PE Annexin V/ Dead Cell Apoptosis Kit and APC Annexin V/Dead Cell Apoptosis Kit

The PE Annexin V/ Dead Cell Apoptosis Kit and APC Annexin V/Dead Cell Apoptosis Kit (V35112, V35113) are similar to the Single Channel Annexin V/Dead Cell Apoptosis Kit, except that they contain either R-phycoerythrin (R-PE) annexin V or allophycocyanin (APC) annexin V instead of Alexa Fluor® 488 annexin V. In addition to the phycoerythrin-conjugated annexin V, these kits include the SYTOX® Green nucleic acid stain, which is impermeant to live cells and apoptotic cells but stains necrotic cells with intense green fluorescence. After staining a cell population with R-PE annexin V and SYTOX® Green stain, apoptotic cells show orange fluorescence with very little green fluorescence, late apoptotic cells show a higher level of green and orange fluorescence and live cells show little or no fluorescence; these populations can easily be distinguished using a flow cytometer with the 488 nm spectral line of an argon-ion laser for excitation. After staining a cell population with APC annexin V and the SYTOX® Green stain, apoptotic cells show far-red fluorescence with very little green fluorescence, late apoptotic cells show a higher level of green and far-red fluorescence and live cells show little or no fluorescence (Figure 15.5.16); these populations can easily be distinguished using a flow cytometer

Figure 15.5.17 Flow cytometric analysis of Jurkat cells using the Metabolic Activity/Annexin V/Dead Cell Apoptosis Kit (V35114). Jurkat human T-cell leukemia cells were first exposed to either 10 μ M camptothecin or 2 mM hydrogen peroxide for 4 hours at 37°C, 5% CO₂. The cells were then combined, treated with the reagents in the kit and analyzed by flow cytometry. **A)** The SYTOX® Green fluorescence versus allophycocyanin (APC) annexin fluorescence dot plot shows resolution of live, apoptotic and dead cell populations. The cell populations can be evaluated for metabolic activity using **B)** the dodecylresorufin fluorescence versus SYTOX® Green fluorescence dot plot and **C)** the dodecylresorufin fluorescence versus allophycocyanin fluorescence dot plot.

with both the 488 nm spectral line of an argon-ion laser and the 633 nm spectral line of a He-Ne laser for excitation. The kit components, number of assays and assay principles are summarized in Table 15.4.

Metabolic Activity/Annexin V/Dead Cell Apoptosis Kit

The Metabolic Activity/Annexin V/Dead Cell Apoptosis Kit (V35114) is an enhanced version of the APC Annexin V/Dead Cell Apoptosis Kit. Nonfluorescent C₁₂-resazurin is reduced by viable cells to orange-fluorescent C₁₂-resorufin.⁷¹ After staining a cell population with allophycocyanin annexin V, C₁₂-resazurin and the SYTOX® Green stain, apoptotic cells show far-red fluorescence, intermediate orange fluorescence and no green fluorescence; late apoptotic cells show intense far-red and green fluorescence and little orange fluorescence; live cells show little or no green or far-red fluorescence but significant orange fluorescence (Figure 15.5.17). The kit components, number of assays and assay principles are summarized in Table 15.4.

Mitochondrial Membrane Potential/Annexin V Apoptosis Kit

The Mitochondrial Membrane Potential/Annexin V Apoptosis Kit (V35116) provides a rapid and convenient assay for two hallmarks of apoptosis—phosphatidylserine externalization and changes in mitochondrial membrane potential. Recombinant annexin V conjugated to the Alexa Fluor® 488 dye, our brightest and most photostable green fluorophore, provides maximum sensitivity for detecting phosphatidylserine externalization in apoptotic cells. Live cells are labeled with MitoTracker® Red CMXRos, which exhibits bright red fluorescence in the presence of a mitochondrial transmembrane potential. After staining a cell population with Alexa Fluor® 488 annexin V and MitoTracker® Red CMXRos dye in the provided binding buffer, live cells exhibit very little green fluorescence and bright red fluorescence, whereas apoptotic cells exhibit bright green fluorescence and decreased red fluorescence (Figure 15.5.18). These populations can easily be distinguished using a flow cytometer, and the 488 nm line of an argon-ion laser can be used to excite both dyes. The kit components, number of assays and assay principles are summarized in Table 15.4.

Violet Chromatin Condensation/Dead Cell Apoptosis Kit

The Violet Chromatin Condensation/Dead Cell Apoptosis Kit (A35135) provides a rapid and convenient assay for apoptosis based upon fluorescence analysis of the compacted state of the chromatin in apoptotic cells. The kit contains the cell-permeant Vybrant® DyeCycle™ Violet stain and the impermeant red-fluorescent SYTOX® AADvanced™ dead cell stain. The condensed chromatin of apoptotic cells are stained more brightly by Vybrant® DyeCycle™ Violet stain than the chromatin of normal cells. The SYTOX® AADvanced™ stain labels only necrotic cells, based on membrane integrity. The staining pattern resulting from the simultaneous use of these stains makes it possible to distinguish normal, apoptotic and necrotic cell populations by flow cytometry (Figure 15.5.19). The Vybrant® DyeCycle™ Violet and SYTOX® AADvanced™ stains are excited with the 405 nm violet diode laser and the 488 nm argon-ion laser, respectively.

Violet Annexin V/Dead Cell Apoptosis Kit

Like the Single Channel Annexin V/Dead Cell Apoptosis Kit, the Violet Annexin V/Dead Cell Apoptosis Kit (A35136) detects the externalization of phosphatidylserine in apoptotic cells.⁷⁰ This kit provides a sensitive two-color assay that employs our violet laser-excitable Pacific Blue™ annexin V (excitation/emission maxima ~415/460 nm) and the impermeant red-fluorescent SYTOX® AADvanced™ dead cell stain. The SYTOX® AADvanced™ stain labels only necrotic cells, based on membrane integrity. After staining a cell population with Pacific Blue™ annexin V and SYTOX® AADvanced™ stain in the provided binding buffer, apoptotic cells show blue fluorescence, dead cells show red fluorescence, and live cells show little or no fluorescence. These populations can easily be distinguished with a flow cytometer equipped with both a 405 nm violet diode laser and an argon-ion laser for excitation. The kit components, number of assays and assay principles are summarized in Table 15.4.

Figure 15.5.18 Flow cytometric analysis of Jurkat cells using the Mitochondrial Membrane Potential/Annexin V Apoptosis Kit (V35116). Jurkat human T-cell leukemia cells in complete medium were B) first exposed to 10 μM camptothecin for 4 hours or A) left untreated. Both cell populations were then treated with the reagents in the kit and analyzed by flow cytometry. Note that the apoptotic cells show higher reactivity for annexin V and lower MitoTracker® Red dye fluorescence than do live cells.

Figure 15.5.19 Jurkat cells (human T-cell leukemia) treated with 10 μM camptothecin for 6 hours (B) or untreated (as control, A). Cells were then mixed with the reagents in the kit and analyzed by flow cytometry using 405/488 nm dual excitation. Note that the camptothecin-treated cells (B) have a higher percentage of apoptotic cells than the basal level of apoptosis seen in the control cells (A). A=apoptotic cells, V = viable cells, N = necrotic cells.

Figure 15.5.20 Detection of apoptosis in SK-N-MC neuroblastoma cells. Following a 6-hour exposure to hydrogen peroxide, cells were labeled with Hoechst 33342 (H1399, H3570, H21492), tetramethylrhodamine ethyl ester (TMRE, T669) and rhodamine 110, bis-L-aspartic acid amide (R22122) for 15 minutes. Apoptotic cells show green cytosolic fluorescence resulting from cleavage of the rhodamine 110, bis-L-aspartic acid amide substrate by active caspase-3. The staining pattern of the Hoechst 33342 dye reveals that the majority of the rhodamine 110-positive cells also contain condensed or fragmented nuclei characteristic of apoptosis. Furthermore, the rhodamine 110-positive cells are also characterized by an absence of polarized mitochondria, as indicated by their failure to load the positively charged mitochondrial indicator TMRE. The image was contributed by A.K. Stout and J.T. Greenamyre, Emory University.

Apoptosis Assays Based on Protease Activity

Caspase-3 Substrates

A distinctive feature of the early stages of apoptosis is the activation of caspase enzymes. Members of the caspase (CED-3/ICE) family of cysteine-aspartic acid specific proteases have been identified as crucial mediators of the complex biochemical events associated with apoptosis.⁷²⁻⁷⁵ The recognition site for caspases is marked by three to four amino acids followed by an aspartic acid residue, with the cleavage occurring after the aspartate.⁷⁶ The caspase proteases are typically synthesized as inactive precursors. Inhibitor release or cofactor binding activates the caspase through cleavage at internal aspartates, either by autocatalysis or by the action of another protease.⁷³

Caspase-3 (CPP32/apopain) is a key effector in the apoptosis pathway, amplifying the signal from initiator caspases (such as caspase-8) and signifying full commitment to cellular disassembly. In addition to cleaving other caspases in the enzyme cascade, caspase-3 has been shown to cleave poly(ADP-ribose) polymerase (PARP), DNA-dependent protein kinase, protein kinase C δ and actin.^{74,77} We offer a selection of fluorogenic caspase substrates (Table 15.5). The Z-DEVD-R110 substrate^{78,79}—a component of our EnzChek® Caspase-3 Assay Kit #2 (E13184) and RediPlate™ 96 EnzChek® Caspase-3 Assay Kit (R35100)—is available separately in a 20 mg unit size for high-throughput screening applications (R22120). This nonfluorescent bisamide is first converted by caspase-3 (or a closely related protease) to the fluorescent monoamide and then to the even more fluorescent rhodamine 110 (excitation/emission maxima ~496/520 nm). In addition, the bis-L-aspartic acid amide of R110 (D₂-R110, R22122), which contains rhodamine 110 (R110) flanked by aspartic acid residues, may serve as a substrate for a variety of apoptosis-related proteases, including caspase-3 and caspase-7,⁷⁸ and does not appear to require any invasive techniques such as osmotic shock to gain entrance into the cytoplasm (Figure 15.5.20).

Caspase-8 Substrates

Caspase-8 plays a critical role in the early cascade of apoptosis, acting as an initiator of the caspase activation cascade. Activation of the enzyme itself is accomplished through direct interaction with the death domains of cell-surface receptors for apoptosis-inducing ligands.^{80,81} The activated protease has been shown to be involved in a pathway that mediates the release of cytochrome *c* from the mitochondria⁸² and is also known to activate downstream caspases, such as caspase-3.⁸³ A R110-based fluorogenic substrate containing the caspase-8 recognition sequence Ile-Glu-Thr-Asp (IETD) is available (Z-IETD-R110, R22125, A22126; Table 15.5).

Other Caspase and Granzyme B Substrates

In addition to our R110-derived caspase-3 and -8 substrates, we offer R110-based substrates for caspase-1, -2, -6, -9 and -13, as well as for granzyme B (Table 15.5). Granzyme B, a serine protease contained within cytotoxic T lymphocytes and natural killer cells, is thought to induce apoptosis in target cells by activating caspases and causing mitochondrial cytochrome *c* release.⁸⁴

* Caspase substrates can often be cleaved by multiple enzymes. The caspase most often associated with the given peptide sequence is listed first. † R110 = rhodamine 110; AMC = 7-amino-4-methylcoumarin. The absorption and emission maxima for the cleaved fluorophores at pH 7 are: 496/520 nm for R110 and 342/441 nm for AMC. ‡ EnzChek® Caspase-3 Assay Kit. § Bulk packaging. ** RediPlate™ 96 EnzChek® Caspase-3 Assay Kit.

EnzChek® Caspase-3 Assay Kits

Molecular Probes® EnzChek® Caspase-3 Assay Kits permit the detection of apoptosis by assaying for increases in caspase-3 and caspase-3-like protease activities. Our EnzChek® Caspase-3 Assay Kit #1 (E13183) contains the 7-amino-4-methylcoumarin (AMC)-derived substrate Z-DEVD-AMC (Figure 15.5.21) (where Z represents a benzyloxycarbonyl group). This substrate, which is weakly fluorescent in the UV spectral range (excitation/emission maxima ~330/390 nm), yields the blue-fluorescent product AMC (A191, Section 10.1, Figure 15.5.22), which has excitation/emission maxima of 342/441 nm upon proteolytic cleavage.

The EnzChek® Caspase-3 Assay Kit #2 (E13184) contains the R110-derived substrate, Z-DEVD-R110^{78,79} (Figure 15.5.23). This substrate is a bisamide derivative of R110, containing DEVD peptides covalently linked to each of R110's amino groups, thereby suppressing both the dye's visible absorption and fluorescence. Upon enzymatic cleavage by caspase-3 (or a closely related protease), the nonfluorescent bisamide substrate is converted in a two-step process first to the fluorescent monoamide and then to the even more fluorescent R110 (R6479, Section 10.1, Figure 15.5.24). Both of these hydrolysis products exhibit spectral properties similar to those of fluorescein, with excitation/emission maxima of 496/520 nm. The Z-DEVD-R110 substrate (R22120) is also available separately in a 20 mg unit size for high-throughput screening applications.

Either kit can be used to continuously measure the activity of caspase-3 and closely related proteases in cell extracts and purified enzyme preparations using a fluorescence microplate reader or fluorometer. AMC-based DEVD substrates, which yield blue fluorescence upon proteolytic cleavage, are widely used to monitor caspase-3 activity.^{77,85} The longer-wavelength spectra and higher extinction coefficient of the green-fluorescent products of the R110-based substrate in Kit #2 (E13184) should provide even greater sensitivity.^{78,79} The reversible aldehyde-based inhibitor Ac-DEVD-CHO can be used to confirm that the observed fluorescence signal in both induced and control cell populations is due to the activity of caspase-3-like proteases.⁷⁷ The EnzChek® Caspase-3 Assay Kits contain:

- Z-DEVD-AMC^{86,87} (in Kit #1, E13183) or Z-DEVD-R110^{78,88} (in Kit #2, E13184)
- Dimethylsulfoxide (DMSO)
- Concentrated cell-lysis buffer
- Concentrated reaction buffer
- Dithiothreitol (DTT)
- Ac-DEVD-CHO, a reversible aldehyde-based inhibitor
- 7-Amino-4-methylcoumarin (AMC) (in Kit E13183) or rhodamine 110 (in Kit E13184) reference standard to quantitate the amount of fluorophore released in the reaction
- Detailed protocols

Each kit provides sufficient reagents for performing ~500 assays using a volume of 100 µL per assay.

RediPlate™ 96 EnzChek® Caspase-3 Assay Kit

Our EnzChek® Caspase-3 Assay Kit #2 is also available as a convenient RediPlate™ 96 EnzChek® Caspase-3 Assay Kit (R35100), which includes one 96-well microplate, contained in a resealable foil packet to help ensure the integrity of the fluorogenic components, plus all necessary buffers and reagents for performing the assay. The enzyme sample to be assayed is added to the microplate in a suitable buffer, along with any compounds to be tested. Then, after incubation, the resultant fluorescence is quantitated on a fluorescence microplate reader equipped with filters appropriate for the green-fluorescent R110, with excitation/emission maxima of 496/520 nm. The microplate consists of twelve removable strips, each with eight wells, allowing researchers to

Figure 15.5.24 Absorption and fluorescence emission spectra of rhodamine 110 in pH 7.0 buffer.

Figure 15.5.23 Z-DEVD-R110 substrate, a component of the EnzChek® Caspase-3 Assay Kit #2 (E13184).

perform only as many assay as required for the experiment. Eleven of the strips (88 wells) are preloaded with the Z-DEVD-R110 substrate. The remaining strip, marked with blackened tabs, contains a dilution series of free R110 that may be used as a fluorescence reference standard. The reversible aldehyde-based inhibitor Ac-DEVD-CHO, which is supplied in a separate vial, can be used to confirm that the observed fluorescence signal in both induced and control cell populations is due to the activity of caspase-3–like proteases.⁷⁷ Table 10.3 summarizes our other RediPlate™ 96 and RediPlate™ 384 Assay Kits for protease activity (Section 10.4), phosphatase activity (Section 10.3) and RNA quantitation (Section 8.3).

Image-iT® LIVE Green Caspase Detection Kits for Fluorescence Microscopy

The Image-iT® LIVE Green Caspase-3 and -7 Detection Kit, Image-iT® LIVE Green Caspase-8 Detection Kit and Image-iT® LIVE Green Poly Caspases Detection Kit (I35106, I35105, I35104) employ a novel approach to detect active caspases that is based on a fluorescent inhibitor of caspases (FLICA® methodology). The FLICA® inhibitor comprises a fluoromethyl ketone (FMK) moiety, which can react covalently with a cysteine, a caspase-selective amino acid sequence and a fluorescent carboxyfluorescein (FAM) reporter group. Essentially an affinity label, the FLICA® inhibitor is thought to interact with the enzymatic reactive center of an activated caspase via the recognition sequence, and then to attach covalently to a cysteine through the reactive FMK moiety.⁸⁹ The FLICA® inhibitor's recognition sequence is aspartic acid–glutamic acid–valine–aspartic acid (DEVD) for caspase-3 and -7 detection, leucine–glutamic acid–threonine–aspartic acid (LETD) for caspase-8 detection and valine–alanine–aspartic acid (VAD) for detection of most caspases (including caspase-1, -3, -4, -5, -6, -7, -8 and -9). Importantly, the FLICA® inhibitor is cell permeant and not cytotoxic; unbound FLICA® molecules diffuse out of the cell and are washed away. The remaining green-fluorescent signal (excitation/emission maxima ~488/530 nm) can be used as a direct measure of the amount of active caspase that was present at the time the inhibitor was added. FLICA® reagents have been used widely to study apoptosis with flow cytometry and microscopy.^{90–94} Recent work indicates that cellular fluorescence from the bound FLICA® reagent is strongly linked to caspase activity in apoptotic cells; however, the interaction of the FLICA® reagent with other cellular sites may contribute to signal intensity in nonapoptotic cells.⁹⁵ The Image-iT® LIVE Green Caspase Detection Kit includes:

- FAM-DEVD-FMK caspase-3 and -7 reagent (in Kit I35106), FAM-LETD-FMK caspase-8 reagent (in Kit I35105) or FAM-VAD-FMK poly caspases reagent (in Kit I35104)
- Hoechst 33342
- Propidium iodide
- Dimethylsulfoxide (DMSO)
- Apoptosis fixative solution
- Concentrated apoptosis wash buffer
- Detailed protocols for fluorescence microscopy assays

In addition to a specific FLICA® reagent, each kit provides Hoechst 33342 and propidium iodide stains, which allow the simultaneous evaluation of caspase activation, nuclear morphology and plasma membrane integrity. Sufficient reagents are provided for 25 assays, based on labeling volumes of 300 µL. These Image-iT® LIVE Green Caspase Detection Kits can also be used in combination with other reagents for multiparametric study of apoptosis.

Image-iT® LIVE Red Caspase Detection Kits for Fluorescence Microscopy

The Image-iT® LIVE Red Caspase-3 and -7 Detection Kit and Image-iT® LIVE Red Poly Caspases Detection Kit (I35102, I35101) are analogous to the Image-iT® LIVE Green Caspase Detection Kits except that the FLICA® reagent contains a red-fluorescent sulforhodamine (SR) reporter group instead of a green-fluorescent carboxyfluorescein (FAM) reporter group. This assay's red-fluorescent signal (excitation/emission maxima ~550/595 nm) can be used as a direct measure of the amount of active caspase that was present at the time the inhibitor was added. The Image-iT® LIVE Red Caspase Detection Kit includes:

- SR-DEVD-FMK caspase-3 and -7 reagent (in Kit I35102) or SR-VAD-FMK poly caspases reagent (in Kit I35101)
- Hoechst 33342
- SYTOX® Green nucleic acid stain
- Dimethylsulfoxide (DMSO)
- Apoptosis fixative solution
- Concentrated apoptosis wash buffer
- Detailed protocols for fluorescence microscopy assays

In addition to a specific FLICA® reagent, each kit provides Hoechst 33342 and SYTOX® Green nucleic acid stains, which allow the simultaneous evaluation of caspase activation, nuclear morphology and plasma membrane integrity. Sufficient reagents are provided for 25 assays, based on labeling volumes of 300 µL.

Vybrant® FAM Caspase Assay Kits for Flow Cytometry

Like the Image-iT® Kits described above, the Vybrant® FAM Caspase Assay Kits for flow cytometry are based on a fluorescent caspase inhibitor (FLICA® methodology). We offer three different Vybrant® FAM Caspase Assay Kits designed to target different caspases. The Vybrant® FAM Caspase-3 and -7 Assay Kit (V35118) provides a FLICA® inhibitor containing the caspase-3 and -7 recognition sequence DEVD; the Vybrant® FAM Caspase-8 Assay Kit (V35119) provides a FLICA® inhibitor containing the caspase-8 recognition sequence Leu-Glu-Thr-Asp (LETD); and the Vybrant® FAM Poly Caspases Assay Kit (V35117) provides a FLICA® inhibitor containing the caspase recognition sequence Val-Ala-Asp (VAD), which is recognized by caspase-1, -3, -4, -5, -6, -7, -8 and -9. In addition to the selective FLICA® reagent, these kits contain the Hoechst 33342 and propidium iodide nucleic acid stains to permit simultaneous evaluation of caspase activation, membrane permeability and cell cycle. The Vybrant® FAM Caspase Assay Kits include:

- FAM-DEVD-FMK caspase-3 and -7 reagent (in Kit V35118), FAM-LETD-FMK caspase-8 reagent (in Kit V35119) or FAM-VAD-FMK poly caspases reagent (in Kit V35117)
- Hoechst 33342
- Propidium iodide
- Dimethylsulfoxide (DMSO)
- Apoptosis fixative solution
- Concentrated apoptosis wash buffer
- Detailed protocols for flow cytometry assays

Sufficient reagents are provided for 25 assays, based on labeling volumes of 300 µL. These Vybrant® FAM Caspase Assay Kits can be used in combination with other fluorescent probes, such as the

far-red-fluorescent allophycocyanin annexin V (A35110), for a multi-parameter study of apoptosis.

Cathepsins and Calpains

The role of intracellular cathepsins and calpains in apoptosis is unclear, although an upstream role of cathepsin B in activation of some caspases^{96,97} and cathepsins during apoptosis has been established.⁹⁸ Pepstatin A, which is a selective inhibitor of carboxyl (acid) proteases such as cathepsin D, has been reported to inhibit apoptosis in microglia, lymphoid cells and HeLa cells.^{99–101} Consequently, our cell-permeant BODIPY® FL pepstatin derivative (P12271), which we have shown to inhibit cathepsin D *in vitro* (IC₅₀ ~10 nM) and to target cathepsin D within lysosomes of live and fixed cells, has demonstrable utility for following the intracellular translocation of cathepsin D.^{102,103}

Calpains are a family of ubiquitous calcium-activated thiol proteases that are implicated in a variety of cellular functions including exocytosis, cell fusion, apoptosis and cell proliferation.^{101,104} Caspase-dependent downstream processing of calpain has been reported, suggesting that calpain may play a role in the degradation phase of apoptosis that is distinct from that of caspases.^{105–107} One mechanism of caspase dependence appears to be processing of the endogenous calpain inhibitor calpastin by caspases.¹⁰⁸ However, calpain activation has also been reported to be upstream of caspases in radiation-induced apoptosis.¹⁰⁹ Our *t*-BOC-Leu-Met-CMAC fluorogenic substrate (A6520) has been used to measure calpain activity in hepatocytes following the addition of extracellular ATP¹¹⁰ and may be of utility in detecting caspase-activated processing of procalpain in live single cells. Peptidase substrates based on our CMAC fluorophore (7-amino-4-chloromethylcoumarin, C2110; Section 10.1) passively diffuse into several types of cells, where the thiol-reactive chloromethyl group is enzymatically conjugated to glutathione by intracellular glutathione *S*-transferase or reacts with protein thiols, thus transforming the substrate into a membrane-impermeant probe. Subsequent peptidase cleavage results in a bright blue-fluorescent glutathione conjugate; see Section 10.4 for more information on AMC- and CMAC-based peptidase substrates.

Apoptosis Assays Using Mitochondrial Stains

A distinctive feature of the early stages of programmed cell death is the disruption of active mitochondria.^{111–113} This mitochondrial disruption includes changes in the membrane potential and alterations to the oxidation–reduction potential of the mitochondria. Changes in the membrane potential are presumed to be due to the opening of the mitochondrial permeability transition pore, allowing passage of ions and small molecules. The resulting equilibration of ions leads in turn to the decoupling of the respiratory chain and then the release of cytochrome *c* into the cytosol.^{114,115} These changes can be monitored using our extensive selection of potential-sensitive mitochondrial stains^{3,5,64} (Section 12.2). We also offer several kits providing ready-to-use formulations of these reagents in flow cytometry or imaging protocols.

Image-iT® LIVE Mitochondrial Transition Pore Assay Kit for Fluorescence Microscopy

The Image-iT® LIVE Mitochondrial Transition Pore Assay Kit (I35103), based on published experimentation for mitochondrial transition pore opening,^{116,117} provides a more direct method of measuring mitochondrial permeability transition pore opening than assays relying

on mitochondrial membrane potential alone. This assay employs the acetoxymethyl (AM) ester of calcein, a colorless and nonfluorescent esterase substrate, and CoCl₂, a quencher of calcein fluorescence, to selectively label mitochondria. Cells are loaded with calcein AM, which passively diffuses into the cells and accumulates in cytosolic compartments, including the mitochondria. Once inside cells, calcein AM is cleaved by intracellular esterases to liberate the very polar fluorescent dye calcein, which does not cross the mitochondrial or plasma membranes in appreciable amounts over relatively short periods of time. The fluorescence from cytosolic calcein is quenched by the addition of CoCl₂, while the fluorescence from the mitochondrial calcein is maintained. As a control, cells that have been loaded with calcein AM and CoCl₂ can also be treated with a Ca²⁺ ionophore such as ionomycin (I24222, Section 19.8) to allow entry of excess Ca²⁺ into the cells, which triggers mitochondrial pore activation and subsequent loss of mitochondrial calcein fluorescence. This ionomycin response can be blocked with cyclosporine A, a compound reported to prevent mitochondrial transition pore formation by binding cyclophilin D.

The Image-iT® LIVE Mitochondrial Transition Pore Assay Kit has been tested with HeLa cells and bovine pulmonary artery endothelial cells (BPAEC). Each Image-iT® LIVE Mitochondrial Transition Pore Assay Kit provides:

- Calcein AM
- MitoTracker® Red CMXRos, a red-fluorescent mitochondrial stain (excitation/emission maxima ~579/599 nm)
- Hoechst 33342, a blue-fluorescent nuclear stain (excitation/emission maxima ~350/461 nm)
- Ionomycin
- CoCl₂
- Dimethylsulfoxide (DMSO)
- Detailed protocols

Sufficient reagents are provided for 100 assays, based on labeling volumes of 1 mL.

MitoProbe™ Transition Pore Assay Kit for Flow Cytometry

The MitoProbe™ Transition Pore Assay Kit (M34153), based on published experimentation for mitochondrial transition pore opening,^{116,117} provides a more direct method of measuring mitochondrial permeability transition pore opening than assays relying on mitochondrial membrane potential alone. As with the Image-iT® LIVE mitochondrial transition pore assay described above, this assay employs the acetoxymethyl (AM) ester of calcein, a colorless and nonfluorescent esterase substrate, and CoCl₂, a quencher of calcein fluorescence, to selectively label mitochondria. Cells are loaded with calcein AM, which passively diffuses into the cells and accumulates in cytosolic compartments, including the mitochondria. Once inside cells, calcein AM is cleaved by intracellular esterases to liberate the very polar fluorescent dye calcein, which does not cross the mitochondrial or plasma membranes in appreciable amounts over relatively short periods of time. The fluorescence from cytosolic calcein is quenched by the addition of CoCl₂, while the fluorescence from the mitochondrial calcein is maintained. As a control, cells that have been loaded with calcein AM and CoCl₂ can also be treated with a Ca²⁺ ionophore such as ionomycin (I24222, Section 19.8) to allow entry of excess Ca²⁺ into the cells, which triggers mitochondrial pore activation and subsequent loss of mitochondrial calcein fluorescence. This ionomycin response can be blocked with cyclosporine A, a compound reported to prevent mitochondrial transition pore formation by binding cyclophilin D.

The MitoProbe™ Transition Pore Assay Kit has been tested with Jurkat cells, MH1C1 cells and bovine pulmonary artery endothelial cells (BPAEC). Each MitoProbe™ Transition Pore Assay Kit provides:

- Calcein AM
- CoCl₂
- Ionomycin
- Dimethylsulfoxide (DMSO)
- Detailed protocols

Sufficient reagents are provided for 100 assays, based on labeling volumes of 1 mL.

MitoProbe™ JC-1 Assay Kit for Flow Cytometry

The MitoProbe™ JC-1 Assay Kit (M34152) provides the cationic dye JC-1 and a mitochondrial membrane potential uncoupler, CCCP (carbonyl cyanide 3-chlorophenylhydrazone), for the study of mitochondrial membrane potential. JC-1 (Figure 15.5.25) exhibits potential-dependent accumulation in mitochondria, indicated by a fluorescence emission shift from green (~529 nm) to red (~590 nm), due to concentration-dependent formation of red-fluorescent J-aggregates.^{118–120} Consequently, mitochondrial depolarization is indicated by a decrease in the red/green fluorescence intensity ratio, which is dependent only on the membrane potential and not on other factors such as mitochondrial size, shape and density, which may influence single-component fluorescence measurements. Use of fluorescence ratio detection therefore allows researchers to make comparative measurements of membrane potential and to determine the percentage of mitochondria within a population that respond to an applied stimulus. Subtle heterogeneity in cellular responses can be discerned in this way.^{119,121} For example, four distinct patterns of mitochondrial membrane potential change in response to glutamate receptor activation in neurons have been identified using confocal ratio imaging of JC-1 fluorescence.¹²²

JC-1 can be used as an indicator of mitochondrial potential in a variety of cell types, including myocytes¹¹⁸ and neurons,¹²² as well as in intact tissues¹²³ and isolated mitochondria.¹²¹ JC-1 is more specific for mitochondrial versus plasma membrane potential and more consistent in its response to depolarization than some other cationic dyes such as DiOC₆(3) and rhodamine 123.¹²⁴ The most widely implemented application for JC-1 is the detection of mitochondrial depolarization occurring in apoptosis.^{124–127} Each MitoProbe™ JC-1 Assay Kit provides:

- JC-1
- Dimethylsulfoxide (DMSO)
- CCCP
- Concentrated phosphate-buffered saline (PBS)
- Detailed protocols

Figure 15.5.25 5,5',6,6'-Tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarbocyanine iodide (JC-1; T3168).

Sufficient reagents are provided for 100 assays, based on a labeling volume of 1 mL.

MitoProbe™ DiIC₁(5) and MitoProbe™ DiOC₂(3) Assay Kits for Flow Cytometry

Cationic carbocyanine dyes have been shown to accumulate in cells in response to membrane potential,¹²⁸ and membrane potential changes have been studied in association with apoptosis.^{129,130} The MitoProbe™ DiIC₁(5) and MitoProbe™ DiOC₂(3) Assay Kits (M34151, M34150) provide solutions of the far-red-fluorescent DiIC₁(5) (1,1',3,3,3',3'-hexamethylindodicarbocyanine iodide) and green-fluorescent DiOC₂(3) (3,3'-diethyloxacarbocyanine iodide) carbocyanine dyes, respectively, along with a mitochondrial membrane potential disrupter, CCCP, for the study of mitochondrial membrane potential. These DiIC₁(5) and DiOC₂(3) carbocyanine dyes penetrate the cytosol of eukaryotic cells and, at concentrations below 100 nM, accumulate primarily in mitochondria with active membrane potentials. In the case of DiOC₂(3), this accumulation is accompanied by a shift from green to red emission due to dye stacking, allowing the use of a ratiometric parameter (red/green fluorescence ratio) that corrects for size differences when measuring membrane potential in bacteria.^{131,132} DiIC₁(5) and DiOC₂(3) stain intensities decrease when cells are treated with reagents that disrupt mitochondrial membrane potential, such as CCCP. Each MitoProbe™ DiIC₁(5) and MitoProbe™ DiOC₂(3) Assay Kit provides:

- DiIC₁(5) (in Kit M34151) or DiOC₂(3) (in Kit M34150)
- CCCP
- Detailed protocols for labeling cells with the short-chain carbocyanine dye, as well as with annexin V conjugates (not included)

Cells stained with DiIC₁(5) can be visualized by flow cytometry with red excitation and far-red emission filters; cells stained with DiOC₂(3) can be visualized by flow cytometry with blue excitation and green and red emission filters. DiIC₁(5) can be paired with other reagents, such as propidium iodide and the green-fluorescent Alexa

Figure 15.5.26. Schematic depiction of the multistep autophagy pathway in a eukaryotic cell. The first step involves the formation and elongation of isolation membranes, or phagophores. In the second step, which involves the LC3B protein, the cytoplasmic cargo is sequestered, and the double-membrane autophagosome is formed. Fusion of a lysosome with the autophagosome to generate the autolysosome is the penultimate step. In the fourth and final phase, the cargo is degraded.

Fluor® 488 annexin V (both provided in the Alexa Fluor® 488 Annexin V/Dead Cell Apoptosis Kit, V13241), for multiparameter study of vitality and apoptosis. DiOC₂(3) can be paired with other reagents, such as the far-red-fluorescent allophycocyanin annexin V (A35110), for multiparameter study of vitality and apoptosis. Combining these short-chain carbocyanine dyes with annexin V conjugates results in superior resolution of subpopulations when compared with results obtained with other commonly used dyes.

Assays for Autophagy

Autophagy describes the segregation and delivery of cytoplasmic cargo, including proteins and organelles for degradation by hydrolytic enzymes. The process of autophagy begins with the formation and elongation of isolation membranes, or phagophores (Figure 15.5.26). The cytoplasmic cargo is then sequestered, and the double-membrane autophagosome fuses with a lysosome to generate the autolysosome. Finally, degradation is achieved through the action of hydrolytic enzymes within the autolysosome.

Autophagy was first described in 1963; however, only in the past decade has this pathway become the subject of intense study. Researchers have sought to gain further insight into the role basal autophagy plays in cell homeostasis and development, and to further elucidate the role of induced autophagy in the cell's response to stress, microbial infection, and disease.^{1,133,134}

Autophagy Analysis Through Observation of LC3B

The LC3 protein plays a critical role in autophagy. Normally this protein resides in the cytosol, but following cleavage and lipidation with phosphatidylethanolamine, LC3 associates with the phagophore and can be used as a general marker for autophagic membranes (Figure 15.5.26). The new Premo™ Autophagy Sensor Kits (P36235, P36236) combine the selectivity of an LC3B–fluorescent protein chimera^{6,135,136} with the transduction efficiency of BacMam technology (BacMam Gene Delivery and Expression Technology—Note 11.1), enabling unambiguous visualization of this protein in live cells (Figure 15.5.27). Recent improvements made to the BacMam system enable efficient transduction in a wider variety of cells, including neurons and neural stem cells (NSCs) with an easy, one-step protocol. To image autophagy, BacMam LC3B-FP is simply added to cells and allowed to incubate overnight for protein expression. Each Premo™ Autophagy Sensor Kit includes:

- BacMam LC3B-FP (GFP fusion, P36235; RFP fusion, P36236)
- Control BacMam LC3B (G120A)-FP
- Chloroquine diphosphate, to artificially induce phagosome formation
- Detailed protocols

Following treatment with chloroquine diphosphate, normal autophagic flux is disrupted, and autophagosomes accumulate as a result of the increase in lysosomal pH. The mutation in the control BacMam LC3B (G120A)-FP prevents cleavage and subsequent lipidation during normal autophagy, and thus protein localization should remain cytosolic and diffuse.

In addition to the Premo™ Autophagy Sensor Kits, we offer the LC3B Antibody Kit for Autophagy (L10382), which includes a rabbit polyclonal anti-LC3B antibody and chloroquine diphosphate for imaging autophagy via LC3B localization in fixed samples. The LC3B Antibody Kit for Autophagy has been validated for use with fluorescence microscopy and high-content imaging and analysis.

Imaging Autophagic Organelles

Two organelles that play a crucial role in autophagy are the mitochondria and lysosomes. Old, damaged and surplus mitochondria are major targets for autophagy, which in this case is sometimes referred to as "mitophagy." Degradation of mitochondria through this process can be used to recover their amino acids and other nutrients, as well as to remove damaged mitochondria from the cell. Fusion of a lysosome with the phagophore to form the autolysosome is the penultimate step of the autophagic pathway (Figure 15.5.26). A variety of reagents including fluorescent

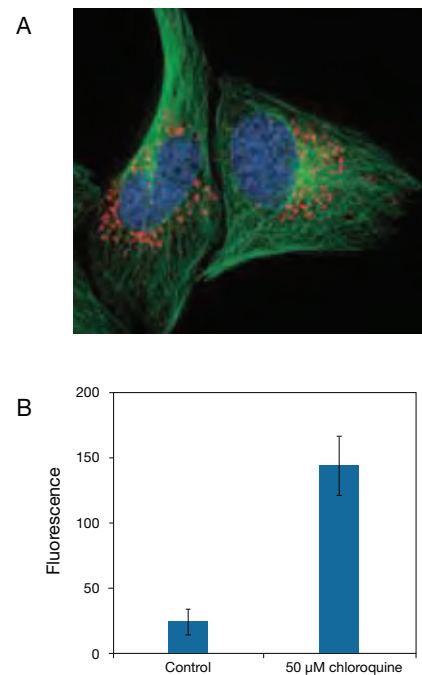

Figure 15.5.27 Detecting autophagy with the Premo™ Autophagy Sensor and fluorescence microscopy (A) or high-content imaging and analysis (B). (A) U2OS cells were co-transduced with the Premo™ Autophagy Sensor LC3B-RFP (P36236) and CellLight® MAP4-GFP (C10598). The following day, cells were treated with 50 μM chloroquine. The following day, cells were incubated with 1 μg/mL Hoechst 33342 before imaging. (B) HeLa cells were plated at 5000 cells per well and left to adhere overnight. Cells were then transduced with the Premo™ Autophagy Sensor LC3B-GFP. The following day, cells were incubated with 50 μM chloroquine or left untreated (control) for 16 hr. Quantitative analysis was performed by quantifying fluorescence from vesicular structures in the perinuclear region using the Thermo Scientific Celloomics® ArrayScan® VTI platform.

dyes, fluorescent protein (FP) chimeras and antibodies can be used to image mitochondria and lysosomes during basal and induced autophagy^{133,137–139} (Table 15.6). For a description of our mitochondrial and lysosomal-selective organelle probes, see Section 12.2 and Section 12.3.

Visualizing Autolysosome Formation

In conjunction with the Premo™ autophagy sensors LC3B-GFP and LC3B-RFP, the fluorogenic protease substrates DQ™ Green BSA and DQ™ Red BSA can be used to accurately image the formation of

the autolysosome in live cells.¹⁴⁰ DQ™ Green BSA and DQ™ Red BSA (D12050, D12051; Section 10.4) are bovine serum albumin (BSA) conjugates that have been labeled to such a high degree that the fluorescence is self-quenched. To visualize autolysosome formation, cells that express a GFP- or RFP-LC3 are incubated with the contrasting color of DQ™ BSA. The convergence of the lysosome with the autophagosome results in dequenching and release of brightly fluorescent fragments. The autolysosomes can then be identified by co-localization of green and red fluorescence.

Table 15.6 Fluorescent detection reagents for imaging mitochondria and lysosomes.

	Organic Dyes (e.g., MitoTracker® and LysoTracker® dyes)	BacMam-Based Fluorescent Proteins (e.g., CellLight® reagents)	Antibodies
How they work	Positively charged MitoTracker® dyes localize to actively respiring mitochondria; weakly basic LysoTracker® dyes accumulate in compartments with low pH.	Combine targeting sequence–fluorescent protein fusion with the transduction efficiency of BacMam to label organelles independently of function (i.e., pH, mitochondrial membrane potential).	Recognize specific target of interest (e.g., LAMP1, a lysosomal protein).
Applications	Live-cell imaging applications; fixable, thus compatible with antibody-based imaging applications.*	Live-cell imaging applications; fixable, thus compatible with antibody-based imaging applications.*†	Imaging fixed cells or tissue. Compatible with labeling with MitoTracker®, LysoTracker® and CellLight® reagents.
Typical workflow	Incubate cells with the MitoTracker® or LysoTracker® reagent for approximately 5–30 min.	The ready-to-use CellLight® reagent is added to live cells, followed by an overnight incubation to allow for protein expression.	Cells are fixed and permeabilized, then incubated with the antibody for labeling, and visualized with a fluorescently labeled secondary antibody. ‡

* Please consult the product manual or contact technical service for additional information on the fixability of these reagents. † With fluorescent protein constructs, anti-GFP or anti-RFP antibodies can be used to amplify fluorescence signals. ‡ Secondary antibody is required if the primary antibody is not directly labeled.

DATA TABLE 15.5 ASSAYS FOR APOPTOSIS AND AUTOPHAGY

Cat. No.	MW	Storage	Soluble	Abs	EC	Em	Solvent	Notes
A6520	554.10	F,D	DMSO	330	13,000	403	MeOH	1, 2
C7604	~993	FFL	H ₂ O	496	68,000	523	pH 8	3, 4
C7614	~908	FF,L	H ₂ O	504	68,000	513	pH 8	3, 4
E13183	767.74	F,D,L	DMSO	325	16,000	395	pH 7	1, 2, 5
E13184	1515.46	F,D,L	DMSO	232	52,000	none	MeOH	5, 6
P3581	579.26	F,D,L	DMSO	435	50,000	455	H ₂ O/DNA	4, 7, 8, 9
P12271	1044.14	F,D,L	DMSO	504	86,000	511	MeOH	
R22120	1515.46	F,D	DMSO, DMF	232	52,000	none	MeOH	6
R22122	788.57	F,D	DMSO, DMF	232	55,000	none	MeOH	6
R22125	1515.55	F,D	DMSO, DMF	232	52,000	none	MeOH	6
R22126	1515.55	F,D	DMSO, DMF	232	52,000	none	MeOH	6
R33750	1495.56	F,D	DMSO, DMF	230	76,000	none	MeOH	6
R33752	1113.10	F,D	DMSO, DMF	232	57,000	none	MeOH	6
R33753	1571.57	F,D	DMSO, DMF	232	57,000	none	MeOH	6
R33754	1511.60	F,D	DMSO, DMF	232	57,000	none	MeOH	6
R33755	1597.65	F,D	DMSO, DMF	232	57,000	none	MeOH	6
Y3603	629.32	F,D,L	DMSO	491	52,000	509	H ₂ O/DNA	4, 7, 8, 9

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. Peptidase cleavage of this substrate yields 7-amino-4-methylcoumarin (A191).
2. Fluorescence of the unhydrolyzed substrate is very weak.
3. The molecular weight (MW) of this product is approximate because the degree of hydration and/or salt form has not been conclusively established.
4. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
5. Data represent the substrate component of this kit.
6. Peptidase cleavage of this substrate yields rhodamine 110 (R6479).
7. Spectra represent aqueous solutions of nucleic acid-bound dye. EC values are derived by comparing the absorbance of the nucleic acid-bound dye with that of free dye in a reference solvent (H₂O or MeOH).
8. This product is essentially nonfluorescent except when bound to DNA or RNA.
9. Although this compound is soluble in water, preparation of stock solutions in water is not recommended because of possible adsorption onto glass or plastic.

PRODUCT LIST 15.5 ASSAYS FOR APOPTOSIS AND AUTOPHAGY

Cat. No.	Product	Quantity
V13241	Alexa Fluor® 488 Annexin V/Dead Cell Apoptosis Kit *Alexa Fluor® 488 annexin V/propidium iodide* *50 assays* *for flow cytometry*	1 kit
A6520	7-amino-4-chloromethylcoumarin, t-BOC-L-leucyl-L-methionine amide (CMAC, A-BOC-Leu-Met)	5 mg
A23202	annexin V, Alexa Fluor® 350 conjugate *100 assays*	500 µL
A13201	annexin V, Alexa Fluor® 488 conjugate *100 assays*	500 µL
A35108	annexin V, Alexa Fluor® 555 conjugate *100 assays*	500 µL
A13202	annexin V, Alexa Fluor® 568 conjugate *100 assays*	500 µL
A13203	annexin V, Alexa Fluor® 594 conjugate *100 assays*	500 µL
A23204	annexin V, Alexa Fluor® 647 conjugate *100 assays*	500 µL
A35109	annexin V, Alexa Fluor® 680 conjugate *100 assays*	500 µL
A35110	annexin V, allophycocyanin conjugate (APC annexin V) *50 assays*	250 µL
A13204	annexin V, biotin-X conjugate *100 assays*	500 µL
A13199	annexin V, fluorescein conjugate (FITC annexin V) *100 assays*	500 µL
A13200	annexin V, Oregon Green® 488 conjugate *100 assays*	500 µL
A35122	annexin V, Pacific Blue™ conjugate *for flow cytometry* *100 assays*	500 µL
A35111	annexin V, R-phycoerythrin conjugate (R-PE annexin V) *50 assays*	250 µL
V35113	APC Annexin V/Dead Cell Apoptosis Kit *with APC annexin V and SYTOX® Green* *50 assays* *for flow cytometry*	1 kit
A23210	APO-BrdU™ TUNEL Assay Kit *with Alexa Fluor® 488 anti-BrdU* *60 assays*	1 kit
C7614	ChromaTide® BODIPY® FL-14-dUTP *1 mM in TE buffer*	25 µL
C7604	ChromaTide® fluorescein-12-dUTP *1 mM in TE buffer*	25 µL
V13244	Chromatin Condensation/Dead Cell Apoptosis Kit *Hoechst 33342/propidium iodide* *200 assays* *for flow cytometry*	1 kit
V23201	Chromatin Condensation/Membrane Permeability/Dead Cell Apoptosis Kit. *Hoechst 33342/YO-PRO®-1/propidium iodide* *200 assays* *for flow cytometry*	1 kit
C10245	Click-iT® TUNEL Alexa Fluor® 488 Imaging Assay *for microscopy and HCS* *50–100 assays*	1 kit
C10246	Click-iT® TUNEL Alexa Fluor® 594 Imaging Assay *for microscopy and HCS* *50–100 assays*	1 kit
C10247	Click-iT® TUNEL Alexa Fluor® 647 Imaging Assay *for microscopy and HCS* *50–100 assays*	1 kit
E13183	EnzChek® Caspase-3 Assay Kit #1 *Z-DEVD-AMC substrate* *500 assays*	1 kit
E13184	EnzChek® Caspase-3 Assay Kit #2 *Z-DEVD-R110 substrate* *500 assays*	1 kit
V13242	FITC Annexin V/ Dead Cell Apoptosis Kit *FITC annexin V/propidium iodide* *50 assays* *for flow cytometry*	1 kit
H10292	HCS DNA Damage Kit *2-plate size*	1 kit
H10290	HCS LIVE/DEAD® Green Kit *2-plate size*	1 kit
H10295	HCS Mitochondrial Health Kit *2-plate size*	1 kit
I10291	Image-iT® DEAD Green™ viability stain *1 mM solution in DMSO*	25 µL
I35106	Image-iT® LIVE Green Caspase-3 and -7 Detection Kit *for microscopy* *25 tests*	1 kit

V35114	Metabolic Activity/Annexin V/Dead Cell Apoptosis Kit *with C ₁₂ resazurin, APC annexin V, and SYTOX® Green* *50 assays* *for flow cytometry*	1 kit
V35116	Mitochondrial Membrane Potential/Annexin V Apoptosis Kit *Alexa Fluor® 488 annexin V/MitoTracker® Red CMXRos* *50 assays* *for flow cytometry*	1 kit
M34151	MitoProbe™ DiIC ₁ (5) Assay Kit *for flow cytometry* *100 assays*	1 kit
M34150	MitoProbe™ DiOC ₂ (3) Assay Kit *for flow cytometry* *100 assays*	1 kit
M34152	MitoProbe™ JC-1 Assay Kit *for flow cytometry* *100 assays*	1 kit
M34153	MitoProbe™ Transition Pore Assay Kit *for flow cytometry* *100 assays*	1 kit
V35112	PE Annexin V/ Dead Cell Apoptosis Kit *with SYTOX® Green* *50 assays* *for flow cytometry*	1 kit
P12271	pepstatin A, BODIPY® FL conjugate	25 µg
P3581	PO-PRO™-1 iodide (435/455) *1 mM solution in DMSO*	1 mL
P36235	Premo™ Autophagy Sensor LC3B-GFP	1 kit
P36236	Premo™ Autophagy Sensor LC3B-RFP	1 kit
R35100	RediPlate™ 96 EnzChek® Caspase-3 Assay Kit *Z-DEVD-R110 substrate* *one 96-well microplate*	1 kit
R22122	rhodamine 110, bis-(L-aspartic acid amide), trifluoroacetic acid salt	1 mg
R33752	rhodamine 110, bis-(N-CBZ-L-alanyl-L-alanyl-L-aspartic acid amide) (Z-AAD-R110)	2 mg
R22120	rhodamine 110, bis-(N-CBZ-L-aspartyl-L-glutamyl-L-valyl-L-aspartic acid amide) (Z-DEVD-R110) *bulk packaging*	20 mg
R22125	rhodamine 110, bis-(N-CBZ-L-isoleucyl-L-glutamyl-L-threonyl-L-aspartic acid amide) (Z-IETD-R110)	2 mg
R22126	rhodamine 110, bis-(N-CBZ-L-isoleucyl-L-glutamyl-L-threonyl-L-aspartic acid amide) (Z-IETD-R110) *bulk packaging*	20 mg
R33753	rhodamine 110, bis-(N-CBZ-L-leucyl-L-glutamyl-L-glutamyl-L-aspartic acid amide) (Z-LEED-R110)	2 mg
R33750	rhodamine 110, bis-(N-CBZ-L-tyrosinyl-L-valyl-L-alanyl-L-aspartic acid amide) (Z-YVAD-R110)	2 mg
R33755	rhodamine 110, bis-(N-CBZ-L-valyl-L-aspartyl-L-valyl-L-alanyl-L-aspartic acid amide) (Z-VDVAD-R110)	2 mg
R33754	rhodamine 110, bis-(N-CBZ-L-valyl-L-glutamyl-L-isoleucyl-L-aspartic acid amide) (Z-VEID-R110)	2 mg
V13240	Single Channel Annexin V/ Dead Cell Apoptosis Kit *Alexa Fluor® 488 annexin V/SYTOX® Green* *50 assays* *for flow cytometry*	1 kit
A35136	Violet Annexin V/Dead Cell Apoptosis Kit *Pacific Blue™ annexin V/SYTOX® AADvanced™** *for flow cytometry* *50 assays*	1 kit
A35135	Violet Chromatin Condensation/Dead Cell Apoptosis Kit *Vybrant® DyeCycle™ Violet and SYTOX® AADvanced™** *for flow cytometry* *200 assays*	1 kit
V35123	Violet Membrane Permeability/Dead Cell Apoptosis Kit *with PO-PRO™-1 and 7- aminoactinomycin D* *200 assays* *for flow cytometry*	1 kit
A35137	Violet Ratiometric Membrane Asymmetry Probe/Dead Cell Apoptosis Kit *for flow cytometry* *100 assays*	1 kit
V23200	Vybrant® Apoptosis Assay Kit #6 *biotin-X annexin V/Alexa Fluor® 350 streptavidin/propidium iodide* *50 assays*	1 kit
V35118	Vybrant® FAM Caspase-3 and -7 Assay Kit *for flow cytometry* *25 assays*	1 kit
V35119	Vybrant® FAM Caspase-8 Assay Kit *for flow cytometry* *25 assays*	1 kit
V35117	Vybrant® FAM Poly Caspases Assay Kit *for flow cytometry* *25 assays*	1 kit
Y3603	YO-PRO®-1 iodide (491/509) *1 mM solution in DMSO*	1 mL

15.6 Probes for Cell Adhesion, Chemotaxis, Multidrug Resistance and Glutathione

Cell Adhesion Assays

The fundamental role of cell–cell and cell–matrix adhesion in the morphology and development of organisms, organs and tissues has made identification of molecular mediators of cell adhesion an important research focus in cell biology and immunology.^{1–3} The useful review by Löster and Hortstkorte describes a number of different assays that can detect cell adhesion.⁴ In a typical fluorescence-based cell adhesion assay, unlabeled cell monolayers in multiwell plates are incubated with fluorescently labeled cells and then washed to separate the adherent and nonadherent populations. Cell adhesion can then be determined simply by correlating the retained fluorescence with cell number. An ideal fluorescent marker will retain proportionality between fluorescence and cell number and introduce minimal interference with the cell adhesion process. Because adhesion is a cell-surface phenomenon, cytoplasmic markers that can be passively loaded are preferable to compounds that label cell-surface molecules, provided they are retained in the cell for the duration of the experiment or their leakage rate can be independently measured. Adhesion of fluorescent dye-labeled cells to matrices such as bone⁵ can be directly observed by fluorescence microscopy using cells loaded with the permeant live-cell tracers described in Section 14.2 and Section 15.2 or the lipophilic dyes in Section 14.4. Alternatively, high molecular weight, cell-impermeant, fluorescent dextrans (Section 14.5) have been used to define the area *outside* of adherent cells, with the adherent cells themselves remaining unstained.⁶ This same “negative-staining” method can also be used to assess cell spreading and progress toward confluency.

Cell Adhesion Assays Using Enzyme Substrates

Essentially all of the esterase substrates in Table 15.1 useful for monitoring cell viability can also be used for studying cell adhesion. As with cell viability studies, calcein AM (C1430, C3099, C3100MP) appears to best satisfy the criteria for assaying cell adhesion^{7–9} and to have the least effect on cell viability and other cell functions.⁷ The results obtained with leukocyte adhesion assays using calcein AM correlate well with those obtained with ⁵¹Cr assays,^{10,11} but the calcein AM protocols take less time and avoid the special handling required when using radioactive material. Calcein AM has been used in numerous cell adhesion assays, including those designed to measure:

- Binding of labeled Jurkat cells to vascular cell adhesion molecule-1 (VCAM1) in cell membrane preparations¹²
- Effects of E-selectin-binding peptides¹³ and integrins¹⁴ on neutrophil adhesion
- Integrin-mediated cell adhesion in transfected K562 cells^{15,16} and BSC-1 cells¹⁷
- Leukocyte^{7,11,18} and neutrophil^{18–20} adhesion to endothelial cells
- Monocyte adhesion in HIV-infected cells²¹

Other fluorogenic esterase substrates that have been used to assess cell adhesion include BCECF AM^{5,22–29} (B1150, B1170, B3051), carboxyfluorescein diacetate^{7,30–32} (5(6)-CFDA, C195), fluorescein diacetate³³ (F1303), the succinimidyl ester of carboxyfluorescein diacetate¹⁴

(5(6)-CFDA, SE; CFSE; C1157) and CellTracker™ Green CMFDA²³ (C2925, C7025), all of which are discussed in Section 15.2. Because of the possibility of slow calcein leakage from calcein AM-labeled cells, CellTracker™ Green CMFDA and 5(6)-CFDA SE are recommended for quantitative adhesion or aggregation assays that require incubation for more than about an hour.^{14,34,35} Use of a combination of a green-fluorescent dye (usually calcein AM, BCECF AM or CMFDA) and a red-fluorescent dye—especially chloromethyl SNARF®-1 acetate (C6826), SNARF®-1 carboxylic acid, acetate, succinimidyl ester (S22801, Section 15.4) or carboxynaphthofluorescein diacetate (C13196, Section 15.2)—enables two-color measurements of adhesion or cell–cell aggregation in mixed cell cultures.³⁶ Calcein AM has also been used in a quantitative microplate assay of spreading of adherent cells on artificial or biological surfaces.¹⁸

In their review,⁴ Löster and Hortstkorte describe the use of a number of other fluorogenic substrates for quantitating cell adhesion; among these are fluorescein diphosphate (F2999, Section 10.3) and ELF® 97 phosphate (Section 6.3) for lysosomal and membrane phosphatases, as well as various substrates for glycosidases (Section 10.2) and oxidases (Section 10.5).

Vybrant® Cell Adhesion Assay Kit

The Vybrant® Cell Adhesion Assay Kit (V13181) utilizes calcein AM to provide a fast and sensitive method for measuring cell–cell or cell–substratum adhesion.^{7,13,14} Calcein AM is nonfluorescent but, once loaded into cells, is cleaved by endogenous esterases to produce calcein, a highly fluorescent and well-retained dye. Calcein provides a bright green-fluorescent, pH-independent, cytoplasmic cell marker that does not appear to affect the cell adhesion process.⁹

To perform this assay, samples of calcein AM-labeled cells are added to monolayers of unlabeled cells in a microplate. Following incubation to allow the labeled cells to adhere to the unlabeled cells, the samples are washed to remove any nonadhering labeled cells (Figure 15.6.1). The calcein fluorescence in this sample, as compared with that of an unlabeled control sample, can then be used to calculate the number of adherent cells. The absorption/emission maxima of calcein (~494/517 nm) are ideally suited for detection by a fluorescence microplate reader equipped with standard fluorescein optical filters.

Figure 15.6.1 Principle of the Vybrant® Cell Adhesion Assay Kit (V13181). Microplate wells may be left untreated or precoated with extracellular matrix proteins, antibodies or other reagents.

Figure 15.6.2 Quantitation of NIH 3T3 fibroblasts using the CyQUANT® Cell Proliferation Assay Kit (C7026). Fluorescence measurements were made using a microplate reader with excitation at 485 nm and emission detection at 530 nm. The linear range of the assay under these conditions is from 50 to 50,000 cells per 200 μ L sample. The inset shows the linearity that can be obtained at very low numbers of cells.

Figure 15.6.3 Schematic view of the microsphere adhesion assay. Membrane-coated microspheres are added to a living tissue slice in a drop of medium (A). The microspheres disperse through the medium and eventually cover the tissue slice (B and C). After incubation, nonadherent microspheres are removed by extensive washing, and the sample is ready for analysis by fluorescence microscopy (D).

In addition to calcein AM, the Vybrant® Cell Adhesion Assay Kit includes SYTOX® Green nucleic acid stain, an easy-to-use dead-cell indicator for assessing overall health of cells prior to performing the cell adhesion assay. As a fluorescent substitute for trypan blue, this high-affinity nucleic acid stain easily penetrates cells that have compromised membranes but will not cross the membranes of live cells. Upon binding to nucleic acids, the SYTOX® Green dye exhibits a >500-fold fluorescence enhancement and can be observed with standard fluorescein optical filters (excitation/emission ~504/523 nm).

The Vybrant® Cell Adhesion Assay Kit contains sufficient reagents to perform about 1000 assays using a fluorescence microplate reader, including:

- Calcein AM
- SYTOX® Green nucleic acid stain, an easy-to-use green-fluorescent indicator of the overall health of cells prior to performing the cell adhesion assay
- Detailed protocols

Cell Adhesion Assays Using the CyQUANT® Cell Proliferation Assay Kits

Our CyQUANT® Cell Proliferation Assay Kits (C7026, C35006, C35007, C35011, C35012; Section 15.4) can also serve as important tools for quantitating both cell–cell and cell–surface adhesion. The CyQUANT® GR, CyQUANT® NF and CyQUANT® Direct assays detect total nucleic acids in cells, with a linear detection range from 100 to at least 20,000 cells per well (Figure 15.6.2). To quantitate cell–surface adhesion, cells are simply permitted to adhere to the surface, gently washed to remove nonadherent cells and then analyzed to determine total nucleic acids in the adherent cells using the CyQUANT® assay protocol. As a control, the fluorescence of the total number of cells added to the well before the wash step can be determined by the same assay method to yield the percentage of adherent cells. It should also be possible to extend the CyQUANT® assay to studies of cell–cell adhesion by quantitating both the number of surface-adhering cells originally plated and the number of total cells after a second cell line has been introduced and allowed to adhere. A similar assay for cell adhesion based on DAPI (D1306, D3571, D21490; Section 8.1) has been reported.³⁷

Microsphere Adhesion Assays

In a novel method for studying adhesion in live neural tissue slices, including hippocampal slices, fluorescent 4 μ m microspheres (F8858, F8859; Section 6.5) are coated with isolated cell membranes from dissociated live cells. The membrane-coated microspheres are then seeded on live tissue slices, and after a short incubation time, the nonadherent microspheres are eliminated by washing (Figure 15.6.3). The pattern of tissue labeling of adherent microspheres can then be visualized by epifluorescence microscopy.³⁸ A flow cytometry–based microsphere adhesion assay has also been developed to determine integrin-specific adhesion, as well as to analyze integrin-mediated adhesion defects in B-lineage acute lymphoblastic leukemia.^{39,40} FluoSpheres® microspheres of different colors (or sizes or intensities) (Section 6.5) can be used for simultaneous labeling of different adhesion factors.

Fluorescent Fibrinogen

Fibrinogen is a key component in the blood clotting process and can support both platelet–platelet and platelet–surface interactions by binding to the glycoprotein IIb–IIIa (GPIIb–IIIa) receptor^{41–44} (also called integrin $\alpha_{IIb}\beta_3$). Although the mechanism is not well understood, activation of GPIIb–IIIa is required for fibrinogen binding, which leads to platelet activation, adhesion, spreading and microfilament reorganization of human endothelial cells *in vitro*.^{41,44–46} Soluble fibrinogen binds to its receptor with a Ca^{2+} -dependent apparent K_d of 0.18 μ M.⁴⁷ This binding is apparently mediated by the tripeptide sequence Arg–Gly–Asp (RGD), found both in fibrinogen and fibronectin, as well as some other proteins.^{44,48–50}

Fluorescently labeled fibrinogen has proven to be a valuable tool for investigating platelet activation and subsequent fibrinogen binding. Fluorescein fibrinogen has been used to identify activated platelets by flow cytometry.^{45,51–53} The binding of fluorescein fibrinogen to activated platelets has been shown to be saturable and can be inhibited completely by underivatized fibrinogen.⁵² The preferential binding and accumulation of fluorescein fibrinogen at

the endothelial border of venular blood vessels has been studied by quantitative fluorescence microscopy.⁵⁴ We offer five fluorescent conjugates of human fibrinogen, which are useful for investigating platelet activation and subsequent fibrinogen binding using fluorescence microscopy or flow cytometry (Figure 15.6.4):

- Alexa Fluor® 488 human fibrinogen (F13191)
- Oregon Green® 488 human fibrinogen (F7496)
- Alexa Fluor® 546 human fibrinogen (F13192)
- Alexa Fluor® 594 human fibrinogen conjugate (F13193)
- Alexa Fluor® 647 human fibrinogen conjugate (F35200)

Fluorescent Gelatin and Collagen

Collagen is a major component of the extracellular matrix and, in vertebrates, constitutes approximately 25% of total cellular protein. This important protein not only serves a structural role, but also is important in cell adhesion and migration. Specific collagen receptors, fibronectin and a number of other proteins involved in cell–cell and cell–surface adhesion have been demonstrated to bind collagen and gelatin^{55,56} (denatured collagen). We offer fluorescent conjugates of gelatin and collagen for use in studying collagen-binding proteins and collagen metabolism, as well as gelatinases and collagenases (Section 10.4), which are metalloproteins that digest gelatin and collagen.

We offer two green-fluorescent gelatin conjugates—fluorescein gelatin (G13187) and Oregon Green® 488 gelatin (G13186). When compared with the fluorescein conjugate, the Oregon Green® 488 conjugate exhibits almost identical fluorescence spectra but its fluorescence is much more photostable and less pH dependent. We also offer collagen-coated FluoSpheres® yellow-green–fluorescent microspheres (F20892, F20893; Section 16.1). By analogy to results obtained with fluorescein conjugates of these proteins, these highly fluorescent gelatin conjugates and collagen-coated microspheres are potentially useful for:

- Following integrin-mediated phagocytosis⁵⁷
- Localizing surface fibronectin on cultured cells⁵⁸
- Studying fibronectin–gelatin interactions in solution using fluorescence polarization^{56,59}
- Visualizing gelatinase activity using *in situ* gel zymography⁶⁰

Figure 15.6.4 Interaction of fluorescently labeled fibrinogen with activated platelets. Whole blood was first incubated with an R-phycoerythrin (R-PE)-labeled anti-CD41 antibody to label the platelets. 20 μ M adenosine 5'-diphosphate (ADP) was added in order to activate the platelets, then 2 μ g/mL Alexa Fluor® 488 fibrinogen (F13191) was added and incubated with the sample for 5 minutes. Cells were analyzed by flow cytometry using excitation at 488 nm. Both activated and unactivated platelets show binding of the anti-CD41 antibody; however, only the activated platelets show strong binding by fibrinogen. A total of 5000 platelets are shown in each experiment.

Chemotaxis Assays

Direct Detection of Chemotaxis Using Cell Counting

Chemotaxis, defined as directed cell motion toward an extracellular gradient, plays an important role during fertilization, inflammation, wound healing and hematopoiesis.⁶¹ Chemotaxis is typically assayed by determining the number of viable cells that have migrated through a special “chemotaxis chamber.” A 96-well disposable chemotaxis chamber is reported to be suitable for fluorescence-based assays that are faster, less labor intensive and more sensitive than visually detected migration assays.⁶² The probes used to follow chemotaxis in live cells are often the same esterase substrates that are used for assaying cell viability and cell adhesion (Table 15.1), including calcein AM^{63–67} (C1430, C3099, C3100MP), BCECF AM^{7,24} (B1150, B1170, B3051) and CellTracker™ Green CMFDA⁶⁸ (C2925, C7025). Calcein AM does not interfere with lymphocyte proliferation or with granulocyte or neutrophil chemotaxis or superoxide production,^{7,64} and, unlike BCECF AM, calcein AM does not affect chemotaxis in leukocytes.⁶⁵

Because chemotaxis involves translocation of whole cells, assays that simply count cell numbers—such as our CyQUANT® Cell Proliferation Assay Kit (C7026, Section 15.4)—are also quite reliable for following chemotaxis.⁶⁹ In addition, the green-fluorescent SYTO® 13 dye (S7575, Section 8.1) has been used to track the co-migration of separately stained populations of neutrophils using opposing gradients of leukotriene B₄ and interleukin 8 as the chemoattractants.⁷⁰

Figure 15.6.5 Principle of the Vybrant® Multidrug Resistance Assay Kit (V13180). In normal cells, nonfluorescent calcein AM readily diffuses across the cell membrane. Fluorescent calcein accumulates in the cytoplasm after cleavage of calcein AM by endogenous esterases. In MDR cells, overexpression of MDR transporter proteins increases expulsion of calcein AM from the cell membrane before enzymatic hydrolysis of its AM esters, thus reducing accumulation of intracellular calcein.

Probes for Chemotaxis Receptors

We prepare the fluorescein conjugate of the chemotactic hexapeptide *N*-formyl-Nle-Leu-Phe-Nle-Tyr-Lys (F1314), which binds to the fMLF receptor^{71,72} (Section 16.1). We also offer fluorescein-labeled casein (C2990), which has been used to demonstrate casein-specific chemotaxis receptors in human neutrophils and monocytes with flow cytometry.^{73,74} Neutrophils activated with phorbol myristate acetate have been shown to undergo a dose-dependent increase in binding of fluorescein-labeled casein.⁷⁵

Multidrug Resistance Assays

Multidrug resistance (MDR) is a phenomenon representing a complex group of biological processes that are of growing interest in both clinical and experimental oncology.^{76–78} The MDR phenotype is characterized by the acquired resistance of tumor cells to structurally and functionally dissimilar anticancer drugs. Among the many mechanisms contributing to this multidrug resistance are the following:

- Amplification of genes encoding drug-metabolizing enzymes
- Elevated levels of glutathione and glutathione-conjugating enzymes
- Mutated DNA topoisomerases
- Overexpression of plasma membrane ATP-dependent drug efflux pumps

Based on substrate and inhibitor profiles, at least four different plasma membrane ATP-dependent drug efflux pumps have been identified.^{79,80} The activity of the verapamil-sensitive P-glycoprotein (Pgp) encoded by the *MDR1* gene leads to extrusion of anthracyclins, epipodophyllotoxins, *Vinca* alkaloids, coelenterazine and other cytostatic drugs.^{81,82} BODIPY® FL paclitaxel (P7500; Section 11.2) is a substrate for Pgp-mediated transport that has been used as a probe for tumor spheroids.⁸³

Many tumor cells do not express Pgp but export daunorubicin via a second, energy-dependent drug export mechanism.⁸⁴ A third, energy-dependent drug exporting mechanism is associated with a MDR-associated protein⁸⁵ (MRP), which shows high selectivity toward glutathione *S*-conjugates and is inhibited by *Vinca* alkaloids and probenecid.^{86,87} A fourth vanadate- and verapamil-resistant but probenecid-sensitive glutathione *S*-conjugate-exporting system in mouse and rat fibroblasts has also been reported.⁸⁸ The probes commonly used to follow the transport of glutathione adducts are the same probes used to measure intracellular levels of glutathione (see below): monochlorobimane^{89–92} (M1381MP) and CellTracker™ Green CMFDA^{91,93,94} (C2925, C7025).

Obviously, the mechanisms of MDR are complex and, in some cases, have overlapping selectivity for the substrates.⁸⁰ We offer the Vybrant® Multidrug Resistance Assay Kit, along with a variety of useful fluorescent probes for monitoring various aspects of the MDR phenotype.

MDR Assays Using Acetoxymethyl Esters

The discovery that fluorescent calcium indicators such as indo-1 AM and fluo-3 AM (I1203, F1241, F23915; Section 19.3) and other dyes such as calcein AM (C1430, C3099, C3100MP), are rapidly extruded from cells expressing Pgp⁹⁵ presented a new class of highly sensitive probes for functional assays of the *MDR1*-encoded Pgp. Calcein AM—but not calcein—is an activator of Pgp in isolated membranes with a $K_d \leq 1 \mu\text{M}$.⁹⁶ Cells expressing the *MDR1*-encoded Pgp rapidly remove the nonfluorescent probe calcein AM, resulting in decreased accumulation of the highly fluorescent calcein in the cytoplasmic compartment.^{87,96–98} Calcein AM is also a substrate for the MDR-associated protein (MRP), although in this case the hydrophilic free calcein anion is also exported.^{99–101} Because calcein itself is not a substrate for the *MDR1*-encoded Pgp, MDR can be quantitatively assessed by measuring the net accumulation of intracellular fluorescence.¹⁰² Cellular depletion of glutathione does not affect the extrusion of calcein AM by the *MDR1*-encoded Pgp.⁹⁹ Fluorescence of intracellular calcein can be distinguished from that of calcein that has leaked into the medium by adding Co^{2+} to totally quench the fluorescence of the extracellular dye.¹⁰¹ The patented calcein AM assay for Pgp-related MDR is suitable for either flow cytometry¹⁰³ or fluorometry and is more rapid and significantly more sensitive than conventional assays based on doxorubicin accumulation.¹⁰⁴ Reduced accumulation of calcein in MDR cells can also be observed in single cells by fluorescence microscopy.^{97,100}

Vybrant® Multidrug Resistance Assay Kit

The Vybrant® Multidrug Resistance Assay Kit (V13180), which is based on the fluorescence microplate-based method developed by Tiberghien and Loor,⁹⁸ provides a rapid and simple method for large-scale screening of MDR inhibitors. This assay utilizes the fluorogenic dye calcein AM as a substrate for efflux activity of Pgp. Upon hydrolysis by intracellular esterases, calcein is well retained in the cytosol and, unlike the hydrolysis product of other fluorescent Pgp substrates such as BCECF AM or fura-2 AM, its fluorescence is neither pH nor calcium dependent. MDR cells expressing high levels of Pgp rapidly extrude nonfluorescent calcein AM from the plasma membrane, reducing accumulation of fluorescent calcein in the cytosol^{87,96,102} (Figure 15.6.5). The amount of Pgp activity is inversely proportional to the accumulation of intracellular calcein fluorescence. This assay is designed for use with fluorescence microplate readers and is particularly useful for rapid and sensitive screening of candidate Pgp inhibitors in MDR cell lines. The absorption/emission maxima of calcein (494/517 nm) are ideally suited for detection by instruments equipped with standard fluorescein filters. The Vybrant® Multidrug Resistance Assay Kit (V13180) contains sufficient reagents to perform approximately 10,000 assays using a fluorescence microplate reader, including:

- Calcein AM
- Cyclosporin A, a competitive inhibitor of drug binding to Pgp
- Verapamil, a calcium channel blocker that noncompetitively inhibits Pgp activity
- Detailed protocols

MDR Assays Using Mitochondrial Probes

In the classical functional assay for MDR, doxorubicin efflux is measured.^{105–107} The principal weakness of this assay is its low sensitivity, which has stimulated the search for other fluorochromes to monitor drug efflux. MDR cells overexpressing the Pgp have been identified using various mitochondrial probes (Section 12.2), including rhodamine 123 (R302, R22420), acridine orange 10-nonyl bromide (nonyl acridine orange, A1372) and rhodamine 6G^{79,108–115} (R634). Furthermore, it has been reported that the fluorescence excitation spectrum of rhodamine 123 is different in drug-resistant and drug-sensitive cells.^{116,117}

The potential-sensitive carbocyanine dyes, including dipentyl-, dihexyl- and diheptyloxa-carbocyanines (D272, D273, D378; Section 22.3), also have advantages over the common doxorubicin assay for MDR.^{105,118} Not only are these carbocyanine dyes more fluorescent, permitting use of lower dye concentrations, but their fluorescence increases upon binding to cell membranes,¹¹⁹ unlike the fluorescence of doxorubicin, which is substantially quenched inside cells.¹²⁰ The ratiometric, potential-sensitive di-4-ANEPPS probe (D1199, Section 22.2) has been used to demonstrate that MDR cells have decreased electrical potentials.¹²¹

MDR Assays Using Nucleic Acid Stains

MDR cells have also been identified by their decreased accumulation of nucleic acid-binding dyes such as Hoechst 33258 (H1398, H3569, H21491; Section 8.1), Hoechst 33342 (H1399, H3570, H21492; Section 8.1) and ethidium bromide^{115,122–124} (E1305, 15585-011; Section 8.1). SYTO® 16 green-fluorescent nucleic acid stain (S7578; Section 8.1) was shown to be a useful substrate for detecting Pgp-mediated resistance by flow cytometry and in single cells by confocal laser-scanning microscopy.¹²⁵ Our four SYTO® Fluorescent Nucleic Acid Stain Sampler Kits (S7572, S11340, S11350, S11360; Section 8.1) provide samples of SYTO® dyes with fluorescence covering the entire visible spectrum; these dyes may be screened for their utility in detecting MDR cells.

BODIPY® FL Verapamil and Dihydropyridine

The Ca²⁺-channel blocker verapamil is one of several molecules known to inhibit Pgp-mediated drug efflux.¹²⁶ We offer the green-fluorescent BODIPY® FL verapamil probe (B7431, Figure 15.6.6) for the study of Pgp function and localization. Verapamil appears to inhibit drug efflux by acting as a substrate for Pgp, thereby overwhelming the transporter's capacity to expel other drugs. Our BODIPY® FL conjugate of verapamil, with spectral properties similar to fluorescein, also serves as a substrate for Pgp. This fluorescent verapamil derivative preferentially accumulates in the lysosomes of normal, drug-sensitive NIH 3T3 cells but is rapidly transported out of MDR cells, as revealed by fluorescence microscopy.^{127–131} The outward transport of BODIPY® FL verapamil from MDR cells is inhibited by underivatized verapamil, as well as by excess vinblastine.¹²⁹

Figure 15.6.6 BODIPY® FL verapamil, hydrochloride (B7431).

Figure 15.6.7 BODIPY® FL prazosin (B7433).

Figure 15.6.9 Analysis of dihydrofolate reductase (DHFR) content in CHO cells. A mixture of DHFR+ and DHFR- cells was stained with 1 μ M fluorescein methotrexate (M1198MP) for 2 hours at 37°C. Following incubation with fluorescein methotrexate, cells were trypsinized, washed in phosphate-buffered saline and analyzed by flow cytometry using 488 nm excitation. Emission was collected at 525 nm.

Like verapamil, dihydropyridines are known to inhibit drug efflux. Consequently, our fluorescent dihydropyridines^{132,133} labeled with either the green-fluorescent DM-BODIPY® (D7443, Section 16.3) or the orange-fluorescent ST-BODIPY® (S7445, Section 16.3) fluorophores may be useful MDR probes.

BODIPY® FL Vinblastine

The antimetabolic agent vinblastine inhibits the Pgp-mediated efflux of a number of drugs and other probes from multidrug-resistant cells. Our BODIPY® FL conjugate of vinblastine (V12390) is useful as a highly fluorescent vinblastine analog.¹³⁴ A biologically active coumarin dye-labeled vinblastine has previously been described.¹³⁵

BODIPY® FL Prazosin and BODIPY® FL Forskolin

Photoaffinity analogs of prazosin, an α_1 -adrenergic receptor antagonist,^{136,137} and forskolin, an adenylate cyclase activator, have been shown to selectively photolabel isolated Pgp.^{138–141} Our green-fluorescent BODIPY® FL prazosin (B7433, Figure 15.6.7) and BODIPY® FL forskolin (B7469, Figure 15.6.8) are useful tools for probing MDR mechanisms.⁸²

Methotrexate Resistance and Gene Amplification

Tumor cells often undergo gene amplification that leads to overexpression of dihydrofolate reductase (DHFR). This increased DHFR expression (Figure 15.6.9) confers enhanced tolerance to the cytotoxic effects of methotrexate.^{76,115} For the study of antimetabolite resistance and spontaneous gene amplification, we offer fluorescent methotrexate conjugates. In addition to green-fluorescent fluorescein methotrexate (M1198MP), which has been used to visualize biochemical networks in living cells,¹⁴² we provide Alexa Fluor® 488 methotrexate (M23271), which exhibits fluorescein-like spectral characteristics. The quantitative binding of fluorescein methotrexate (M1198MP) to dihydrofolate reductase (DHFR) enables researchers to isolate cells based on DHFR expression.^{143–146} Our fluorescein cadaverine adduct, which was originally described by Gapski and colleagues,¹⁴⁷ appears to be equivalent to fluorescein lysine methotrexate in its applications.¹⁴³

Glutathione Determination

The tripeptide glutathione (γ -L-glutamyl-L-cysteinylglycine) is the most abundant nonprotein thiol in mammalian cells. Glutathione plays a central role in protecting cells of all organs, including the brain,¹⁴⁹ against damage produced by free radicals, oxidants and electrophiles. A distinct mechanism of MDR involves the overexpression of energy-dependent membrane pumps dedicated to removal of glutathione S-conjugates from the cytoplasm by a multidrug resistance-associated protein^{85,150} (MRP). An increased rate of efflux of glutathione from Jurkat T lymphocytes during anti-FAS/APO-1 antibody-induced apoptosis has been reported.¹⁵¹

Several fluorescent reagents have been proposed for determining cellular levels of glutathione and glutathione S-transferase (GST), which catalyzes the formation of glutathione S-conjugates, but no probe is without drawbacks in quantitative studies of live cells. The high but variable levels of intracellular glutathione and the multitude of GST isozymes make kinetic measurements under saturating substrate conditions difficult or impossible.^{152,153} Isozymes of GST vary both in abundance and activity, further complicating the analysis.¹⁵⁴ Moreover, the fluorescent reagents designed to measure glutathione may react with intracellular thiols other than glutathione, including proteins in glutathione-depleted cells.¹⁵⁵ Therefore, precautions must be

Figure 15.6.8 BODIPY® FL forskolin (B7469).

taken in applying the reagents mentioned here to quantitate either glutathione or GST in cells. A useful strategy is to test a variety of glutathione-sensitive dyes—those requiring glutathione S-transferase activity, as well as GST-independent fluorophores—under controlled experimental conditions in which glutathione is depleted.¹⁵⁶

ThiolTracker™ Violet Glutathione Detection Reagent

The ThiolTracker™ Violet reagent (T10095, T10096) reacts with reduced thiols in intact cells and is up to 10-fold brighter than the bimanes traditionally used for glutathione (GSH) detection. Staining is achieved by applying ThiolTracker™ Violet dye to live cells in thiol-free buffer and then directly imaging labeled cells using excitation with either a 405 nm violet diode laser or conventional xenon or mercury arc lamps (excitation/emission maxima ~404/526 nm, Figure 15.6.10). Alternatively, because this cell-permeant stain survives formaldehyde fixation and detergent extraction, labeled cells can be subjected to immunochemical analysis prior to imaging.

Glutathione Determination with Monochlorobimane

Cell-permeant monochlorobimane (mBCL, M1381MP), which is essentially nonfluorescent until conjugated to thiols, has long been the preferred thiol-reactive probe for quantitating glutathione levels in cells and for measuring GST activity.^{157,158} Because the blue-fluorescent glutathione adduct of monochlorobimane eventually accumulates in the nucleus, it is not a reliable indicator of the nuclear and cytoplasmic distribution of cellular glutathione.¹⁵⁹ Tissue glutathione levels can also be measured fluorometrically by adding both monochlorobimane and glutathione S-transferase to tissue homogenates.¹⁶⁰

Monochlorobimane is reported to react more selectively with glutathione in whole cells than does monobromobimane (M1378, M20381; Section 2.3; Figure 15.6.11) and has proven useful for assaying drug resistance by flow cytometry^{153,158,161} and by fluorescence microscopy.^{162,163} Moreover, HPLC analysis has shown that glutathione is the only low molecular weight thiol in hepatocytes that reacts with monochlorobimane.¹⁶⁴ Results from glutathione determination with monochlorobimane have been shown to match those from an independent glutathione-specific assay using glutathione reductase.^{165,166} However, although monochlorobimane was shown to be highly selective for glutathione in rodent cells, it was reported to inadequately label glutathione in human cells because of its low affinity for human glutathione S-transferases.¹⁵³ The reducing agent tris-(2-carboxyethyl)phosphine (TCEP, T2556; Section 2.1) has been used in place of dithiothreitol (DTT, D1532; Section 2.1) in a simplified monobromobimane-based assay for glutathione¹⁶⁷ and thus may also prove useful for monochlorobimane-based assays. In this monobromobimane-based glutathione assay, an extraction step is reportedly necessary to remove a fluorescent, reductive-dehalogenation side product of TCEP and monobromobimane.¹⁶⁸ Probenecid (P36400; Section 19.8) inhibits the ATP-dependent organic anion pump and blocks the loss of the fluorescent bimane–glutathione adduct from rat fibroblasts.¹⁶⁹ Monochlorobimane has also been employed to sort cells based on their expression of recombinant GST.¹⁷⁰

Glutathione Determination with Visible Light–Excitable Thiol-Reactive Probes

CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate, C2925, C7025) is a useful alternative to the UV light–excitable monochlorobimane for determining levels of intracellular glutathione.^{171,172} CellTracker™ Green CMFDA can be excited by the argon-ion laser, and is compatible with flow cytometry and confocal laser-scanning microscopy applications. CellTracker™ Green CMFDA's enzymatic product has a much higher absorbance and fluorescence quantum yield than that of monochlorobimane. In conjunction with Hoechst 33342 (H1399, H3570, H21492; Section 8.1), CellTracker™ Green CMFDA has also been shown to be effective for analyzing intracellular thiol levels as a function of cell cycle using flow cytometry,^{171,173} for following transport of the glutathione adduct to secretory vesicles in multidrug-resistant cells⁹¹ and for detecting apoptotic cells, which have reduced levels of intracellular reduced glutathione.¹⁷⁴ Selectivity of CellTracker™ Green CMFDA for glutathione (versus thiolated proteins) was shown by the isolation of >95% of the intracellular fluorescent products as a mixture of the glutathione adduct and the unconjugated hydrolysis product, chloromethylfluorescein.¹⁵³ However, in these experiments, the high fluorescence of unconjugated chloromethylfluorescein resulted in significantly increased background levels. Because glutathione-depleting chemicals may also cause cell death, it has been recommended that

Figure 15.6.10 Fluorescence excitation and emission spectra of ThiolTracker™ Violet dye conjugated to glutathione (GSH) in pH 7.2 buffer.

Figure 15.6.11 Monobromobimane (mBBr, M1378).

calcein AM be used to independently assess cell viability in assays that use CellTracker™ Green CMFDA to measure changes in the level of intracellular glutathione.¹⁷²

Like CMFDA, chloromethyl SNARF®-1 acetate (C6826, Figure 15.6.12) forms adducts with intracellular thiols that are well retained by viable cells. The glutathione adduct of chloromethyl SNARF®-1 can be excited by the 488 nm spectral line of the argon-ion laser yet emits beyond 630 nm, which may prove advantageous in multicolor applications or when assaying autofluorescent samples. A number of our other CellTracker™ (Section 14.2) and MitoTracker® (Section 12.2) probes have thiol-reactive chloromethyl moieties and may be similarly useful for glutathione determination. All of these probes form glutathione S-conjugates that are likely to be transported from the cytoplasm by an MDR-associated protein^{85,150} (MRP).

Glutathione Detection with BioGEE

Biotinylated glutathione ethyl ester (BioGEE, G36000; Figure 15.6.13) is a cell-permeant, biotinylated glutathione analog for detecting glutathiolation. Under conditions of oxidative stress, cells may transiently incorporate glutathione into proteins. Stressed cells incubated with BioGEE will also incorporate this biotinylated glutathione derivative into proteins, facilitating the identification of oxidation-sensitive proteins.¹⁷⁵ Once these cells are fixed and permeabilized,

Figure 15.6.12 5-(and-6)-Chloromethyl SNARF®-1, acetate (C6826).

glutathiolation levels can be detected with a fluorescent streptavidin conjugate (Section 7.6, Table 7.9) using either flow cytometry or fluorescence microscopy. Proteins glutathiolated with BioGEE can also be extracted and analyzed by mass spectrometry or by western blotting methods in conjunction with fluorophore- or enzyme-labeled streptavidin conjugates.

Glutathione Determination With *o*-Phthaldialdehyde and Naphthalene-2,3-Dicarboxaldehyde

The reagent *o*-phthaldialdehyde (OPA, P2331MP) reacts with both the thiol and the amine functions of glutathione, yielding a cyclic derivative that is fluorescent. The spectra of the glutathione adduct of OPA (excitation/emission maxima of 350/420 nm) are shifted from those of its protein adducts.¹⁷⁶ This effect has occasionally been used to estimate glutathione levels in cells.^{153,177} OPA has also been used as a derivatization reagent for the chromatographic determination of glutathione in cells, blood and tissues.^{178,179}

The membrane-permeant naphthalene-2,3-dicarboxaldehyde (NDA, N1138) has been used to determine glutathione levels in single cells. Cells were treated with the NDA reagent and then analyzed by capillary electrophoresis;¹⁸⁰ glutathione labeling was reported to be complete within two minutes. The glutathione adduct of NDA can be excited by the 458 nm spectral line of the argon-ion laser.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- MW value is approximate. BCECF AM is a mixture of molecular species.
- BCECF AM is colorless and nonfluorescent until converted to BCECF (B1151) by acetoxyethyl ester hydrolysis.
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- Calcein AM is converted to fluorescent calcein (C481) after acetoxyethyl ester hydrolysis.
- Acetate hydrolysis of this compound yields a fluorescent product with similar pH-dependent spectral characteristics to C1904.
- C6826 is converted to a fluorescent product with spectra similar to C1270 after acetate hydrolysis.
- Bimanes are almost nonfluorescent until reacted with thiols. For monobromobimane conjugated to glutathione, Abs = 394 nm, Em = 490 nm (QY ~0.1–0.3) in pH 8 buffer. (Methods Enzymol (1987) 143:76, Methods Enzymol (1995) 251:133)
- Spectral data are for the reaction product with glycine in the presence of cyanide, measured in pH 7.0 buffer/MeCN (40:60). (Anal Chem (1987) 59:1102) Unreacted reagent in MeOH: Abs = 279 nm (EC = 5500 cm⁻¹M⁻¹), Em = 330 nm.
- Spectral data are for the reaction product of P2331MP with alanine and 2-mercaptoethanol. The spectra and stability of the adduct depend on the amine and thiol reactants. (Biochim Biophys Acta (1979) 576:440) Unreacted reagent in H₂O: Abs = 257 nm (EC = 1000 cm⁻¹M⁻¹).

PRODUCT LIST 15.6 PROBES FOR CELL ADHESION, CHEMOTAXIS, MULTIDRUG RESISTANCE AND GLUTATHIONE

Cat. No.	Product	Quantity
B1150	2,7'-bis-(2-carboxyethyl) -5-(and-6)-carboxyfluorescein, acetoxymethyl ester (BCECF, AM)	1 mg
B3051	2,7'-bis-(2-carboxyethyl) -5-(and-6)-carboxyfluorescein, acetoxymethyl ester (BCECF, AM) *1 mg/mL solution in anhydrous DMSO*	1 mL
B1170	2,7'-bis-(2-carboxyethyl) -5-(and-6)-carboxyfluorescein, acetoxymethyl ester (BCECF, AM) *special packaging*	20 x 50 µg
B7469	BODIPY® FL forskolin	100 µg
B7433	BODIPY® FL prazosin	100 µg
B7431	BODIPY® FL verapamil, hydrochloride	1 mg
C1430	calcein, AM	1 mg
C3099	calcein, AM *1 mg/mL solution in anhydrous DMSO*	1 mL
C3100MP	calcein, AM *special packaging*	20 x 50 µg
C2990	casein, fluorescein conjugate	25 mg
C2925	CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate)	1 mg
C7025	CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate) *special packaging*	20 x 50 µg
C6826	5-(and-6)-chloromethyl SNARF®-1, acetate *mixed isomers* *special packaging*	20 x 50 µg
C7026	CyQUANT® Cell Proliferation Assay Kit *for cells in culture* *1000 assays*	1 kit
C35011	CyQUANT® Direct Cell Proliferation Assay *for 10 microplates*	1 kit
C35012	CyQUANT® Direct Cell Proliferation Assay *for 100 microplates*	1 kit
C35007	CyQUANT® NF Cell Proliferation Assay Kit *200 assays*	1 kit
C35006	CyQUANT® NF Cell Proliferation Assay Kit *1000 assays*	1 kit
F13191	fibrinogen from human plasma, Alexa Fluor® 488 conjugate	5 mg
F13192	fibrinogen from human plasma, Alexa Fluor® 546 conjugate	5 mg
F13193	fibrinogen from human plasma, Alexa Fluor® 594 conjugate	5 mg
F35200	fibrinogen from human plasma, Alexa Fluor® 647 conjugate	5 mg
F7496	fibrinogen from human plasma, Oregon Green® 488 conjugate	5 mg
F1314	formyl-Nle-Leu-Phe-Nle-Tyr-Lys, fluorescein derivative	1 mg
G13187	gelatin from pig skin, fluorescein conjugate	5 mg
G13186	gelatin from pig skin, Oregon Green® 488 conjugate	5 mg
G36000	glutathione ethyl ester, biotin amide (BioGEE) *glutathiolation detection reagent* *special packaging*	10 x 100 µg
M23271	methotrexate, Alexa Fluor® 488, inner salt (Alexa Fluor® 488 methotrexate) *mixed isomers*	500 µg
M1198MP	methotrexate, fluorescein, triammonium salt (fluorescein methotrexate)	1 mg
M1381MP	monochlorobimane (mBCl)	25 mg
N1138	naphthalene-2,3-dicarboxaldehyde (NDA)	100 mg
P2331MP	o-phthalaldehyde (OPA) *high purity*	1 g
T10095	ThiolTracker™ Violet (Glutathione Detection Reagent) *180 assays* *set of 3 vials*	1 set
T10096	ThiolTracker™ Violet (Glutathione Detection Reagent) *for 5 microplates*	each
V12390	vinblastine, BODIPY® FL conjugate (BODIPY® FL vinblastine)	100 µg
V13181	Vybrant® Cell Adhesion Assay Kit	1 kit
V13180	Vybrant® Multidrug Resistance Assay Kit	1 kit

CHAPTER 16

Probes for Endocytosis, Receptors
and Ion Channels

16.1 Probes for Following Receptor Binding and Phagocytosis	741
Ligands for Studying Receptor-Mediated Endocytosis	741
Fc OxyBURST® Green Assay Reagent: Fluorogenic Immune Complex	741
OxyBURST® Green H ₂ HFF BSA Reagent	742
Amine-Reactive OxyBURST® Green Reagent	742
Fluorescent Low-Density Lipoprotein Complexes	742
Fluorescent Acetylated LDL Complexes	743
Fluorescent Lipopolysaccharides	744
Epidermal Growth Factor Derivatives	744
Transferrin Conjugates	745
Fluorescent Fibrinogen	746
DQ™ Ovalbumin: A Probe for Antigen Processing and Presentation	747
Fluorescent Gelatin	747
Fluorescent Casein	747
Fluorescent Chemotactic Peptide	747
Fluorescent Insulin	748
Fluorescent Dexamethasone Probe for Glucocorticoid Receptors	748
Fluorescent Histone H1	748
Fluorescent Probes for the Acrosome Reaction	748
Methods for Detecting Internalized Fluorescent Ligands	748
Membrane Markers of Endocytosis and Exocytosis	749
FM® 1-43	749
Other Analogs of FM® 1-43	750
FM® 1-43FX and FM® 4-64FX: Fixable FM® Dyes	750
4-Di-1-ASP and 4-Di-2-ASP	750
TMA-DPH	750
Fluorescent Cholera Toxin Subunit B: Markers of Lipid Rafts	750
Fluorescent Protein-Based Lipid Raft Markers	751
Fluorescent Protein-Based Synaptic Vesicle Markers	751
Anti-Synapsin I Antibody	752
High Molecular Weight Polar Markers	752
Fluorescent Protein-Based Endosomal Markers	752
BioParticles® Fluorescent Bacteria and Yeast	753
Vybrant® Phagocytosis Assay Kit	753
pHrodo™ BioParticles® Fluorescent Bacteria	753
pHrodo™ Phagocytosis Particle Labeling Kit	754
Opsonizing Reagents and Nonfluorescent BioParticles® Products	754
Fluorescent Polystyrene Microspheres	754
Fluorescent Microspheres Coated with Collagen	754
Fluorescent Dextrans	755
pH Indicator Dextrans	755

Low Molecular Weight Polar Markers	755
Data Table 16.1 Probes for Following Receptor Binding and Phagocytosis	757
Product List 16.1 Probes for Following Receptor Binding and Phagocytosis	758
16.2 Probes for Neurotransmitter Receptors	760
α-Bungarotoxin Probes for Nicotinic Acetylcholine Receptors	760
Fluorescent α-Bungarotoxins	760
Biotinylated α-Bungarotoxin	760
Unlabeled α-Bungarotoxin	761
Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit	761
BODIPY® FL Prazosin for α ₁ -Adrenergic Receptors	762
BODIPY® TMR-X Muscimol for GABA _A Receptors	762
Fluorescent Angiotensin II for AT1 and AT2 Receptors	762
Naloxone Fluorescein for μ-Opioid Receptors	763
Probes for Amino Acid Neurotransmitter Receptors	763
Caged Amino Acid Neurotransmitters	763
Anti-NMDA Receptor Antibodies	763
Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit	763
Probes for Other Receptors	764
Data Table 16.2 Probes for Neurotransmitter Receptors	765
Product List 16.2 Probes for Neurotransmitter Receptors	765
16.3 Probes for Ion Channels and Carriers	766
Probes for Ca ²⁺ Channels and Carriers	766
Fluorescent Dihydropyridine for L-Type Ca ²⁺ Channels	766
BODIPY® FL Verapamil	766
Eosin Derivatives: Inhibitors of the Calcium Pump	767
Premo™ Cameleon Calcium Sensor	767
Probes for Na ⁺ Channels and Carriers	768
Amiloride Analogs: Probes for the Na ⁺ Channel and the Na ⁺ /H ⁺ Antiporter	768
Ouabain Probes for Na ⁺ /K ⁺ -ATPase	768
Using BacMam Technology to Deliver and Express Sodium Channel cDNA	768
Probes for K ⁺ Channels and Carriers	768
Glibenclamide Probes for the ATP-Dependent K ⁺ Channel	768
FluxOR™ Potassium Ion Channel Assay	769
Using BacMam Technology to Deliver and Express Potassium Channel cDNA	770
Probes for Anion Transporters	770
Stilbene Disulfonates: Anion-Transport Inhibitors	770
DiBAC ₄ (5)	771
Eosin Maleimide	771
Premo™ Halide Sensor	771
Data Table 16.3 Probes for Ion Channels and Carriers	772
Product List 16.3 Probes for Ion Channels and Carriers	772

16.1 Probes for Following Receptor Binding and Phagocytosis

The plasma membrane defines the inside and outside of the cell. It not only encloses the cytosol to maintain the intracellular environment but also serves as a formidable barrier to the extracellular environment. Because cells require input from their surroundings—in the form of hydrated ions, small polar molecules, large biomolecules and even other cells—they have developed strategies for overcoming this barrier. Some of these mechanisms involve initial formation of receptor–ligand complexes, followed by transport of the ligand across the cell membrane.^{1–5}

This section focuses on probes for following receptor binding, endocytosis and exocytosis. Section 16.2 describes tools for studying neurotransmitter receptors, which mediate external chemical messenger control over the electrical activity of neurons. Section 16.3 discusses strategies for monitoring ion channels and carriers, which are the molecular centerpiece of neural transmission and bioenergetics.

Ligands for Studying Receptor-Mediated Endocytosis

We offer a variety of fluorescent and fluorogenic ligands that bind to membrane receptors and are subsequently internalized. In some cases, the bound ligand is released intracellularly and the receptor is then recycled to the plasma membrane. Receptor binding may also result in signal transduction (Chapter 17), Ca^{2+} mobilization (Chapter 19), intracellular pH changes (Chapter 20) and formation of reactive oxygen species (ROS, Chapter 18).

Fc OxyBURST® Green Assay Reagent: Fluorogenic Immune Complex

When soluble or surface-bound IgG immune complexes interact with Fc receptors on phagocytic cells, a number of host defense mechanisms are activated, including phagocytosis and activation of an NADPH oxidase–mediated oxidative burst.⁶ Dichlorodihydrofluorescein diacetate (H_2DCFDA , D399; Section 18.2; Figure 16.1.1), a cell-permeant fluorogenic probe that localizes in the cytosol, has frequently been used to monitor this oxidative burst.⁷ Its fluorescence response, however, is limited by the diffusion rate of the reactive oxygen species into the cytosol from the phagosome where it is generated. In contrast, Fc OxyBURST® assay reagents permit direct measurement of the kinetics of Fc receptor–mediated internalization and the subsequent oxidative burst in the phagosome, yielding signals that are many times brighter than those generated by H_2DCFDA (Figure 16.1.2, Figure 16.1.3).

Fc OxyBURST® Green assay reagent (F2902) was developed in collaboration with Elizabeth Simons of Boston University to monitor the oxidative burst in phagocytic cells using fluorescence instrumentation. Fc OxyBURST® Green assay reagent comprises bovine serum albumin (BSA) that has been covalently linked to dichlorodihydrofluorescein (H_2DCF) and then complexed with a purified rabbit polyclonal anti-BSA antibody (A11133). When these immune complexes bind to Fc receptors, the nonfluorescent H_2DCF molecules are internalized within the phagosome and subsequently oxidized to green-fluorescent 2',7'-dichlorofluorescein (DCF; Figure 16.1.2, Figure 16.1.3). Unlike H_2DCFDA , Fc OxyBURST® Green assay reagent does not require intracellular esterases for activation, making this reagent particularly suitable for detecting the oxidative burst in cells with low esterase activity such as monocytes.⁸ Fc OxyBURST® Green assay reagent reportedly produces >8 times more fluorescence than does H_2DCFDA at 60 seconds and >20 times more at 15 minutes following internalization of the immune complex.⁹

Published reports have described the use of Fc OxyBURST® Green assay reagent to study the oxidative burst in phagosomes.^{10–12} Neutrophils from patients with chronic granulomatous disease, a genetic deficiency known to disable NADPH oxidase–mediated oxidative bursts, were

Figure 16.1.1 2',7'-dichlorodihydrofluorescein diacetate (2',7'-dichlorofluorescein diacetate; H_2DCFDA , D399).

Figure 16.1.2 Fc OxyBURST® Green assay reagent (F2902) for fluorescent detection of the Fc receptor–mediated phagocytosis pathway. Dichlorodihydrofluorescein (H_2DCF) is covalently attached to bovine serum albumin (BSA), then complexed with a rabbit polyclonal anti-BSA antibody (A11133). Upon binding to an Fc receptor, the nonfluorescent immune complex is internalized and subsequently oxidized to the fluorescent DCF.

Figure 16.1.3 Fluorescence emission of human neutrophils challenged either with Fc OxyBURST® Green assay reagent (H_2DCF -BSA immune complexes, F2902) or with unlabeled immune complexes in the presence of dichlorodihydrofluorescein diacetate (H_2DCFDA ; D399). Fc OxyBURST® Green assay reagent generates significantly more fluorescence than does the more commonly used H_2DCFDA . Flow cytometry data provided by Elizabeth Simons, Boston University.

Figure 16.14 Oxidative bursts of human neutrophils from a healthy donor (control) compared with those from a patient with chronic granulomatous disease (CGD), as detected using the Fc OxyBURST[®] Green assay reagent (F2902). Flow cytometry data provided by Elizabeth Simons, Boston University.

Figure 16.15 Immune complex of DQ[™] BSA conjugate (D12050, D12051) with an anti-bovine serum albumin (BSA) antibody (A11133) for the fluorescent detection of the Fc receptor-mediated phagocytosis pathway. The DQ[™] BSA is a derivative of BSA that is labeled to such a high degree with either the green-fluorescent BODIPY[®] FL or red-fluorescent BODIPY[®] TR-X dye that the fluorescence is self-quenched. Upon binding to an Fc receptor, the nonfluorescent immune complex is internalized and the protein is subsequently hydrolyzed to fluorescent peptides within the phagosome.

Figure 16.16 2,7-dichlorodihydrofluorescein diacetate, succinimidyl ester (OxyBURST[™] Green H₂DCFDA, SE, D2935).

observed to bind but not oxidize Fc OxyBURST[®] Green assay reagent⁹ (Figure 16.1.4). Using microfluorometry to detect the Fc OxyBURST[®] Green signal, researchers were able to simultaneously monitor oxidative activity and membrane currents in voltage-clamped human mononuclear cells.¹³

OxyBURST[®] Green H₂HFF BSA Reagent

OxyBURST[®] Green H₂HFF BSA reagent^{14–16} (O13291) is similar to Fc OxyBURST[®] Green assay reagent, except that it is prepared by reacting the succinimidyl ester of a reduced form of our Oregon Green[®] 488 dye with BSA. The absorption maximum of the oxidation product of this reagent (~492 nm) matches the 488 nm spectral line of the argon-ion laser better than does that of Fc OxyBURST[®] Green assay reagent (~495 nm). OxyBURST[®] Green H₂HFF BSA reagent can also be complexed with anti-BSA antibody to form an immune complex that can be utilized like the Fc OxyBURST[®] Green assay reagent (F2902).

All of the OxyBURST[®] reagents are slowly oxidized by molecular oxygen and are also susceptible to oxidation catalyzed by illumination in a fluorescence microscope. These reagents are reasonably stable in solution for at least six months when stored under nitrogen or argon in the dark at 4°C. We also offer a purified rabbit polyclonal anti-BSA antibody (A11133), which can bind any of our BSA conjugates (Section 14.7) or fluorogenic DQ[™] BSA conjugates (D12050, D12051; Section 10.4) to create immune complexes for analyzing the Fc receptor-mediated phagocytosis pathway. In the case of the anti-BSA antibody complex with DQ[™] BSA, initial binding and internalization of the probe is followed by hydrolysis to fluorescent peptides by proteases in the phagosome¹⁷ (Figure 16.1.5).

Amine-Reactive OxyBURST[®] Green Reagent

As an alternative to Fc OxyBURST[®] Green assay reagent and OxyBURST[®] Green H₂HFF BSA, we offer amine-reactive OxyBURST[®] Green H₂DCFDA succinimidyl ester (2',7'-dichlorodihydrofluorescein diacetate, SE; D2935; Figure 16.1.6), which can be used to prepare oxidation-sensitive conjugates of a wide variety of biomolecules and particles, including antibodies, antigens, peptides, proteins, dextrans, bacteria, yeast and polystyrene microspheres.^{9,18,19} Following conjugation to amines, the two acetates of OxyBURST[®] Green H₂DCFDA reagent can be removed by treatment with hydroxylamine at near-neutral pH to yield the oxidant-sensitive dichlorodihydrofluorescein conjugates. Thus, like our Fc OxyBURST[®] Green assay reagent, they provide a means of detecting the oxidative burst in phagocytic cells.¹⁸

Several other reagents—dihydrofluoresceins, dihydrorhodamines, dihydroethidium and chemiluminescent probes—that have been used to detect the reactive oxygen species (ROS) produced during phagocytosis are described in Section 18.2.

Fluorescent Low-Density Lipoprotein Complexes

The human LDL complex, which delivers cholesterol to cells by receptor-mediated endocytosis, comprises a core of about 1500 molecules of cholesteryl ester and triglyceride, surrounded by a 20 Å-thick shell of phospholipids, unesterified cholesterol and a single copy of apoprotein B 100²⁰ (MW ~500,000 daltons). Once internalized, LDL dissociates from its receptor and eventually appears in lysosomes.²¹ In addition to unlabeled LDL (L3486), which has been reported to be an effective vehicle for selectively delivering antitumor drugs to cancer cells,²² we offer two classes of labeled LDL probes—those containing an unmodified apoprotein, used to study the mechanisms of normal cholesterol delivery and internalization, and those with an acetylated apoprotein, used to study endothelial, microglial and other cell types that express receptors that specifically bind this modified LDL.

For the class of labeled LDL probes containing unmodified apoprotein, we prepare LDL non-covalently labeled with either DiI (DiI LDL, L3482) or the BODIPY[®] FL fluorophore (BODIPY[®] FL LDL, L3483), highly fluorescent lipophilic dyes that diffuse into the hydrophobic portion of the LDL complex without affecting the LDL-specific binding of the apoprotein. As compared with DiI LDL, BODIPY[®] FL LDL is more efficiently excited by the 488 nm spectral line of the argon-ion laser, making it better suited for flow cytometry and confocal laser-scanning microscopy studies. Like our BODIPY[®] FL C₅-ceramide (D3521, Section 12.4), BODIPY[®] FL LDL may exhibit concentration-dependent long-wavelength emission (>550 nm), precluding its use for

multicolor labeling with red fluorophores. Both DiI LDL and BODIPY® FL LDL have been used to investigate the binding specificity and partitioning of LDL throughout the *Schistosoma mansoni* parasite²³ (Figure 16.1.7). Fluorescent LDL complexes have also proven useful in a variety of experimental systems to:

- Count the number of cell-surface LDL receptors, analyze their motion and clustering and follow their internalization^{24–26}
- Demonstrate that fibroblasts grown continuously in the presence of DiI LDL (L3482) proliferate normally and exhibit normal morphology,²⁷ making DiI LDL a valuable alternative to ¹²⁵I-labeled LDL for quantitating LDL receptor activity²⁸
- Identify LDL receptor-deficient Chinese hamster ovary (CHO) cell mutants²⁹
- Image LDL receptor endocytosis in COS7 cells expressing Green Fluorescent Protein (GFP)-tagged GTPase³⁰
- Investigate the modulation of LDL receptor expression by statin drugs^{31,32}

We prepare fluorescent LDL products from fresh human plasma, and they should be stored refrigerated and protected from light; LDL products must not be frozen. Because preparation of these complexes involves several variables, some batch-to-batch variability in degree of labeling and fluorescence yield is expected.

Fluorescent Acetylated LDL Complexes

If the lysine residues of LDL's apoprotein have been acetylated, the LDL complex no longer binds to the LDL receptor,³³ but rather is taken up by macrophage and endothelial cells that possess “scavenger” receptors specific for the modified LDL.^{34,35} Once the acetylated LDL (AcLDL) complexes accumulate within these cells, they assume an appearance similar to that of foam cells found in atherosclerotic plaques.^{36–38} We offer unlabeled AcLDL (L35354), as well as AcLDL noncovalently labeled with DiI L(3484) and AcLDL covalently labeled with Alexa Fluor® 488 dye (L23380), Alexa Fluor® 594 dye (L35353) or BODIPY® FL dye (L3485). Fluorescent dye conjugates of high-density lipoproteins, including one prepared using Alexa Fluor® 488 succinimidyl ester (A20000, A20100; Section 1.3), are taken up via the same receptor as acetylated LDL complexes.³⁹

Using DiI AcLDL, researchers have discovered that the scavenger receptors on rabbit fibroblasts and smooth muscle cells appear to be up-regulated through activation of the protein kinase C pathway.⁴⁰ DiI AcLDL has also been used to show that Chinese hamster ovary (CHO) cells express AcLDL receptors that are distinct from macrophage scavenger receptors.^{41,42} Ultrastructural localization of endocytic compartments that maintain a connection to the extracellular space has been achieved by photoconversion of DiI AcLDL in the presence of diaminebenzidine⁴³ (Fluorescent Probes for Photoconversion of Diaminebenzidine Reagents—Note 14.2). A quantitative assay for LDL- and scavenger-receptor activity in adherent and nonadherent cultured cells that avoids the use of both radioactivity and organic solvents has been described.⁴⁴

It has now become routine to identify endothelial cells and microglial cells in primary cell culture by their ability to take up DiI AcLDL^{45,46} (Figure 16.1.8). DiI AcLDL was employed in order to confirm endothelial cell identity in investigations of shear stress⁴⁷ and P-glycoprotein expression,⁴⁸ as well as to identify blood vessels in a growing murine melanoma.⁴⁹ In addition, patch-clamp techniques have been used to investigate membrane currents in mouse microglia, which were identified both in culture and in brain slices by their staining with DiI AcLDL.^{50,51} For some applications, Alexa Fluor® 488, Alexa Fluor® 594 and BODIPY® FL AcLDL may be the preferred probes because the dyes are covalently bound to the modified apoprotein portion of the LDL complex and are therefore not extracted during subsequent manipulations of the cells. Furthermore, the green-fluorescent Alexa Fluor® 488 AcLDL has spectral characteristics similar to fluorescein and is useful for analyses with instruments equipped with the 488 nm argon-ion laser excitation sources, including flow cytometers and confocal laser-scanning microscopes. The bright and photostable red-fluorescent Alexa Fluor® 594 AcLDL conjugate is useful for multicolor labeling experiments with green-fluorescent probes and can be efficiently excited by the 594 nm spectral line of the orange He-Ne laser.⁵²

Figure 16.1.7 DiI LDL (L3482) bound to the surface and internalized in the gut of the parasite *Schistosoma mansoni*. The distribution of LDL in the parasite is used to study a putative mechanism by which the parasite may avoid host immune recognition. Image contributed by John P. Caulfield, Harvard School of Public Health.

Figure 16.1.8 Microglial cells in a rat hippocampus cryosection labeled with red-orange-fluorescent DiI acetylated low-density lipoprotein (L3484) and stained using blue-fluorescent DAPI (D1306, D3571, D21490).

Figure 16.1.9 Structure of the lipid A component of *Salmonella minnesota* lipopolysaccharide.

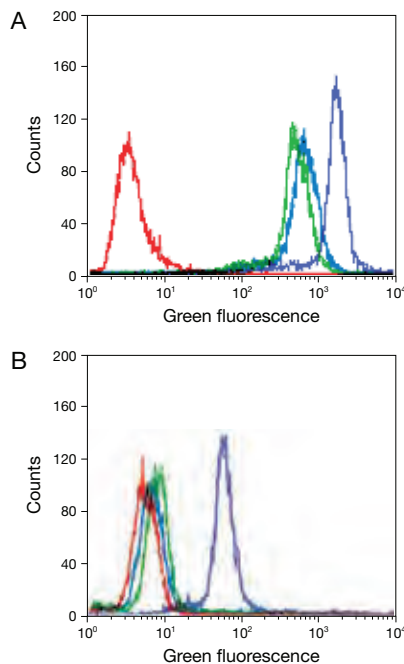

Figure 16.1.10 Detection of epidermal growth factor (EGF) receptors directly or with signal amplification. Cells expressing high (A431 cells, panel A) and low (NIH 3T3 cells, panel B) levels of EGF receptors were either directly labeled with the preformed Alexa Fluor® 488 complex of biotinylated epidermal growth factor (E13345, blue) or indirectly labeled with biotinylated EGF (E3477) followed by either Alexa Fluor® 488 streptavidin (S11223, green) or HRP-conjugated streptavidin and Alexa Fluor® 488 tyramide (purple), components of our TSA™ Kit #22 (T20932).

Fluorescent Lipopolysaccharides

We offer fluorescent conjugates of lipopolysaccharides (LPS) from *Escherichia coli* and *Salmonella minnesota* (Table 16.1), including:

- Alexa Fluor® 488 LPS from *E. coli* serotype 055:B5 (A23351)
- Alexa Fluor® 488 LPS from *S. minnesota* (A23356)
- Alexa Fluor® 568 LPS from *E. coli* serotype 055:B5 (A23352)
- Alexa Fluor® 594 LPS from *E. coli* serotype 055:B5 (A23353)
- BODIPY® FL LPS from *E. coli* serotype 055:B5 (A23350)

LPS, also known as endotoxins, are a family of complex glycolipid molecules located on the surface of gram-negative bacteria. LPS play a large role in protecting the bacterium from host defense mechanisms and antibiotics. Binding of LPS to the CD14 cell-surface receptor of phagocytes is the key initiation step in the mammalian immune response to infection by gram-negative bacteria.⁵³ The structural core of LPS, and the primary determinant of its biological activity, is an *N*-acetylglucosamine derivative, lipid A (Figure 16.1.9). In many gram-negative bacterial infections, LPS are responsible for clinically significant symptoms like fever, low blood pressure and tissue edema, which can lead to disseminated intravascular coagulation, organ failure and death.

The fluorescent BODIPY® FL and Alexa Fluor® LPS conjugates, which are labeled with succinimidyl esters of these dyes, allow researchers to follow LPS-elicited inflammatory responses.^{53,54} Lipopolysaccharide internalization activates endotoxin-dependent signal transduction in cardiomyocytes.⁵⁵ Alexa Fluor® 488 LPS conjugates (L23351, L23356) have been shown to selectively label microglia in a mixed culture containing oligodendrocyte precursors, astrocytes and microglia.⁵⁶

The BODIPY® FL derivative of LPS from *E. coli* strain LCD25 (L23350) was used to measure the transfer rate of LPS from monocytes to high-density lipoprotein⁵⁷ (HDL). Another study utilized a BODIPY® FL derivative of LPS from *S. minnesota* to demonstrate transport to the Golgi apparatus in neutrophils,^{58,59} although this could have been due to probe metabolism. It has been reported that organelles other than the Golgi are labeled by some fluorescent or nonfluorescent LPS.^{60,61} Cationic lipids are reported to assist the translocation of fluorescent lipopolysaccharides into live cells;⁶² cell surface-bound LPS can be quenched by trypan blue.⁵⁷

Other probes useful for analyzing lipopolysaccharides include fluorescent analogs of the LPS-binding antibiotic polymyxin B (Section 17.3) and BODIPY® TR cadaverine (D6251, Section 3.4). BODIPY® TR cadaverine binds with high selectivity to lipid A, forming the basis for high-throughput ligand displacement assays for identifying endotoxin antagonists.^{63,64}

Epidermal Growth Factor Derivatives

Epidermal growth factor (EGF) is a 53-amino acid polypeptide hormone (MW 6045 daltons) that stimulates division of epidermal and other cells. The EGF receptors include the HER-2/neu receptor (where “HER-2” is an acronym for human epidermal growth factor receptor-2 and “neu” refers to an original mouse origin); HER-2/neu overexpression has evolved as a prognostic/predictive factor in some solid tumors.^{65–67} Binding of EGF to its 170,000-dalton receptor protein results in the activation of kinases, phospholipases and Ca²⁺ mobilization and precipitates a wide variety of cellular responses related to differentiation, mitogenesis, organ development and cell motility.

We offer unlabeled mouse submaxillary gland EGF (E3476), as well as the following EGF conjugates, each containing a single fluorophore or biotin on the N-terminal amino acid:

- Fluorescein EGF (E3478)
- Oregon Green® 514 EGF (E7498)
- Tetramethylrhodamine EGF (E3481)
- Biotin-XX EGF (E3477)

The dissociation constant of the EGF conjugates in DMEM-HEPES medium is in the low nanomolar range for human epidermoid carcinoma (A431) cells,⁶⁸ a value that approximates that of the unlabeled EGF. Fluorescently labeled EGF has enabled scientists to use fluorescence resonance energy transfer techniques to assess EGF receptor–receptor and receptor–membrane interactions^{69–71} (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). Using fluorescein

Table 16.1 Fluorescent lipopolysaccharide conjugates.

Fluorophore	Abs *	Em *	<i>Escherichia coli</i>	<i>Salmonella minnesota</i>
Alexa Fluor® 488	495	519	L23351	L23356
BODIPY® FL	503	513 †	L23350	
Alexa Fluor® 568	578	603	L23352	
Alexa Fluor® 594	590	617	L23353	

* Approximate absorption (Abs) and fluorescence emission (Em) maxima for conjugates, in nm. † At high concentrations, the emission maximum for the BODIPY® FL dye may shift from ~513 nm to ~620 nm.^{1,2}
1. J Immunol (1997) 158:3925; 2. J Biol Chem (1996) 271:4100.

EGF as the donor and tetramethylrhodamine EGF as the acceptor, researchers examined temperature-dependent lateral and transverse distribution of EGF receptors in A431 cell plasma membranes.⁷¹ When fluorescein EGF binds to A431 cells, it apparently undergoes a biphasic quenching, which can be attributed first to changes in rotational mobility upon binding and then to receptor–ligand internalization. By monitoring this quenching in real time, the rate constants for the interaction of fluorescein EGF with its receptor were determined.⁷² Although fluorescently labeled EGF can be used to follow lateral mobility and endocytosis of the EGF receptor,^{73,74} the visualization of fluorescent EGF may require low-light imaging technology or Qdot® nanocrystals, especially in cells that express low levels of the EGF receptor.⁷⁵ In cells with few EGF receptors, it can be difficult to detect signal over background fluorescence unless signal amplification methods are employed (Figure 16.1.10).

Biotin-XX EGF contains a long spacer arm that enhances the probe's affinity for the EGF receptor and facilitates binding of dye-, Qdot® nanocrystal- or enzyme-conjugated streptavidins^{75–79} (Section 7.6). Using biotinylated EGF and phycoerythrin-labeled secondary reagents (Section 6.4), researchers were able to detect as few as 10,000 EGF cell-surface receptors by confocal laser-scanning microscopy.⁸⁰ Tyramide signal amplification (TSA) technology (Section 6.2) is particularly valuable for detection and localization of low-abundance EGF receptors by both imaging and flow cytometry (Figure 16.1.10). For additional sensitivity, we prepare biotinylated EGF precomplexed to fluorescent streptavidin:

- Biotinylated EGF complexed to Alexa Fluor® 488 streptavidin (E13345, Figure 16.1.11)
- Biotinylated EGF complexed to Alexa Fluor® 555 streptavidin (E35350)
- Biotinylated EGF complexed to Alexa Fluor® 647 streptavidin (E35351)
- Biotinylated EGF complexed to Texas Red® streptavidin^{81,82} (E3480)

These products yield several-fold brighter signals per EGF receptor when compared with the direct conjugates. We have found that EGF receptors can easily be detected with these complexes without resorting to low-light imaging technology (Figure 16.1.12). A quantitative high-content screening (HCS) assay for EGF receptor modulators based on imaging the internalization of the Alexa Fluor® 555 EGF complex internalization has been reported.⁸³

Transferrin Conjugates

Transferrin is a monomeric serum glycoprotein (MW ~80,000 daltons) that binds up to two Fe³⁺ atoms for delivery to vertebrate cells through receptor-mediated endocytosis. Once iron-carrying transferrin proteins are inside endosomes, the acidic environment favors dissociation of the sequestered iron from the transferrin–receptor complex. Following the release of iron, the apotransferrin is recycled to the plasma membrane, where it is released from its receptor to scavenge more iron. Transferrin uptake is a prototypical and ubiquitous example of clathrin-mediated endocytosis. Although transferrin uptake is widely regarded as a surrogate measure of total clathrin-mediated endocytosis, perturbations that are specific to transferrin endocytosis impel caution in making such extrapolations.²

Our fluorescent and biotinylated di-ferric (Fe³⁺) human transferrin conjugates (Table 16.2) include:

- Fluorescein transferrin (T2871)
- Alexa Fluor® 488 transferrin^{84–87} (T13342)
- Alexa Fluor® 546 transferrin^{88,89} (T23364)
- Alexa Fluor® 555 transferrin⁹⁰ (T35352)

Figure 16.1.11 Early endosomes in live HeLa cells identified after a 10-minute incubation with green-fluorescent Alexa Fluor® 488 epidermal growth factor (E13345). The cells were subsequently fixed with formaldehyde and labeled with an antibody to the late endosomal protein, RhoB. That antibody was visualized with a red-orange-fluorescent secondary antibody. Nuclei were stained with TO-PRO®-3 iodide (T3605, pseudocolored blue). The image was contributed by Harry Mellor, University of Bristol.

Figure 16.1.12 Lightly fixed human epidermoid carcinoma cells (A431) stained with biotinylated epidermal growth factor (EGF) complexed to Texas Red® streptavidin (E3480). An identical cell preparation stained in the presence of a 100-fold excess of unlabeled EGF (E3476) showed no fluorescent signal.

Table 16.2 Transferrin conjugates.

Cat. No.	Label	Abs *	Em *
T2871	Fluorescein	494	518
T13342	Alexa Fluor® 488	495	518
T2872	Tetramethylrhodamine	555	580

T13343	Alexa Fluor® 594	589	616
T2875	Texas Red®	595	615
T23362	Alexa Fluor® 633	632	647
T23366	Alexa Fluor® 647	650	665
T35357	Alexa Fluor® 680	679	702
T23363	Biotin-XX	NA	NA

* Approximate absorption (Abs) and fluorescence emission (Em) maxima for conjugates, in nm. NA = Not applicable.

Figure 16.1.13 Live HeLa cells incubated with Alexa Fluor® 594 transferrin (T13343) for 10 minutes to label early endosomes. The cells were subsequently fixed with formaldehyde and labeled with an antibody to the endosomal protein RhoD. That antibody was visualized with a green-fluorescent secondary antibody. Yellow fluorescence indicates regions of co-localization. To illustrate the staining pattern, the cells were imaged by both fluorescence (top panel) and differential interference contrast (DIC) microscopy (bottom panel). The image was contributed by Harry Mellor, University of Bristol.

Figure 16.1.14 Interaction of fluorescently labeled fibrinogen with activated platelets. Whole blood was first incubated with an R-phycoerythrin (R-PE)-labeled anti-CD41 antibody to label the platelets. 20 μM adenosine 5'-diphosphate (ADP) was added in order to activate the platelets, then 2 $\mu\text{g}/\text{mL}$ Alexa Fluor® 488 fibrinogen (F13191) was added and incubated with the sample for 5 minutes. Cells were analyzed by flow cytometry using excitation at 488 nm. Both activated and unactivated platelets show binding of the anti-CD41 antibody; however, only the activated platelets show strong binding by fibrinogen. A total of 5000 platelets are shown in each experiment.

- Alexa Fluor® 568 transferrin⁹¹ (T23365)
- Alexa Fluor® 594 transferrin^{92–94} (T13343, Figure 16.1.13)
- Alexa Fluor® 633 transferrin (T23362)
- Alexa Fluor® 647 transferrin^{73,95,96} (T23366)
- Alexa Fluor® 680 transferrin (T35357)
- Tetramethylrhodamine transferrin (T2872)
- Texas Red® transferrin (T2875)
- Biotin-XX transferrin (T23363)

Alexa Fluor® transferrin conjugates are highly recommended because of their brightness, enhanced photostability and lack of sensitivity to pH (Section 1.3). The pH sensitivity of fluorescein-labeled transferrin has been exploited to investigate events occurring during endosomal acidification.^{97–100} Fluorescent transferrins have also been used to:

- Analyze the role of the γ -chain of type III IgG receptors in antigen–antibody complex internalization¹⁰¹
- Characterize endocytic apparatus phenotypes in drug-resistant cancer cells⁸⁵
- Demonstrate that the fungal metabolite brefeldin A (B7450, Section 12.4) induces an increase in tubulation of transferrin receptors in BHK-21 cells¹⁰² and in the perikaryal–dendritic region of cultured hippocampal neurons¹⁰³
- Image transferrin receptor dynamics using FRET¹⁰⁴
- Observe receptor trafficking in live cells by confocal laser-scanning microscopy⁷⁴

Uptake of a horseradish peroxidase (HRP) conjugate of transferrin by endosomes has been detected using tyramide signal amplification (TSA, Section 6.2) by catalytic deposition of biotin tyramide and use of fluorescent streptavidin conjugates¹⁰⁵ (Section 7.6).

In addition to fluorescent and biotinylated transferrin conjugates, we offer a mouse monoclonal IgG₁ anti-human transferrin receptor antibody (A11130). This antibody can be used with any of our Zenon® Mouse IgG₁ Labeling Kits (Section 7.3, Table 7.7) for rapid preparation of labeling complexes. Antibodies against transferrin receptors have been used for indirect immunofluorescent staining of the transferrin receptor,^{106–108} transport of molecules across the blood–brain barrier,¹⁰⁹ characterization of transferrin in recycling compartments,¹⁰⁶ enzyme-linked immunosorbent assays (ELISAs)¹⁰⁸ and antibody competition with transferrin uptake.¹¹⁰

Fluorescent Fibrinogen

Fibrinogen is a key component in the blood clotting process and can support both platelet–platelet and platelet–surface interactions by binding to the glycoprotein IIb-IIIa (GPIIb-IIIa) receptor (also called integrin $\alpha_{\text{IIb}}\beta_3$) of activated platelets. Activation of GPIIb-IIIa is required for fibrinogen binding, which leads to platelet activation, adhesion, spreading and microfilament reorganization of human endothelial cells *in vitro*. Bone marrow transplant patients have significantly higher levels of fibrinogen binding, as compared with controls Soluble fibrinogen binds to its receptor with a Ca^{2+} -dependent apparent K_d of 0.18 μM .¹¹¹ This binding is mediated by the tripeptide sequence Arg-Gly-Asp (RGD), found in both fibrinogen and fibronectin.

Fluorescently labeled fibrinogen has proven to be a valuable tool for investigating platelet activation and subsequent fibrinogen binding.^{112–114} Alexa Fluor® 647 fibrinogen has been used to identify activated platelets by flow cytometry.¹¹⁵ The binding of fluorescein fibrinogen to activated platelets has been shown to be saturable and can be inhibited completely by underivatized fibrinogen.^{116,117}

We offer four conjugates of human fibrinogen in three different fluorescent colors:

- Alexa Fluor® 488 human fibrinogen conjugate (F13191)
- Oregon Green® 488 human fibrinogen conjugate (F7496)
- Alexa Fluor® 546 human fibrinogen conjugate (F13192)
- Alexa Fluor® 647 human fibrinogen conjugate (F35200)

These highly fluorescent fibrinogen conjugates are useful for investigating platelet activation and subsequent fibrinogen binding using fluorescence microscopy or flow cytometry^{112,115,118} (Figure 16.1.14).

DQ™ Ovalbumin: A Probe for Antigen Processing and Presentation

Although antigen processing and presentation have been extensively studied, the exact sequence and detailed pathways for generating antigenic peptides have yet to be elucidated. In general, the immunogenic protein is internalized by a macrophage, denatured, reduced and proteolyzed, and then the resulting peptides associate with MHC class II molecules that are expressed at the cell surface.¹¹⁹ Ovalbumin is efficiently processed through mannose receptor-mediated endocytosis by antigen-presenting cells and is widely used for studying antigen processing.^{120–122} DQ™ ovalbumin¹²³ (D12053), a self-quenched ovalbumin conjugate, is designed specifically for the study of macrophage-mediated antigen processing in flow cytometry and microscopy assays.

Traditionally, fluorescein-labeled bovine serum albumin (FITC-BSA) has been used as a fluorogenic protein antigen for studying the real-time kinetics of antigen processing in live macrophages by flow cytometry,¹²⁴ two-photon fluorescence lifetime imaging microscopy (FLIM)¹²⁵ and fluorescence polarization.^{124,126,127} FITC-ovalbumin has been employed to study antigen uptake in HIV-1-infected monocytic cells.¹²⁸ The FITC-ovalbumin and FITC-BSA used in these experiments were heavily labeled with fluorescein such that the intact conjugates were relatively nonfluorescent due to self-quenching. Upon denaturation and proteolysis, however, these FITC conjugates became highly fluorescent, allowing researchers to monitor intracellular trafficking and the processing of ovalbumin and BSA in macrophages.

For studies of antigen processing and presentation, DQ™ ovalbumin offers several advantages when compared with FITC-ovalbumin and FITC-BSA. Like the FITC conjugates, DQ™ ovalbumin is labeled with our pH-insensitive, green-fluorescent BODIPY® FL dye such that the fluorescence is almost completely quenched until the probe is digested by proteases (Figure 16.1.15). Unlike fluorescein, which has greatly reduced fluorescence intensity at acidic pH and is not very photostable, our BODIPY® FL dye exhibits bright, relatively photostable and pH-insensitive fluorescence from pH 3 to 9. Furthermore, the intact DQ™ ovalbumin is more highly quenched than unprocessed FITC-ovalbumin or FITC-BSA at a lower degree of substitution, thereby providing a lower background signal while preserving the protein's antigenic epitopes. Although we offer the green-fluorescent DQ™ Green BSA and red-fluorescent DQ™ Red BSA (D12050, D12051; Section 10.4), which are also self-quenched BODIPY® FL and BODIPY® TR conjugates, we highly recommend DQ™ ovalbumin (D12053) for studying antigen processing and presentation^{129,130} because ovalbumin is internalized via the mannose receptor-mediated endocytosis pathway and is thus processed more efficiently by antigen-presenting cells than is BSA.¹³¹

Fluorescent Gelatin

Collagen is a major component of the extracellular matrix and, in vertebrates, constitutes approximately 25% of total protein. This important protein not only serves a structural role, but also is important in cell adhesion and migration. Specific collagen receptors, fibronectin and a number of other proteins involved in cell-cell and cell-surface adhesion have been demonstrated to bind collagen and gelatin^{132,133} (denatured collagen).

We offer highly fluorescent gelatin conjugates for researchers studying collagen-binding proteins and collagen metabolism, as well as gelatinases and collagenases, which are metalloproteins that digest gelatin and collagen. We offer two green-fluorescent gelatin conjugates—fluorescein

gelatin and Oregon Green® 488 gelatin (G13187, G13186). Fluorescent gelatin conjugates have been shown to be useful for:

- Assessing gelatinase activity in podosomes of mouse dendritic cells¹³⁴
- Localizing surface fibronectin on cultured cells¹³⁵
- Performing *in situ* gelatinase zymography on canary brain sections¹³⁶
- Studying fibronectin-gelatin interactions in solution using fluorescence polarization¹³³ (Fluorescence Polarization (FP)—Note 1.4)

We have also developed fluorogenic gelatinase and collagenase substrates—DQ™ gelatin and DQ™ collagen (Figure 16.1.15) (D12054, D12060)—that are described in Section 10.4. In addition, we offer fluorescent microspheres coated with collagen, which are described below.

Fluorescent Casein

Real-time imaging of fluorescein-labeled casein (C2990) and FluoSpheres® fluorescent microspheres has been used to characterize the endocytic apparatus of the protozoan *Giardia lamblia*.¹³⁷ The EnzChek® Protease Assay Kits (E6638, E6639; Section 10.4) provide convenient fluorescence-based assays for protease activity and contain either green-fluorescent BODIPY® FL casein or red-fluorescent BODIPY® TR-X casein¹³⁸ (Figure 16.1.15). BODIPY® FL casein and BODIPY® TR-X casein have significant utility as nontoxic and pH-insensitive general markers for phagocytic cells in culture.^{139,140} Our RediPlate™ 96 (R22132) version of the BODIPY® TR-X casein substrate (Section 10.4) is ideal for high-throughput screening of potential protease inhibitors.

Fluorescent Chemotactic Peptide

A variety of white blood cells containing the formyl-Met-Leu-Phe (fMLF) receptor respond to bacterial *N*-formyl peptides by migrating to the site of bacterial invasion and then initiating an activation pathway to control the spread of infection. Activation involves Ca²⁺ mobilization,¹⁴¹ transient acidification,^{142,143} actin polymerization,¹⁴⁴ phagocytosis¹⁴⁵ and production of oxidative species.¹⁴⁶ We offer the fluorescein conjugate of the hexapeptide formyl-Nle-Leu-Phe-Nle-Tyr-Lys (F1314),

Figure 16.1.15 Principle of enzyme detection via the disruption of intramolecular self-quenching. Enzyme-catalyzed hydrolysis of the heavily labeled and almost totally quenched substrates provided in our EnzChek® Protease Assay Kits (E6638, E6639), EnzChek® Ultra Amylase Assay Kit (E33651), EnzChek® Gelatinase/Collagenase Assay Kit (E12055), EnzChek® Elastase Kit (E12056), EnzChek® Lysozyme Assay Kit (E22013)—as well as the stand-alone quenched substrates DQ™ BSA (D12050, D12051), DQ™ collagen (D12052, D12060), DQ™ ovalbumin (D12053) and DQ™ gelatin (D12054)—relieves the intramolecular self-quenching, yielding brightly fluorescent reaction products.

Figure 16.1.16 Dexamethasone fluorescein (D1383).

Figure 16.1.17 Principle of the Vybrant® Phagocytosis Assay Kit (V6694) for the simple quantitation of phagocytosis. **A)** Briefly, phagocytic cells are incubated with the green-fluorescent fluorescein-labeled *Escherichia coli* BioParticles® conjugates (E2861). **B)** The fluorescence from any noninternalized BioParticles® product is then quenched by the addition of trypan blue, and the samples are subsequently assayed with a fluorescence microplate reader equipped with filters for the detection of fluorescein (FITC).

Figure 16.1.18 Tracking endocytosis inhibition with pHrodo™ dextran conjugates. HeLa cells were plated in 96-well format and treated with dynasore for 3 hours at 37°C prior to the pHrodo™ endocytosis assay. Next, 40 μg/mL of pHrodo™ 10,000 MW dextran (P10361) was incubated for 30 minutes at 37°C, and cells were then stained with HCS NuclearMask™ Blue Stain (H10325) for 10 minutes to reveal total cell number and demarcation for image analysis. Images were acquired on the BD Pathway™ 855 High-Content Biomager (BD Biosciences).

which has been extensively employed to investigate the fMLF receptor.^{147–151} The fluorescein-labeled chemotactic peptide has been used to study G-protein coupling and receptor structure,^{152–154} expression,^{155,156} distribution^{157–159} and internalization.¹⁶⁰

Fluorescent Insulin

We prepare a high-purity, zinc-free fluorescein isothiocyanate conjugate of human insulin (FITC insulin, I13269). Unlike most commercially available preparations, our FITC insulin is purified by HPLC and consists of a singly labeled species of insulin that has been specifically modified at the N-terminus of the B-chain. Because the degree and position of labeling can alter the biological activity of insulin, we have isolated the singly labeled species that has been shown to retain its biological activity in an autophosphorylation assay.¹⁶¹ Our FITC insulin preparation is useful for imaging insulin and insulin receptor distribution,¹⁶² as well as for conducting insulin-binding assays using microfluidic devices.^{163,164}

Fluorescent Dexamethasone Probe for Glucocorticoid Receptors

The synthetic steroid hormone dexamethasone binds to the glucocorticoid receptor, producing a steroid–receptor complex that then localizes in the nucleus and regulates gene transcription. In hepatoma tissue culture (HTC) cells, tetramethylrhodamine-labeled dexamethasone has been shown to have high affinity for the glucocorticoid receptor in a cell-free system and to induce tyrosine aminotransferase (TAT) expression in whole cells, albeit at a much lower rate than unmodified dexamethasone.¹⁶⁵ This labeled dexamethasone also allowed the first observations of the fluorescent steroid–receptor complex in the HTC cell cytosol.¹⁶⁵ Fluorescein dexamethasone (D1383, Figure 16.1.16) should be similarly useful for studying the mechanism of glucocorticoid receptor activation.

Fluorescent Histone H1

The Alexa Fluor® 488 conjugate of the lysine-rich calf thymus histone H1 (H13188) is a useful probe for nuclear protein transport assays.¹⁶⁶ Nuclear-to-mitochondrial translocation of histone H1 is indicative of dsDNA strand breaks. Fluorescent histone H1 conjugates can also be used to detect membrane-surface exposure of acidic phospholipids such as phosphatidylserine.¹⁶⁷

Fluorescent Probes for the Acrosome Reaction

Soybean trypsin inhibitor (SBTI) inhibits the catalytic activity of serine proteases and binds to acrosin, an acrosomal serine protease associated with binding of spermatozoa to the zona pellucida.¹⁶⁸ Alexa Fluor® 488 dye-labeled trypsin inhibitor from soybean (T23011) is useful for real-time imaging of the acrosome reaction in live spermatozoa.¹⁶⁹ A fluorescent peanut lectin has been combined with ethidium homodimer-1 (EthD-1, E1169; Section 15.2) for a combined acrosome reaction assay and vital staining.¹⁷⁰ Alexa Fluor® 488, Alexa Fluor® 568, Alexa Fluor® 594 and Alexa Fluor® 647 conjugates of *Arachis hypogaea* lectin (PNA) (L21409, L32458, L32459, L32460) have similar utility as acrosomal stains.¹⁷¹

Methods for Detecting Internalized Fluorescent Ligands

Many of the fluorescent ligands described in this section first bind to cell-surface receptors, then are internalized and, in some cases, recycled to the cell surface. In most applications, the cell-surface and internalized ligand populations are spatially resolved by imaging. It is often desirable to include noninternalized plasma membrane reference markers in these labeling protocols. CellMask™ Orange and CellMask™ Deep Red plasma membrane stains (C10045, C10046; Section 14.4) are particularly suitable for this purpose.^{172,173} Other useful membrane markers include posttranslationally lipidated fluorescent proteins¹⁷⁴ (O36214, O10139; Section 14.4). When spatial resolution is not possible, there are other means by which these signals can be separated and, in some cases, quantitated. These include:

- Use of antibodies to the Alexa Fluor® 488, BODIPY® FL, fluorescein/Oregon Green®, tetramethylrhodamine, Texas Red® and Alexa Fluor® 405/Cascade Blue® dyes (Section 7.4, Table 7.8) to quench most of the fluorescence of surface-bound or exocytosed probes

- Use of a dye such as trypan blue to quench external fluorescent signals but not internalized signals^{175,176} (Figure 16.1.17)—a method employed in our Vybrant® Phagocytosis Assay Kit (V6694) described below
- Rapid acidification of the medium to quench the fluorescence of pH-sensitive fluorophores such as fluorescein on the cell surface, thus enabling selective detection of endocytosed probe
- Tagging of proteins, polysaccharides, cells, bacteria, yeast, fungi¹⁷⁷ and other materials to be endocytosed with a pH-sensitive dye—such as our pHrodo™,^{178–180} SNARF® or Oregon Green® dyes (Chapter 20)—that undergoes a spectral shift or intensity change in the acidic pH range found in phagovacuoles and late endosomes
- Use of heavily labeled, highly quenched proteins such as our DQ™ BSA and DQ™ gelatin probes, which yield highly fluorescent peptides upon intracellular proteolysis¹⁸¹ (Section 10.4)

Pathway-specific inhibitors—such as chlorpromazine, dynasore (Figure 16.1.18), dansyl cadaverine (D113, Section 3.4), brefeldin A (B7450, Section 12.4), genistein and filipin—are widely used in combination with fluorescently labeled ligands for characterizing endocytic pathways.¹⁸² A critical evaluation¹⁸³ highlights some necessary cautions in the application and interpretation of this approach, relating to decreased cell viability caused by some inhibitors as well as cell type-dependent differences in their efficacy.

Membrane Markers of Endocytosis and Exocytosis

FM® 1-43

FM® dyes—FM® 1-43, FM® 2-10, FM® 4-64, FM® 5-95 and the aldehyde-fixable FM® 1-43FX and FM® 4-64FX—are excellent membrane probes both for identifying actively firing neurons¹⁸⁴ and for investigating the mechanisms of activity-dependent vesicle cycling in widely different species.^{185–188} FM® dyes may also be useful as general-purpose probes for investigating endocytosis and for simply identifying cell membrane boundaries.

FM® 1-43 and its analogs, which are nontoxic to cells and virtually nonfluorescent in aqueous medium, are believed to insert into the outer leaflet of the surface membrane, where they become intensely fluorescent. In a neuron that is actively releasing neurotransmitters, these dyes become internalized within the recycled synaptic vesicles and the nerve terminals become brightly stained (Figure 16.1.19, Figure 16.1.20). The nonspecific staining of cell-surface membranes can simply be washed off prior to viewing. Wash removal of noninternalized dye background is more difficult in tissue preparations than in disseminated cell cultures. Extracellular fluorescence quenching¹⁸⁹ and dye adsorption¹⁹⁰ strategies have been developed to address this problem. Alternatively, the optical sectioning capabilities of confocal microscopy, two-photon excitation microscopy (Fluorescent Probes for Two-Photon Microscopy—Note 1.5) and total internal reflection (TIRF) microscopy provide instrument-based solutions for improving the signal-to-background contrast.¹⁹¹ The amount of FM® 1-43 taken up per vesicle by endocytosis equals the amount of dye released upon exocytosis, indicating that the dye does not transfer from internalized vesicles to an endosome-like compartment during the recycling process.¹⁹² In astrocytes, internalization of FM® 1-43 (and FM® 4-64) is mediated by store-operated calcium channels and not by endocytosis.¹⁹³ Like most styryl dyes, the absorption and fluorescence emission spectra of FM® 1-43 are significantly shifted in the membrane environment and are relatively broad (Figure 16.1.21), requiring careful matching with other fluorophores to avoid channel crosstalk in multiplex detection applications (Using the Fluorescence SpectraViewer—Note 23.1). We offer FM® 1-43 in a 1 mg vial (T3163) or specially packaged in 10 vials of 100 µg each (T35356).

FM® 1-43 was employed in a study showing that synaptosomal endocytosis is independent of both extracellular Ca²⁺ and membrane potential in dissociated hippocampal neurons,¹⁹⁴ as well as in a spectrofluorometric assay demonstrating that nitric oxide-stimulated vesicle release is independent of Ca²⁺ in isolated rat hippocampal nerve terminals.¹⁹⁵ FM® 1-43 has been used in combination with fura-2 (Section 19.2) to simultaneously measure intracellular Ca²⁺ and membrane turnover.^{196,197} FM® 1-43 dye-mediated photoconversion has been used to visualize recycling vesicles in hippocampal neurons.¹⁹⁸

Figure 16.1.19 Live nerve terminals of motor neurons that innervate a rat lumbrical muscle stained with the activity-dependent dye FM® 1-43 (T3163, T35356) and observed under low magnification. The dye molecules, which insert into the outer leaflet of the surface membrane, are captured in recycled synaptic vesicles of actively firing neurons. The image was contributed by William J. Betz, University of Colorado School of Medicine.

Figure 16.1.20 A feline mesenteric Pacinian corpuscle labeled with FM® 1-43 (T3163, T35356). The image was contributed by Michael Chua, University of North Carolina at Chapel Hill.

Figure 16.1.21 Absorption and fluorescence emission spectra of FM® 1-43 bound to phospholipid bilayer membranes.

Figure 16.1.22 Feline muscle spindle, a specialized sensory receptor unit that detects muscle length and changes in muscle length and velocity, was labeled with FM[®] 2-10 (T7508). Image contributed by Michael Chua, University of North Carolina at Chapel Hill.

Figure 16.1.23 Correlated fluorescence imaging of membrane migration, protein translocation and chromosome localization during *Bacillus subtilis* sporulation. Membranes were stained with red-fluorescent FM[®] 4-64 (T3166, T13320). Chromosomes were localized with the blue-fluorescent nuclear counterstain DAPI (D1306, D3571, D21490). The small, green-fluorescent patches (top row) indicate the localization of a GFP fusion to SpoIIIE, a protein essential for both initial membrane fusion and forespore engulfment. Progression of the engulfment is shown from left to right. Green fluorescence in the middle and bottom rows demonstrates fully engulfed sporangia stained with MitoTracker[®] Green FM[®] (M7514). Full details of the experimental methods and interpretation are published in Proc Natl Acad Sci U S A 96, 14553 (1999). Image contributed by Kit Pogliano and Marc Sharp, University of California at San Diego. Reproduced from the 7 December 1999 issue of Proc Natl Acad Sci U S A, with permission.

Figure 16.1.24 FM[®] 1-43FX (F35355).

Figure 16.1.25 FM[®] 4-64FX (F34653).

Figure 16.1.26 TMA-DPH (1-(4-trimethylammonium-phenyl)-6-phenyl-1,3,5-hexatriene *p*-toluenesulfonate) (T204).

Other Analogs of FM[®] 1-43

A comparison of mammalian motor nerve terminals stained with either FM[®] 1-43 or the more hydrophilic analog FM[®] 2-10 (T7508, Figure 16.1.22) revealed that lower background staining by FM[®] 2-10 and its faster destaining rate may make it the preferred probe for quantitative applications.^{199,200} However, staining with FM[®] 2-10 requires much higher dye concentrations¹⁹⁹ (100 μM compared with 2 μM for FM[®] 1-43). Additionally, it has been shown that both FM[®] 1-43 and FM[®] 2-10 are antagonists of muscarinic acetylcholine receptors and may be useful for analyzing receptor distribution and occupancy.²⁰¹ This property may be due to the cationic alkylammonium substituent of FM[®] dyes, which they have in common with choline, and could serve as one of the sources of background FM[®] dye staining in tissues.

FM[®] 4-64 (T3166, T13320) and RH 414 (T1111)—both more hydrophobic than FM[®] 1-43—may also be useful as probes for investigating endocytosis. Because small differences in the polarity of these FM[®] probes can play a large role in their rates of uptake and their retention properties, we have introduced FM[®] 5-95 (T23360), a slightly less lipophilic analog of FM[®] 4-64 with essentially identical spectroscopic properties. FM[®] 4-64 exhibits long-wavelength red fluorescence that can be distinguished from Green Fluorescent Protein (GFP) with the proper optical filter sets.^{202–205}

FM[®] 4-64 is an endosomal marker and vital stain that persists through cell division,^{206,207} as well as a stain for functional presynaptic boutons.²⁰⁸ In addition, FM[®] 4-64 staining has been used to visualize membrane migration and fusion during *Bacillus subtilis* sporulation, and these movements can be correlated with the translocation of GFP-labeled proteins^{202,209,210} (Figure 16.1.23). Sequential pulse-chase application of FM[®] 4-64 and FM[®] 1-43 allows two-color fluorescence discrimination of temporally staged synaptic vesicle populations.¹⁸⁷ FM[®] 4-64 selectively stains yeast vacuolar membranes and is an important tool for visualizing vacuolar organelle morphology and dynamics and for studying the endocytic pathway and vacuole fusion in yeast^{211–213} (Section 12.3). FM[®] 4-64 and FM[®] 1-43 also have many applications for visualizing membrane dynamics in plant^{204,214–216} and algal²¹⁷ cells.

FM[®] 1-43FX and FM[®] 4-64FX: Fixable FM[®] Dyes

FM[®] 1-43FX and FM[®] 4-64FX are FM[®] 1-43 and FM[®] 4-64 analogs, respectively, that have been modified to contain an aliphatic amine (Figure 16.1.24, Figure 16.1.25). This modification makes the probe fixable with aldehyde-based fixatives, including formaldehyde and glutaraldehyde. FM[®] 1-43FX has been used to study synaptic vesicle cycling in cone photoreceptor terminals¹⁸⁷ and to investigate the functional maturation of glutamatergic synapses.²¹⁸ FM[®] 1-43FX (F35355) and FM[®] 4-64FX (F34653) are available specially packaged in 10 vials of 100 μg each.

4-Di-1-ASP and 4-Di-2-ASP

The cationic mitochondrial dyes 4-Di-1-ASP (D288) and 4-Di-2-ASP (D289) stain presynaptic nerve terminals independent of neuronal activity.^{219–222} These aminostyrylpyridinium dyes have also been widely used as substrates for functional analysis of biogenic amine transporters^{223–227} and renal and hepatic organic cation transporters.^{228–230}

TMA-DPH

Also useful as a lipid marker for endocytosis and exocytosis is the cationic linear polyene TMA-DPH (T204, Figure 16.1.26), which readily incorporates in the plasma membrane of live cells.^{231,232} TMA-DPH is virtually nonfluorescent in water and is reported to bind to cells in proportion to the available membrane surface.²³³ Its fluorescence intensity is therefore sensitive to physiological processes that cause a net change in membrane surface area, making it an excellent probe for monitoring events such as changes in cell volume and exocytosis.^{233–236}

Fluorescent Cholera Toxin Subunit B: Markers of Lipid Rafts

Fluorescent cholera toxins, which bind to galactosyl moieties, are markers of lipid rafts—regions of cell membranes high in ganglioside G_{M1} that are thought to be important in cell signaling.^{237,238} Lipid rafts are detergent-insoluble, sphingolipid- and cholesterol-rich membrane microdomains that form lateral assemblies in the plasma membrane.^{239–245} Lipid rafts also sequester glycosphosphatidylinositol (GPI)-linked proteins and other signaling proteins and

receptors, which may be regulated by their selective interactions with these membrane microdomains.^{246–251} Recent research has demonstrated that lipid rafts play a role in a variety of cellular processes—including the compartmentalization of cell-signaling events,^{252–259} the regulation of apoptosis^{260–262} and the intracellular trafficking of certain membrane proteins and lipids^{263–265}—as well as in the infectious cycles of several viruses and bacterial pathogens.^{266–271}

The Vybrant® Lipid Raft Labeling Kits (V34403, V34404, V34405; Section 14.4) provide the key reagents for fluorescently labeling lipid rafts *in vivo* with our bright and extremely photostable Alexa Fluor® dyes (Figure 16.1.27, Figure 16.1.28). Live cells are first labeled with the green-fluorescent Alexa Fluor® 488, orange-fluorescent Alexa Fluor® 555 or red-fluorescent Alexa Fluor® 594 conjugate of cholera toxin subunit B (CT-B). This CT-B conjugate binds to the pentasaccharide chain of plasma membrane ganglioside G_{M1}, which selectively partitions into lipid rafts.^{250,272,273} An antibody that specifically recognizes CT-B is then used to crosslink the CT-B-labeled lipid rafts into distinct patches on the plasma membrane, which are easily visualized by fluorescence microscopy.^{274,275} Each Vybrant® Lipid Raft Labeling Kit contains sufficient reagents to label 50 live-cell samples, including:

- Recombinant cholera toxin subunit B (CT-B) labeled with the Alexa Fluor® 488 (in Kit V34403), Alexa Fluor® 555 (in Kit V34404) or Alexa Fluor® 594 (in Kit V34405) dye
- Anti-cholera toxin subunit B antibody (anti-CT-B)
- Concentrated phosphate-buffered saline (PBS)
- Detailed labeling protocol

Cholera toxin subunit B and its conjugates are also established as superior tracers for retrograde labeling of neurons.^{276,277} Cholera toxin subunit B conjugates bind to the pentasaccharide chain of ganglioside G_{M1} on neuronal cell surfaces and are actively taken up and transported; alternatively, they can be injected by iontophoresis. Unlike the carbocyanine-based neuronal tracers such as DiI (D282, D3911, V22885; Section 14.4), cholera toxin subunit B conjugates can be used on tissue sections that will be fixed and frozen.²⁷⁸

All of our cholera toxin subunit B conjugates are prepared from recombinant cholera toxin subunit B, which is completely free of the toxic subunit A, thus eliminating any concern for toxicity or ADP-ribosylating activity. The Alexa Fluor® 488 (C22841, C34775), Alexa Fluor® 555 (C22843, C34776), Alexa Fluor® 594 (C22842, C34777) and Alexa Fluor® 647 (C34778) conjugates of cholera toxin subunit B combine this versatile tracer with the superior brightness of our Alexa Fluor® dyes to provide sensitive and selective receptor labeling and neuronal tracing. We also offer biotin-XX (C34779) and horseradish peroxidase (C34780) conjugates of cholera toxin subunit B for use in combination with diaminobenzidine (DAB) oxidation,²⁷⁹ tyramide signal amplification (TSA) and Qdot® nanocrystal-streptavidin conjugates.²⁸⁰

Fluorescent Protein–Based Lipid Raft Markers

CellLight® plasma membrane expression vectors (C10606, C10607, C10608; Section 14.4) generate cyan-, green- or red-autofluorescent proteins fused to a plasma membrane targeting sequence consisting of the 10 N-terminal amino acids of Lck tyrosine kinase (Lck10). These fusion proteins are lipid raft markers with well established utility,⁹⁰ providing alternatives to cholera toxin B conjugates or BODIPY® FL C₅-ganglioside G_{M1}⁹¹ (B13950, B34401; Section 13.3) with the inherent advantages of long-lasting and titratable expression conferred by BacMam 2.0 vector technology (BacMam Gene Delivery and Expression Technology—Note 11.1).

Fluorescent Protein–Based Synaptic Vesicle Markers

CellLight® Synaptophysin-GFP (C10609) and CellLight® Synaptophysin-RFP (C10610) are valuable counterparts to FM® dyes for visualizing the distribution and density of presynaptic sites in neurons both *in vitro* and *in vivo*. Synaptophysin is a synaptic vesicle membrane glycoprotein that is involved in the biogenesis and fusion of synaptic vesicles but is not essential for neurotransmitter release. It is found in virtually all synaptically active neurons in the brain and spinal cord. These CellLight® reagents incorporate all the customary advantages of BacMam 2.0 delivery technology including high transduction efficiency and long-lasting and titratable expression (BacMam Gene Delivery and Expression Technology—Note 11.1).

Figure 16.1.27 Live J774 macrophage cells labeled with BODIPY® FL C₅-ganglioside G_{M1} and Alexa Fluor® 555 cholera toxin subunit B conjugate. Live J774 macrophage cells labeled with BODIPY® FL C₅-ganglioside G_{M1} (B13950) and then with Alexa Fluor® 555 cholera toxin subunit B conjugate (C22843; also available as a component of V34404). Cells were then treated with anti-CT-B antibody (a component of V34404) to induce crosslinking. Yellow fluorescence indicates colocalization of the two dyes. Nuclei were stained with the blue-fluorescent Hoechst 33342 dye (H1399, H3570, H21492).

Figure 16.1.28 A J774 mouse macrophage cell stained with BODIPY® FL ganglioside G_{M1} (B13950) and Alexa Fluor® 555 dye-labeled cholera toxin subunit B. A J774 mouse macrophage cell sequentially stained with BODIPY® FL ganglioside G_{M1} (B13950) and then with Alexa Fluor® 555 dye-labeled cholera toxin subunit B (C22843, C34776; also available as a component of V34404). The cell was then treated with an anti-CT-B antibody (a component of V34404) to induce crosslinking. Alexa Fluor® 555 dye fluorescence (top panel, red) and BODIPY® FL dye fluorescence (middle panel, green) were imaged separately and overlaid to emphasize the coincident staining (bottom panel, yellow). Nuclei were stained with blue-fluorescent Hoechst 33258 (H1398, H3569, H21491).

Figure 16.1.29 Peripheral neurons in mouse intestinal cryosections were labeled with rabbit anti-synapsin I antibody (A6442) and detected using Alexa Fluor® 488 goat anti-rabbit IgG antibody (A11008). This tissue was counterstained with DAPI (D1306, D3571, D21490).

Anti-Synapsin I Antibody

Synapsin I is an actin-binding protein that is localized exclusively to synaptic vesicles and thus serves as a reliable marker for synapses in brain and other neuronal tissues.²⁸³ Synapsin I inhibits neurotransmitter release, an effect that is abolished upon its phosphorylation by Ca^{2+} /calmodulin-dependent protein kinase II²⁸⁴ (CaM kinase II). Antibodies directed against synapsin I have proven valuable in molecular and neurobiology research, for example, to estimate synaptic density and to follow synaptogenesis.^{218,285}

We offer a rabbit polyclonal anti-bovine synapsin I antibody as an affinity-purified IgG fraction (A6442). This antibody was isolated from rabbits immunized against bovine brain synapsin I but is also active against human, rat and mouse forms of the antigen; it has little or no activity against synapsin II. The affinity-purified rabbit polyclonal antibody was fractionated from the serum using column chromatography in which bovine synapsin I was covalently bound to the column matrix. Affinity-purified anti-synapsin I antibody is suitable for immunohistochemistry (Figure 16.1.29), western blots, enzyme-linked immunosorbent assays and immunoprecipitations. Our complete selection of antibodies can be found at www.invitrogen.com/handbook/antibodies.

High Molecular Weight Polar Markers

Fluorescent Protein-Based Endosomal Markers

CellLight® Early Endosomes-GFP (O10104) and CellLight® Early Endosomes-RFP (O36231) provide BacMam expression vectors encoding fusions of GFP or RFP with the small GTPase Rab5a. Rab5a fusions with autofluorescent proteins are sensitive and precise early endosome markers for real-time imaging of clathrin-mediated endocytosis in live cells.^{276,286,287} These CellLight® reagents incorporate all the customary advantages of BacMam 2.0 delivery technology, including high transduction efficiency and long-lasting and titratable expression (BacMam Gene Delivery and Expression Technology—Note 11.1).

Figure 16.1.30 The pH sensitivity of pHrodo™ dextran. pHrodo™ 10,000 MW dextran (P10361) was reconstituted in HEPES (20 mM)-buffered PBS and adjusted to pH values from pH 4 to pH 10. The intensity of fluorescence emission increases with increasing acidity, particularly in the pH 5–8 range.

Figure 16.1.31 Time course of pHrodo™ *E. coli* BioParticles® (P35361) uptake by metastatic malignant melanoma cells. Cells were imaged at 37°C in the continued presence of 100 µg/mL pHrodo™ BioParticles®. Uptake of pHrodo™ BioParticles® was observable as early as 20 minutes and reached a plateau within 2 to 3 hours.

Table 16.3 BioParticles® fluorescent bacteria and yeast.

Label (Abs/Em Maxima in nm)	<i>Escherichia coli</i> (K-12 strain)	<i>Staphylococcus aureus</i> (Wood strain without protein A)	Zymosan A (<i>Saccharomyces cerevisiae</i>)
Fluorescein (494/518)	E2861	S2851	Z2841
Alexa Fluor® 488 (495/519)	E13231	S23371	Z23373
BODIPY® FL (505/513)	E2864	S2854	
Tetramethylrhodamine (555/580)	E2862		
pHrodo™ (560/585)	A10025, P35361	A10010	
Alexa Fluor® 594 (590/617)	E23370	S23372	Z23374
Texas Red® (595/615)	E2863		Z2843
Unlabeled		S2859	Z2849

We also offer opsonizing reagents for enhancing the uptake of BioParticles® products. These reagents are derived from purified rabbit polyclonal IgG antibodies that are specific for the *E. coli* (E2870), *S. aureus* (S2860) or zymosan (Z2850) particles. Reconstitution of the lyophilized opsonizing reagents requires only the addition of water, and one unit of opsonizing reagent is sufficient to opsonize ~10 mg of the corresponding BioParticles® product.

BioParticles® Fluorescent Bacteria and Yeast

The BioParticles® product line consists of a series of fluorescently labeled, heat- or chemically killed bacteria and yeast in a variety of sizes, shapes and natural antigenicities. These fluorescent BioParticles® products have been employed to study phagocytosis by fluorescence microscopy,^{288,289} quantitative spectrofluorometry²⁹⁰ and flow cytometry.^{288,291} We offer *Escherichia coli* (K-12 strain), *Staphylococcus aureus* (Wood strain without protein A) and zymosan (*Saccharomyces cerevisiae*) BioParticles® products covalently labeled with a variety of fluorophores, including Alexa Fluor®, fluorescein, BODIPY® FL, tetramethylrhodamine, Texas Red® and pHrodo™ dyes (Table 16.3). Special care has been taken to remove any free dye after conjugation. BioParticles® products are freeze-dried and ready for reconstitution in a buffer of choice and are supplied with a general protocol for measuring phagocytosis; we also offer opsonizing reagents for use with each particle type, as described below.

Unlike the fluorescence of fluorescein-labeled BioParticles® bacteria and yeast, which is strongly quenched in acidic environments, the fluorescence of the Alexa Fluor® 488, BODIPY® FL, tetramethylrhodamine and Texas Red® BioParticles® conjugates is uniformly intense between pH 3 and 10. This property is particularly useful for quantitating fluorescent bacteria and zymosan within acidic phagocytic vacuoles.

Fluorescent bacteria and yeast particles are proven tools for studying a variety of phagocytosis parameters. For example, they have been used to:

- Detect the phagocytosis of yeast by murine peritoneal macrophage²⁹² and human neutrophils²⁹⁰
- Determine the effects of different opsonization procedures on the efficiency of phagocytosis of pathogenic bacteria²⁹³ and yeast²⁹⁰
- Investigate the kinetics of phagocytosis degranulation and actin polymerization in stimulated leukocytes²⁹⁰
- Quantitate the effects of purinergic P2X₇ receptor activation on phagosomal maturation¹⁷⁹
- Show that *Dictyostelium discoideum* depleted of clathrin heavy chains are still able to undergo phagocytosis of fluorescent zymosans²⁹⁴
- Study molecular defects in phagocytic function¹⁷⁸

Vybrant® Phagocytosis Assay Kit

The Vybrant® Phagocytosis Assay Kit (V6694) provides a convenient set of reagents for quantitating phagocytosis and assessing the effects of certain drugs or conditions on this cellular process. In this assay, cells of interest are incubated first with green-fluorescent fluorescein-labeled *E. coli* BioParticles® conjugates, which are internalized by phagocytosis, and then with trypan blue, which quenches the fluorescence of any extracellular BioParticles® product (Figure 16.1.17). The methodology provided by this kit was developed using the adherent murine macrophage cell line J774,¹⁷⁶ however, researchers have adapted this assay to other phagocytic cell types²⁹⁵ and other instrument platforms such as flow cytometers.²⁹⁶ Each kit provides sufficient reagents for 250 tests using a 96-well microplate format and contains:

- BioParticles® fluorescein-labeled *Escherichia coli*
- Hanks' balanced salt solution (HBSS)
- Trypan blue
- Step-by-step instructions for performing the phagocytosis assay

pHrodo™ BioParticles® Fluorescent Bacteria

In contrast to both the fluorescein- and Alexa Fluor® dye-labeled BioParticles® conjugates, the fluorescence of the pHrodo™ *E. coli* and *S. aureus* BioParticles® conjugates (P35361, A10010) increases in acidic environments (Figure 16.1.30), providing a continuous positive indicator of phagocytic uptake. With a simple no-cell background subtraction method, a large and specific signal is obtained from cells that ingest the pHrodo™ BioParticles®, providing a specific index of phagocytosis in the context of a variety of pretreatments or conditions (Figure 16.1.31). The optimal absorption and fluorescence emission maxima of the pHrodo™ BioParticles® conjugates are approximately 560 nm and 585 nm, respectively, but the pHrodo™ fluorophore is also readily excited by the 488 nm spectral line of the argon-ion laser used in most flow cytometers.

With each pHrodo™ BioParticles® conjugate, we provide sufficient reagent for 100 microplate wells in a 96-well format, along with step-by-step instructions for performing phagocytosis assays in a fluorescence microplate reader. This methodology has been developed using adherent J774A.1 murine macrophage cells, but can be adapted for use with other adherent cells,¹⁷⁸ primary cells^{179,297} or cells in suspension,²⁹⁸ as well as for *in vivo* applications.²⁹⁹ Cells assayed for phagocytic activity with pHrodo™ BioParticles® conjugates may be fixed with standard formaldehyde solutions for later analysis, preserving differences in signal between control and experimental samples with high fidelity. pHrodo™ BioParticles® conjugate preparations are also amenable to opsonization (E2870, S2860), which can greatly enhance their uptake and signal strength in the phagocytosis assay.

To facilitate the use of pHrodo™ BioParticles® conjugates for the study of phagocytosis, we offer the pHrodo™ *E. coli* BioParticles® Phagocytosis Kit for Flow Cytometry (A10025), which provides the key reagents for assessing particle ingestion and red blood cell lysis (Figure 16.1.32). Each kit provides sufficient reagents for performing 100 assays when using sample volumes of 100 µL whole blood per assay, including:

- pHrodo™ *E. coli* BioParticles® conjugates
- Lysis and wash buffers
- Detailed protocols

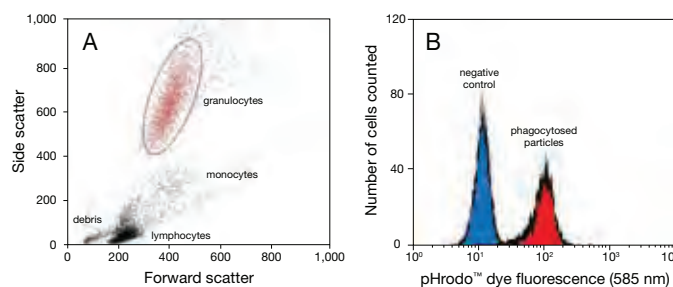

Figure 16.1.32 Flow cytometry analysis showing increased fluorescence of granulocytes treated with pHrodo™ *E. coli* BioParticles® (P35361). A whole blood sample was collected and treated with heparin, and two 100 µL aliquots were prepared. Both aliquots were treated with pHrodo™ BioParticles® and vortexed. One sample was placed in a 37°C water bath, and the other sample (negative control) was placed in an ice bath. After a 15-minute incubation, red blood cells were lysed with an ammonium chloride-based lysis buffer. The samples were centrifuged for 5 minutes at 500 rcf, washed once, and resuspended with HBSS. The samples were then analyzed on a BD FACSCalibur™ cytometer (BD Biosciences) using a 488 nm argon laser and 564–606 nm emission filter. A) Granulocytes were gated using forward and side scatter. B) The sample incubated at 37°C shows the increased fluorescence of the phagocytosed pHrodo™ BioParticles® (red), in contrast to the negative control sample, which was kept on ice to inhibit phagocytosis (blue).

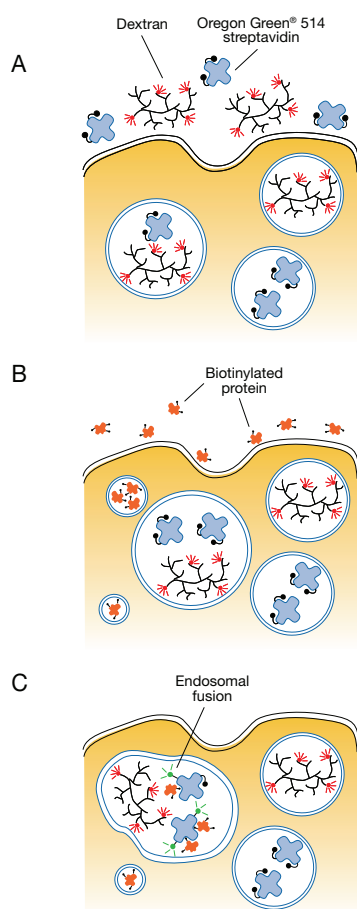

Figure 16.133 Detection of endosomal fusion. **A)** Cells are first incubated with a combination of a high molecular weight, red-fluorescent dextran (D1829, D1830, D1864) and the green-fluorescent Oregon Green® 514 streptavidin (S6369), which intrinsically has low fluorescence. **B)** The cells are then incubated with a biotinylated probe, e.g., biotinylated transferrin (T23363), and the excess conjugate is washed. **C)** Endosomal fusion is monitored by an increase in fluorescence of the Oregon Green® 514 dye as it is displaced by the biotinylated protein. The red-fluorescent dextran's fluorescence remains constant and allows for ratiometric measurements of the fused endosomes.

pHrodo™ Phagocytosis Particle Labeling Kit

In addition to the pHrodo™ BioParticles® conjugates, we offer the pHrodo™ Phagocytosis Particle Labeling Kit for Flow Cytometry (A10026), which allows rapid labeling of biological particles, such as bacteria, and subsequent assessment of phagocytic activity in whole blood samples by flow cytometry. Each kit provides sufficient reagents for performing 100 assays when using sample volumes of 100 μ L whole blood per assay, including:

- pHrodo™ succinimidyl ester
- Lysis and wash buffers
- Dimethylsulfoxide (DMSO)
- Sodium bicarbonate
- Detailed protocols

The amine-reactive pHrodo™ succinimidyl ester is also available separately (P36600, Section 20.4) for creating pH-sensitive conjugates for following phagocytosis. pHrodo™ succinimidyl ester was used to label dexamethasone-treated thymocytes for flow cytometry detection of phagocytosis by splenic or peritoneal macrophages.¹⁸⁰

Opsonizing Reagents and Nonfluorescent BioParticles® Products

Many researchers may want to use autologous serum to opsonize their fluorescent zymosan and bacterial particles; however, we also offer special opsonizing reagents (E2870, S2860, Z2850) for enhancing the uptake of each type of particle, along with a protocol for opsonization. These reagents are derived from purified rabbit polyclonal IgG antibodies that are specific for the *E. coli*, *S. aureus* or zymosan particles. Reconstitution of the lyophilized opsonizing reagents requires only the addition of water, and one unit of opsonizing reagent is sufficient to opsonize ~10 mg of the corresponding BioParticles® product.

In addition, we offer nonfluorescent zymosan (Z2849) and *S. aureus* (S2859) BioParticles® products. These nonfluorescent BioParticles® products are useful either as controls or for custom labeling with the reactive dye or indicator of interest.

Fluorescent Polystyrene Microspheres

Fluorescent polystyrene microspheres with diameters between 0.5 and 2.0 μ m have been used to investigate phagocytic processes in murine melanoma cells,³⁰⁰ human alveolar macrophages,²⁸⁹ ciliated protozoa¹³⁷ and *Dictyostelium discoideum*.^{301,302} The phagocytosis of fluorescent microspheres has been quantitated both with image analysis^{289,303,304} and with flow cytometry.³⁰⁵ Section 6.5 includes a detailed description of our full line of FluoSpheres® (Table 6.7) and TransFluoSpheres® (Table 6.9) fluorescent microspheres. Because of their low nonspecific binding, carboxylate-modified microspheres appear to be best for phagocytosis applications. For phagocytosis experiments involving multicolor detection, we particularly recommend our 1.0 μ m TransFluoSpheres® fluorescent microspheres³⁰⁶ (T8880, T8883; Section 6.5). Various opsonizing reagents, such as rabbit serum or fetal calf serum, have been used with the microspheres to facilitate phagocytosis.

Fluorescent Microspheres Coated with Collagen

Fibroblasts phagocytose and subsequently digest collagen. These activities play an important role in the remodeling of the extracellular matrix during normal physiological turnover of connective tissues and wound repair, as well as in development and aging. A well-established procedure for observing collagen phagocytosis by either flow cytometry or fluorescence microscopy entails the use of collagen-coated fluorescent microspheres that attach to the cell surface and become engulfed by fibroblasts.³⁰⁷ We offer yellow-green-fluorescent FluoSpheres® collagen I-labeled microspheres in either 1.0 μ m or 2.0 μ m diameter (F20892, F20893) for use in these applications. In the production of these microspheres, collagen I from calf skin is attached covalently to the microsphere's surface.

Fluorescent Dextrans

Tracing internalization of extracellularly introduced fluorescent dextrans is a standard method for analyzing fluid-phase endocytosis.^{2,73,308,309} We offer dextrans with nominal molecular weights ranging from 3000 to 2,000,000 daltons, many of which can also be used as pinocytosis or phagocytosis markers (see Section 14.5 and Table 14.4 for further discussion and a complete product list). Discrimination of internalized fluorescent dextrans from dextrans in the growth medium is facilitated by use of reagents that quench the fluorescence of the external probe. For example, most of our anti-fluorophore antibodies (Section 7.4, Table 7.8) strongly quench the fluorescence of the corresponding dyes.

Negative staining produced by fluorescent dextrans that have been intracellularly infused via a patch pipette is indicative of nonendocytic vacuoles in live pancreatic acinar cells.³¹⁰ Extracellular addition of a second, color-contrasting dextran then allows discrimination of endocytic and nonendocytic vacuoles. Intracellular fusion of endosomes has been monitored with a BODIPY® FL avidin conjugate by following the fluorescence enhancement that occurs when it complexes with a biotinylated dextran.³¹¹ We have found our Oregon Green® 514 streptavidin (S6369, Section 7.6) to have an over 15-fold increase in fluorescence intensity upon binding free biotin, which may make it the preferred probe for this application (Figure 16.1.33).

pH Indicator Dextrans

The fluorescein dextrans ($pK_a \sim 6.4$) are frequently used to investigate endocytic acidification.^{312,313} Fluorescence of fluorescein-labeled dextrans is strongly quenched upon acidification; however, fluorescein's lack of a spectral shift in acidic solution makes it difficult to discriminate between an internalized probe that is quenched and residual fluorescence of the external medium. Dextran conjugates that either shift their emission spectra in acidic environments, such as the SNARF® dextrans (Section 20.4), or undergo significant shifts of their excitation spectra, such as BCECF and Oregon Green® dextrans (Section 20.4), provide alternatives to fluorescein. The Oregon Green® 488 and Oregon Green® 514 dextrans exhibit a pK_a of approximately 4.7, facilitating measurements in acidic environments.^{312,314} In addition to these pH indicator dextrans, we prepare a dextran that is double-labeled with fluorescein and tetramethylrhodamine (D1951; Section 20.4), which has been used as a ratiometric indicator (Figure 16.1.34) to measure endosomal acidification in Hep G2 cells³¹⁵ and murine alveolar macrophages.¹⁷⁸

In contrast to fluorescein and Oregon Green® 488 dextrans, pHrodo™ 10,000 MW dextran (P10361) exhibits increasing fluorescence in response to acidification¹⁷⁸ (Figure 16.1.30). The minimal fluorescent signal from pHrodo™ dextran at neutral pH prevents the detection of noninternalized and nonspecifically bound conjugates and eliminates the need for quenching reagents and extra wash steps, thus providing a simple fluorescent assay for endocytic activity. pHrodo™ dextran's excitation and emission maxima of 560 and 585 nm, respectively, facilitate multiplexing with other fluorophores including blue-, green- and far-red-fluorescent probes. Although pHrodo™ dextran is optimally excited at approximately 560 nm, it is also readily excited by the 488 nm spectral line of the argon-ion laser found on flow cytometers, confocal microscopes and imaging microplate readers (Figure 16.1.18).

Low Molecular Weight Polar Markers

Hydrophilic fluorescent dyes—including sulforhodamine 101 (S359), lucifer yellow CH (L453), calcein (C481), 8-hydroxypyrene-1,3,6-trisulfonic acid (HPTS, pyranine; H348) and Cascade Blue® hydrazide (C687)—are taken up by actively firing neurons through endocytic recycling of the synaptic vesicles.^{316,317} Unlike the fluorescent FM® membrane probes described above, however, the hydrophilic fluorophores appear to work for only a limited number of species in this application. In some tissue preparations, background due to noninternalized polar markers is easier to wash away than that emanating from membrane markers such as FM® 1-43.³¹⁶ The same dyes have frequently been used as fluid-phase markers of pinocytosis.^{318–321} The highly water-soluble Alexa Fluor® hydrazides and Alexa Fluor® hydroxylamines (Section 14.3, Table 3.2) provide superior spectral properties and can be fixed in cells by aldehyde-based fixatives.³²²

Figure 16.1.34 The excitation spectra of double-labeled fluorescein-tetramethylrhodamine dextran (D1951), which contains pH-dependent (fluorescein) and pH-independent (tetramethylrhodamine) dyes.

S359	606.71	L	H ₂ O	586	108,000	605	H ₂ O	
T204	461.62	D,L	DMF, DMSO	355	75,000	430	MeOH	22
T1111	581.48	D,L	DMSO, EtOH	532	55,000	716	MeOH	4, 23
T3163	611.55	D,L	H ₂ O, DMSO	471	38,000	581	see Notes	24, 25
T3166	607.51	D,L	H ₂ O, DMSO	505	47,000	725	see Notes	24, 26
T7508	555.44	D,L	H ₂ O, DMSO	506	50,000	620	MeOH	4
T13320	607.51	D,L	H ₂ O, DMSO	505	47,000	725	see Notes	24, 26
T23360	565.43	D,L	H ₂ O, DMSO	560	43,000	734	CHCl ₃	26
T35356	611.55	D,L	H ₂ O, DMSO	471	38,000	581	see Notes	24, 25

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- C481 fluorescence is strongly quenched by micromolar concentrations of Fe³⁺, Co²⁺, Ni²⁺ and Cu²⁺ at pH 7. (Am J Physiol (1995) 268:C1354, J Biol Chem (1999) 274:13375)
- The Alexa Fluor® 405 and Cascade Blue® dyes have a second absorption peak at about 376 nm with EC ~80% of the 395–400 nm peak.
- Maximum solubility in water is ~1% for C687, ~1% for C3221 and ~8% for C3239.
- Abs and Em of styryl dyes are at shorter wavelengths in membrane environments than in reference solvents such as methanol. The difference is typically 20 nm for absorption and 80 nm for emission, but varies considerably from one dye to another. Styryl dyes are generally nonfluorescent in water.
- Dihydrofluorescein diacetates are colorless and nonfluorescent until both of the acetate groups are hydrolyzed and the products are subsequently oxidized to fluorescein derivatives. The materials contain less than 0.1% of oxidized derivative when initially prepared. The oxidation products of C400, C2938, C6827, D399 and D2935 are 2',7'-dichlorofluorescein derivatives with spectra similar to C368 (see data).
- α-Bungarotoxin, EGF and phallotoxin conjugates have approximately 1 label per peptide.
- The value of EC listed for this EGF conjugate is for the labeling dye in free solution. Use of this value for the conjugate assumes a 1:1 dye:peptide labeling ratio and no change of EC due to dye-peptide interactions.
- ND = not determined.
- E3480 is a complex of E3477 with Texas Red® streptavidin, which typically incorporates 3 dyes/streptavidin (MW ~52,800).
- E13345 is a complex of E3477 with Alexa Fluor® 488 streptavidin, which typically incorporates 5 dyes/streptavidin (MW ~52,800).
- E35350 is a complex of E3477 with Alexa Fluor® 555 streptavidin, which typically incorporates 3 dyes/streptavidin (MW ~52,800).
- E35351 is a complex of E3477 with Alexa Fluor® 647 streptavidin, which typically incorporates 3 dyes/streptavidin (MW ~52,800).
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- F2902 is essentially colorless and nonfluorescent until oxidized. A small amount (~5%) of oxidized material is normal and acceptable for the product as supplied. The oxidation product is fluorescent (Abs = 495 nm, Em = 524 nm). (J Immunol Methods (1990) 130:223)
- This product consists of a dye-bovine serum albumin conjugate (MW ~66,000) complexed with IgG in a ratio of approximately 1:4 mol:mol (BSA:IgG)
- H348 spectra are pH-dependent.
- The fluorescence quantum yield of lucifer yellow CH in H₂O is 0.21. (J Am Chem Soc (1981) 103:7615)
- Maximum solubility in water is ~8% for L453, ~6% for L682 and ~1% for L1177.
- LDL complexes must be stored refrigerated BUT NOT FROZEN. The maximum shelf-life under the indicated storage conditions is 4–6 weeks.
- This LDL complex incorporates multiple fluorescent labels. The number of dyes per apoprotein B (MW ~500,000) is indicated on the product label.
- LDL complexes are packaged under argon in 10 mM Tris, 150 mM NaCl, 0.3 mM EDTA, pH 8.3 containing 2 mM azide. Spectral data reported are measured in this buffer.
- Diphenylhexatriene (DPH) and its derivatives are essentially nonfluorescent in water. Absorption and emission spectra have multiple peaks. The wavelength, resolution and relative intensity of these peaks are environment dependent. Abs and Em values are for the most intense peak in the solvent specified.
- RH 414 Abs ~500 nm, Em ~635 nm when bound to phospholipid bilayer membranes.
- Abs, EC and Em determined for dye bound to detergent micelles (20 mg/mL CHAPS in H₂O). These dyes are essentially nonfluorescent in pure water.
- FM® 1-43 Abs = 479 nm, Em = 598 nm bound to phospholipid bilayer membranes. Em = 565 nm bound to synaptosomal membranes. (Neuron (1994) 12:1235)
- FM® 4-64 and FM® 5-95 are nonfluorescent in water. For two-color imaging in GFP-expressing cells, these dyes can be excited at 568 nm with emission detection at 690–730 nm. (Am J Physiol Cell Physiol (2001) 281:C624)

PRODUCT LIST 16.1 PROBES FOR FOLLOWING RECEPTOR BINDING AND PHAGOCYTOSIS

Cat. No.	Product	Quantity
A6442	anti-synapsin I (bovine), rabbit IgG fraction *affinity purified*	10 µg
A11130	anti-transferrin receptor (human), mouse IgG ₁ , monoclonal 236-15375	50 µg
C481	calcein *high purity*	100 mg
C687	Cascade Blue® hydrazide, trisodium salt	10 mg
C2990	casein, fluorescein conjugate	25 mg
C10586	CellLight® Early Endosomes-GFP	1 kit
C10587	CellLight® Early Endosomes-RFP	1 kit
C10609	CellLight® Synaptophysin-GFP	1 kit
C10610	CellLight® Synaptophysin-RFP	1 kit
C34775	cholera toxin subunit B (recombinant), Alexa Fluor® 488 conjugate	100 µg
C22841	cholera toxin subunit B (recombinant), Alexa Fluor® 488 conjugate	500 µg
C34776	cholera toxin subunit B (recombinant), Alexa Fluor® 555 conjugate	100 µg
C22843	cholera toxin subunit B (recombinant), Alexa Fluor® 555 conjugate	500 µg
C34777	cholera toxin subunit B (recombinant), Alexa Fluor® 594 conjugate	100 µg
C22842	cholera toxin subunit B (recombinant), Alexa Fluor® 594 conjugate	500 µg
C34778	cholera toxin subunit B (recombinant), Alexa Fluor® 647 conjugate	100 µg
C34779	cholera toxin subunit B (recombinant), biotin-XX conjugate	100 µg
C34780	cholera toxin subunit B (recombinant), horseradish peroxidase conjugate	100 µg
D1383	dexamethasone fluorescein	5 mg
D2935	2,7'-dichlorodihydrofluorescein diacetate, succinimidyl ester (OxyBURST® Green H ₂ DCFDA, SE)	5 mg
D289	4-(4-(diethylamino)styryl)-N-methylpyridinium iodide (4-Di-2-ASP)	1 g
D288	4-(4-(dimethylamino)styryl)-N-methylpyridinium iodide (4-Di-1-ASP)	1 g
D12060	DQ™ collagen, type I from bovine skin, fluorescein conjugate	1 mg
D12054	DQ™ gelatin from pig skin, fluorescein conjugate *special packaging*	5 x 1 mg
D12050	DQ™ Green BSA *special packaging*	5 x 1 mg
D12053	DQ™ ovalbumin *special packaging*	5 x 1 mg
D12051	DQ™ Red BSA *special packaging*	5 x 1 mg
E3476	epidermal growth factor (EGF) *from mouse submaxillary glands*	100 µg
E3477	epidermal growth factor, biotin-XX conjugate (biotin EGF)	20 µg
E13345	epidermal growth factor, biotinylated, complexed to Alexa Fluor® 488 streptavidin (Alexa Fluor® 488 EGF complex)	100 µg
E35350	epidermal growth factor, biotinylated, complexed to Alexa Fluor® 555 streptavidin (Alexa Fluor® 555 EGF complex)	100 µg
E35351	epidermal growth factor, biotinylated, complexed to Alexa Fluor® 647 streptavidin (Alexa Fluor® 647 EGF complex)	100 µg
E3480	epidermal growth factor, biotinylated, complexed to Texas Red® streptavidin (Texas Red® EGF complex)	100 µg
E3478	epidermal growth factor, fluorescein conjugate (fluorescein EGF)	20 µg
E7498	epidermal growth factor, Oregon Green® 514 conjugate (Oregon Green® 514 EGF)	20 µg
E3481	epidermal growth factor, tetramethylrhodamine conjugate (rhodamine EGF)	20 µg
E2870	<i>Escherichia coli</i> BioParticles® opsonizing reagent	1 U
E13231	<i>Escherichia coli</i> (K-12 strain) BioParticles®, Alexa Fluor® 488 conjugate	2 mg
E23370	<i>Escherichia coli</i> (K-12 strain) BioParticles®, Alexa Fluor® 594 conjugate	2 mg
E2864	<i>Escherichia coli</i> (K-12 strain) BioParticles®, BODIPY® FL conjugate	10 mg
E2861	<i>Escherichia coli</i> (K-12 strain) BioParticles®, fluorescein conjugate	10 mg
E2862	<i>Escherichia coli</i> (K-12 strain) BioParticles®, tetramethylrhodamine conjugate	10 mg
E2863	<i>Escherichia coli</i> (K-12 strain) BioParticles®, Texas Red® conjugate	10 mg
F2902	Fc OxyBURST® Green assay reagent *25 assays* *3 mg/mL*	500 µL
F13191	fibrinogen from human plasma, Alexa Fluor® 488 conjugate	5 mg
F13192	fibrinogen from human plasma, Alexa Fluor® 546 conjugate	5 mg
F13193	fibrinogen from human plasma, Alexa Fluor® 594 conjugate	5 mg
F35200	fibrinogen from human plasma, Alexa Fluor® 647 conjugate	5 mg
F7496	fibrinogen from human plasma, Oregon Green® 488 conjugate	5 mg
F20892	FluoSpheres® collagen I-labeled microspheres, 1.0 µm, yellow-green fluorescent (505/515) *0.5% solids*	0.4 mL
F20893	FluoSpheres® collagen I-labeled microspheres, 2.0 µm, yellow-green fluorescent (505/515) *0.5% solids*	0.4 mL
F35355	FM® 1-43FX *fixable analog of FM® 1-43 membrane stain*	10 x 100 µg
F34653	FM® 4-64FX *fixable analog of FM® 4-64 membrane stain*	10 x 100 µg
F1314	formyl-Nle-Leu-Phe-Nle-Tyr-Lys, fluorescein derivative	1 mg
G13187	gelatin from pig skin, fluorescein conjugate	5 mg
G13186	gelatin from pig skin, Oregon Green® 488 conjugate	5 mg
H13188	histone H1 from calf thymus, Alexa Fluor® 488 conjugate	1 mg
H348	8-hydroxypyrene-1,3,6-trisulfonic acid, trisodium salt (HPTS; pyranine)	1 g
I13269	insulin, human, recombinant from <i>E. coli</i> , fluorescein conjugate (FITC insulin) *monolabeled* *zinc free*	100 µg

PRODUCT LIST 16.1 PROBES FOR FOLLOWING RECEPTOR BINDING AND PHAGOCYTOSIS—continued

Cat. No.	Product	Quantity
L21409	lectin PNA from <i>Arachis hypogaea</i> (peanut), Alexa Fluor® 488 conjugate	1 mg
L32458	lectin PNA from <i>Arachis hypogaea</i> (peanut), Alexa Fluor® 568 conjugate	1 mg
L32459	lectin PNA from <i>Arachis hypogaea</i> (peanut), Alexa Fluor® 594 conjugate	1 mg
L32460	lectin PNA from <i>Arachis hypogaea</i> (peanut), Alexa Fluor® 647 conjugate	1 mg
L23351	lipopolysaccharides from <i>Escherichia coli</i> serotype 055:B5, Alexa Fluor® 488 conjugate	100 µg
L23352	lipopolysaccharides from <i>Escherichia coli</i> serotype 055:B5, Alexa Fluor® 568 conjugate	100 µg
L23353	lipopolysaccharides from <i>Escherichia coli</i> serotype 055:B5, Alexa Fluor® 594 conjugate	100 µg
L23350	lipopolysaccharides from <i>Escherichia coli</i> serotype 055:B5, BODIPY® FL conjugate	100 µg
L23356	lipopolysaccharides from <i>Salmonella minnesota</i> , Alexa Fluor® 488 conjugate	100 µg
L3486	low-density lipoprotein from human plasma (LDL) *2.5 mg/mL*	200 µL
L35354	low-density lipoprotein from human plasma, acetylated (AcLDL) *2.5 mg/mL*	200 µL
L23380	low-density lipoprotein from human plasma, acetylated, Alexa Fluor® 488 conjugate (Alexa Fluor® 488 AcLDL) *1 mg/mL*	200 µL
L35353	low-density lipoprotein from human plasma, acetylated, Alexa Fluor® 594 conjugate (Alexa Fluor® 594 AcLDL) *1 mg/mL*	200 µL
L3485	low-density lipoprotein from human plasma, acetylated, BODIPY® FL conjugate (BODIPY® FL AcLDL) *1 mg/mL*	200 µL
L3484	low-density lipoprotein from human plasma, acetylated, Dil complex (Dil AcLDL) *1 mg/mL*	200 µL
L3483	low-density lipoprotein from human plasma, BODIPY® FL complex (BODIPY® FL LDL) *1 mg/mL*	200 µL
L3482	low-density lipoprotein from human plasma, Dil complex (Dil LDL) *1 mg/mL*	200 µL
L453	lucifer yellow CH, lithium salt	25 mg
O13291	OxyBURST® Green H ₂ HFF BSA *special packaging*	5 x 1 mg
P10361	pHrodo™ dextran, 10,000 MW *for endocytosis*	0.5 mg
P35361	pHrodo™ <i>E. coli</i> BioParticles® conjugate for phagocytosis	5 x 2 mg
A10025	pHrodo™ <i>E. coli</i> BioParticles® Phagocytosis Kit *for flow cytometry* *100 tests*	1 kit
A10026	pHrodo™ Phagocytosis Particle Labeling Kit *for flow cytometry* *100 tests*	1 kit
A10010	pHrodo™ <i>S. aureus</i> BioParticles® conjugate for phagocytosis	5 x 2 mg
S2860	<i>Staphylococcus aureus</i> BioParticles® opsonizing reagent	1 U
S23371	<i>Staphylococcus aureus</i> (Wood strain without protein A) BioParticles®, Alexa Fluor® 488 conjugate	2 mg
S23372	<i>Staphylococcus aureus</i> (Wood strain without protein A) BioParticles®, Alexa Fluor® 594 conjugate	2 mg
S2854	<i>Staphylococcus aureus</i> (Wood strain without protein A) BioParticles®, BODIPY® FL conjugate	10 mg
S2851	<i>Staphylococcus aureus</i> (Wood strain without protein A) BioParticles®, fluorescein conjugate	10 mg
S2859	<i>Staphylococcus aureus</i> (Wood strain without protein A) BioParticles®, unlabeled	100 mg
S359	sulforhodamine 101	25 mg
T204	TMA-DPH (1-(4-trimethylammoniumphenyl)-6-phenyl-1,3,5-hexatriene <i>p</i> -toluenesulfonate)	25 mg
T13342	transferrin from human serum, Alexa Fluor® 488 conjugate	5 mg
T23364	transferrin from human serum, Alexa Fluor® 546 conjugate	5 mg
T35352	transferrin from human serum, Alexa Fluor® 555 conjugate	5 mg
T23365	transferrin from human serum, Alexa Fluor® 568 conjugate	5 mg
T13343	transferrin from human serum, Alexa Fluor® 594 conjugate	5 mg
T23362	transferrin from human serum, Alexa Fluor® 633 conjugate	5 mg
T23366	transferrin from human serum, Alexa Fluor® 647 conjugate	5 mg
T35357	transferrin from human serum, Alexa Fluor® 680 conjugate	5 mg
T23363	transferrin from human serum, biotin-XX conjugate	5 mg
T2871	transferrin from human serum, fluorescein conjugate	5 mg
T2872	transferrin from human serum, tetramethylrhodamine conjugate	5 mg
T2875	transferrin from human serum, Texas Red® conjugate	5 mg
T3163	<i>N</i> -(3-triethylammoniumpropyl)-4-(4-(dibutylamino)styryl)pyridinium dibromide (FM® 1-43)	1 mg
T35356	<i>N</i> -(3-triethylammoniumpropyl)-4-(4-(dibutylamino)styryl)pyridinium dibromide (FM® 1-43) *special packaging*	10 x 100 µg
T1111	<i>N</i> -(3-triethylammoniumpropyl)-4-(4-(diethylamino)phenyl)butadienylpyridinium dibromide (RH 414)	5 mg
T3166	<i>N</i> -(3-triethylammoniumpropyl)-4-(6-(4-(diethylamino)phenyl)hexatrienyl)pyridinium dibromide (FM® 4-64)	1 mg
T13320	<i>N</i> -(3-triethylammoniumpropyl)-4-(6-(4-(diethylamino)phenyl)hexatrienyl)pyridinium dibromide (FM® 4-64) *special packaging*	10 x 100 µg
T7508	<i>N</i> -(3-triethylammoniumpropyl)-4-(4-(diethylamino)styryl)pyridinium dibromide (FM® 2-10)	5 mg
T23360	<i>N</i> -(3-trimethylammoniumpropyl)-4-(6-(4-(diethylamino)phenyl)hexatrienyl)pyridinium dibromide (FM® 5-95)	1 mg
T23011	trypsin inhibitor from soybean, Alexa Fluor® 488 conjugate	1 mg
V6694	Vybrant® Phagocytosis Assay Kit *250 assays*	1 kit
Z2850	zymosan A BioParticles® opsonizing reagent	1 U
Z23373	zymosan A (<i>S. cerevisiae</i>) BioParticles®, Alexa Fluor® 488 conjugate	2 mg
Z23374	zymosan A (<i>S. cerevisiae</i>) BioParticles®, Alexa Fluor® 594 conjugate	2 mg
Z2841	zymosan A (<i>S. cerevisiae</i>) BioParticles®, fluorescein conjugate	10 mg
Z2843	zymosan A (<i>S. cerevisiae</i>) BioParticles®, Texas Red® conjugate	10 mg
Z2849	zymosan A (<i>S. cerevisiae</i>) BioParticles®, unlabeled	100 mg

16.2 Probes for Neurotransmitter Receptors

Fluorescent receptor ligands provide a sensitive means of identifying and localizing various cellular receptors, ion channels and ion carriers. Many of these site-selective fluorescent probes may be used on live or fixed cells, as well as in cell-free extracts. The high sensitivity and selectivity of these fluorescent probes make them especially good candidates for measuring low-abundance receptors.^{1–5} Various methods for further amplifying detection of these receptors^{6,7} are discussed in Chapter 6 and Chapter 7.

This section is devoted to our probes for neurotransmitter receptors. Additional fluorescently labeled receptor ligands (including low-density lipoproteins, epidermal growth factors, transferrin and fibrinogen conjugates and chemotactic peptides) are described in Section 16.1, along with other probes for studying receptor-mediated endocytosis. Section 16.3 describes a variety of probes for Ca²⁺, Na⁺, K⁺ and Cl[−] ion channels and carriers. Chapter 17 focuses on reagents for investigating events—such as calcium regulation, kinase, phosphatase and phospholipase activation, and lipid trafficking—that occur downstream from the receptor–ligand interaction (Figure 16.2.1).

α-Bungarotoxin Probes for Nicotinic Acetylcholine Receptors

Fluorescent α-Bungarotoxins

Nicotinic acetylcholine receptors (nAChRs) are neurotransmitter-gated ion channels that produce an increase in Na⁺ and K⁺ permeability, depolarization and excitation upon activation by acetylcholine⁸ (Figure 16.2.1). α-Bungarotoxin is a 74–amino acid (~8000 dalton) peptide containing 5 lysine residues and 10 cysteine residues paired in 5 disulfide bridges. Extracted from *Bungarus multicinctus* venom, α-bungarotoxin binds with high affinity to the α-subunit of the nAChR of neuromuscular junctions.⁹ We provide an extensive selection of fluorescent α-bungarotoxin conjugates (Table 16.4) to facilitate visualization of nAChRs with a variety of instrumentation. We attach approximately one fluorophore to each molecule of α-bungarotoxin, thus retaining optimal binding specificity. The labeled bungarotoxins are then chromatographically separated from unlabeled molecules to ensure adequate labeling of the product.

Alexa Fluor® 488 α-bungarotoxin (B13422) has fluorescence spectra similar to those of fluorescein α-bungarotoxin (F1176) and is

therefore suitable for use with standard fluorescein optical filter sets. Tetramethylrhodamine α-bungarotoxin^{10–12} (T1175) has been the preferred red–orange–fluorescent probe for staining the nAChR (Figure 16.2.2). We not only offer the red–orange–fluorescent Alexa Fluor® 555 α-bungarotoxin (B35451), but also the red–fluorescent Alexa Fluor® 594 α-bungarotoxin (B13423), which has a longer-wavelength emission maximum and therefore offers better spectral separation from green–fluorescent dyes in multicolor experiments. Our two longest-wavelength conjugates—Alexa Fluor® 647 α-bungarotoxin (B35450) and Alexa Fluor® 680 α-bungarotoxin (B35452)—are spectrally separated from both green–fluorescent and orange–fluorescent dyes, allowing researchers to easily perform three- and four-color experiments.

Fluorescent α-bungarotoxins have been used in a variety of informative investigations to:

- Correlate receptor clustering during neuromuscular development with tyrosine phosphorylation of the receptor^{13,14}
- Detect reinnervation of adult muscle after nerve damage and to identify and visualize endplates^{15,16}
- Document nAChR cluster formation after myoblast fusion.¹⁷
- Label proteins fused to the BBS expression tag (a 13–amino acid sequence excerpted from the nAChR) *in situ*^{18,19}
- Monitor nAChR-mediated responses in neuromuscular damage and degeneration models^{20–22}

Biotinylated α-Bungarotoxin

Nicotinic AChRs can also be labeled with biotinylated α-bungarotoxin (B1196), which is then localized using fluorophore- or enzyme-labeled avidin, streptavidin or NeutrAvidin biotin-binding protein conjugates, or NANOGOLD and Alexa Fluor® FluoroNanogold streptavidin^{14,23–25} (Section 7.6, Table 7.9). Based on the intracellular dissociation of biotinylated α-bungarotoxin and streptavidin, researchers were able to distinguish new, preexisting and recycled pools of nAChR at the synapses of live mice by sequentially labeling with biotinylated α-bungarotoxin and fluorescent streptavidin conjugates.²⁶ Complexation of biotinylated α-bungarotoxin with Qdot® nanocrystal–streptavidin conjugates (Section 6.6) enables single-molecule detection of nAChR.^{1,2} The nanocrystal labeling methodology allows detection and tracking of diffuse, nonclustered nAChRs, whereas dye-labeled α-bungarotoxin conjugates primarily detect nAChR clusters.¹

Table 16.4 Labeled and unlabeled α-bungarotoxins.

Cat. No.	Label	Ex/Em (nm)	Notes	Size
F1176	Fluorescein	494/518	Original green-fluorescent conjugate	500 µg
B13422	Alexa Fluor® 488	495/519	Brightest and most photostable green-fluorescent conjugate	500 µg
T1175	Tetramethylrhodamine	553/577	An extensively used red–orange–fluorescent conjugate	500 µg
B35451	Alexa Fluor® 555	555/565	Bright and photostable red–orange–fluorescent conjugate	500 µg
B13423	Alexa Fluor® 594	590/617	Excellent dye to combine with green-fluorescent probes	500 µg
B35450	Alexa Fluor® 647	650/668	Excellent dye to combine with green- and orange-fluorescent probes	500 µg
B35452	Alexa Fluor® 680	679/702	Excellent dye to combine with green-, orange-, and red-fluorescent probes	500 µg
B1196	Biotin-XX	NA	Visualized with labeled avidins and streptavidins (Table 7.9)	500 µg
B1601	Unlabeled	NA	Useful as a control, as well as for radioiodination and for preparation of new conjugates	1 mg

NA = Not applicable.

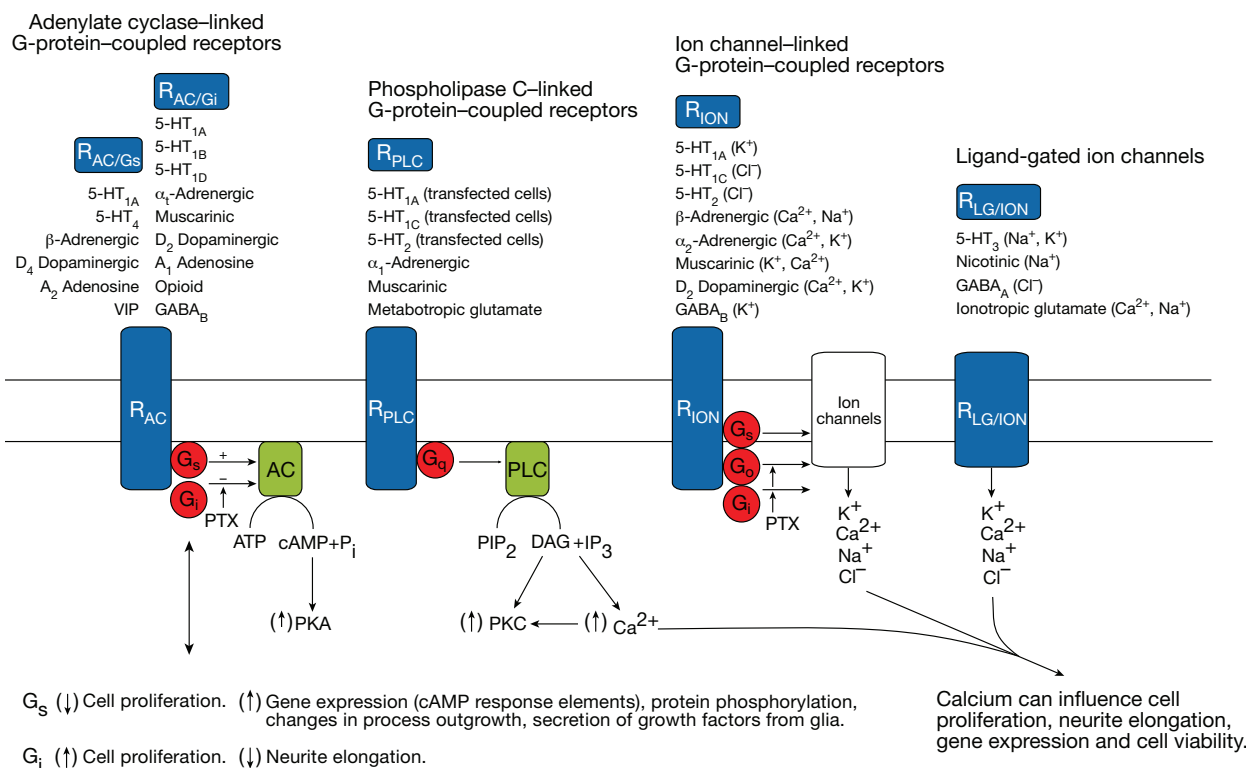

Figure 16.2.1 Neurotransmitter receptors linked to second messengers mediating growth responses in neuronal and nonneuronal cells. Abbreviations: R_{AC/Gs} = Receptors coupled to G-proteins that stimulate adenylate cyclase (AC) activity, leading to cAMP formation and enhanced activity of protein kinase A (PKA). R_{AC/Gi} = Receptors coupled to pertussis toxin (PTX)-sensitive G-proteins that inhibit adenylate cyclase activity. R_{PLC} = Receptors promoting the hydrolysis of phosphatidylinositol 4,5-diphosphate (PIP₂) to inositol 1,4,5-triphosphate (IP₃), which increases intracellular Ca²⁺, and diacylglycerol (DAG), which activates protein kinase C (PKC). R_{ION} = Receptors indirectly promoting ion fluxes due to coupling to various G-proteins. R_{LG/ION} = Receptors that promote ion fluxes directly because they are structurally linked to ion channels (members of the superfamily of ligand-gated ion channel receptors). Stimulation of proliferation is most often associated with activation of G-proteins negatively coupled to adenylate cyclase (G_i), or positively coupled to phospholipase C (G_q) or to pertussis toxin-sensitive pathways (G_o, G_i). In contrast, activation of neurotransmitter receptors positively coupled to cAMP usually inhibits cell proliferation and causes changes in cell shape indicative of differentiation. Reprinted and modified with permission from J.M. Lauder and Trends Neurosci (1993) 16:233.

In addition, the biotinylated toxin can be employed for affinity isolation of the nAChR using a streptavidin or CaptAvidin™ agarose (S951, C21386; Section 7.6) column.^{27,28}

Unlabeled α-Bungarotoxin

In addition to the fluorescent and biotinylated derivatives, we have unlabeled α-bungarotoxin (B1601), which has been shown to be useful for radioiodination.^{9,29} Unlabeled α-bungarotoxin has also been employed for ELISA testing of nAChR binding,³⁰ as well as for investigating the function of the α-bungarotoxin-binding component (α-BgtBC) in vertebrate neurons.³¹

Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit

The action of acetylcholine (ACh) at neuromuscular junctions is regulated by acetylcholinesterase (AChE), the enzyme that hydrolyzes ACh to choline and acetate. The Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit (A12217) provides an ultrasensitive method for continuously monitoring AChE activity and for detecting ACh in a fluorescence microplate reader or fluorometer. Other potential uses for this kit include screening for AChE inhibitors and measuring the release of ACh from synaptosomes. The Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit can also be used for the ultrasensitive, specific assay of free choline, classified as an essential nutrient in foods.³²

Figure 16.2.2 Pseudocolored photomicrograph of the synaptic region of fluorescently labeled living muscle fibers from the lumbricalis muscle of the adult frog *Rana pipiens*. Six hours after isolation of the muscle fibers, acetylcholine receptors were stained with red-fluorescent tetramethylrhodamine α-bungarotoxin (T1175) and myonuclei were stained with the green-fluorescent SYTO® 13 live-cell nucleic acid stain (S7575). Photo contributed by Christian Brösamle, Brain Research Institute, University of Zurich, and Damien Kuffler, Institute of Neurobiology, University of Puerto Rico.

Figure 16.2.3 Absorption and fluorescence emission spectra of resorufin in pH 9.0 buffer.

Figure 16.2.4 Detection of electric eel acetylcholinesterase activity using the Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit (A12217). Each reaction contained 50 μ M acetylcholine, 200 μ M Amplex® Red reagent, 1 U/mL HRP, 0.1 U/mL choline oxidase and the indicated amount of acetylcholinesterase in 1X reaction buffer. Reactions were incubated at room temperature. After 15 and 60 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 560 ± 10 nm and fluorescence detection at 590 ± 10 nm. The inset shows the sensitivity of the 15 min (□) and 60 min (●) assays at low levels of acetylcholinesterase activity (0–13 mU/mL).

Figure 16.2.5 Detection of acetylcholine using the Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit (A12217). Each reaction contained 200 μ M Amplex® Red reagent, 1 U/mL HRP, 0.1 U/mL choline oxidase, 0.5 U/mL acetylcholinesterase and the indicated amount of acetylcholine in 1X reaction buffer. Reactions were incubated at room temperature. After 15 and 60 minutes, fluorescence was measured with a fluorescence microplate reader using excitation at 560 ± 10 nm and fluorescence detection at 590 ± 10 nm. The inset shows the sensitivity of the 15 min (□) and 60 min (●) assays at low levels of acetylcholine (0–3 μ M).

In this assay, AChE activity is monitored indirectly using the Amplex® Red reagent (10-acetyl-3,7-dihydroxyphenoxazine), a highly sensitive and stable fluorogenic probe for H_2O_2 that is also useful in assaying other enzymes and analytes (Section 10.5). First, AChE converts the acetylcholine substrate to choline. Choline is in turn oxidized by choline oxidase to betaine and H_2O_2 , the latter of which, in the presence of horseradish peroxidase, reacts with the Amplex® Red reagent to generate the red-fluorescent product resorufin (R363, Section 10.1) with excitation/emission maxima of $\sim 570/585$ nm (Figure 16.2.3). Experiments with purified AChE from electric eel indicate that the Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit can detect AChE levels as low as 0.002 U/mL using a reaction time of only 1 hour (Figure 16.2.4). In our laboratories, we have been able to detect acetylcholinesterase activity from a tissue sample with total protein content as low as 200 ng/mL or 20 ng/well in a microplate assay.³³ By providing an excess of AChE in the assay, the kit can also be used to detect acetylcholine levels as low as 0.3 μ M, with a detection range between 0.3 μ M and ~ 100 μ M acetylcholine (Figure 16.2.5).

The Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- H_2O_2 for use as a positive control
- Concentrated reaction buffer
- Choline oxidase from *Alcaligenes* sp.
- Acetylcholine (ACh)
- Acetylcholinesterase (AChE) from electric eel
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using a fluorescence microplate reader and a reaction volume of 200 μ L per assay.

BODIPY® FL Prazosin for α_1 -Adrenergic Receptors

Prazosin is a high-affinity antagonist for the α_1 -adrenergic receptor. The green-fluorescent BODIPY® FL prazosin (B7433, Figure 16.2.6) can be used to localize the α_1 -adrenergic receptor on cultured cortical neurons³⁴ and in vascular smooth muscle cells from α_1 -adrenergic receptor–knockout mice.³⁵ BODIPY® FL prazosin has also been successfully employed in multidrug resistance (MDR) transporter activity assays.^{36,37}

BODIPY® TMR-X Muscimol for GABA_A Receptors

Muscimol is a powerful agonist of the GABA_A receptor and has been widely used to reversibly inactivate localized groups of neurons.^{38,39} Using red-fluorescent BODIPY® TMR-X muscimol (M23400, Figure 16.2.7), researchers can correlate the distribution of muscimol with its pharmacological effects⁴⁰ and detect the presence of GABA_A receptors on cell surfaces.⁴¹

Fluorescent Angiotensin II for AT1 and AT2 Receptors

Angiotensin II (Asp-Arg-Val-Tyr-Ile-His-Pro-Phe) stimulates smooth muscle contraction and plays an important role in blood pressure control and in water and salt homeostasis. These effects are exerted via two G-protein–coupled receptor subtypes, referred to as AT1 and AT2. Our N-terminal–labeled fluorescein and Alexa Fluor® 488 analogs of angiotensin II (A13438, A13439) are useful tools for imaging the distribution of these receptors,^{42,43} as well as for flow cytometric analysis of angiotensin II endocytosis.⁴⁴ These fluorescent peptides have been characterized for purity by HPLC and mass spectrometry and generally display selectivity for AT1 over AT2 binding.⁴²

Naloxone Fluorescein for μ -Opioid Receptors

The μ -opioid receptor plays a critical role in analgesia. Among the antagonists that have been used to define and characterize these receptors are naloxone, a drug used to counteract the effects of opioid overdose, and naltrexone, a drug used in the treatment of opioid addiction. Naloxone fluorescein (N1384, Figure 16.2.8) has been reported to bind to the μ -opioid binding site with high affinity,^{45–47} permitting receptor visualization in transfected Chinese hamster ovary (CHO) cells.⁴⁸ Flow cytometry analysis of the binding of naloxone fluorescein to NMDA and μ -opioid receptors (which was displaced by NMDA and met-enkephalin, respectively) has been used to deduce the effects of operant conditioning on visual cortex receptor pattern.⁴⁹

Figure 16.2.6 BODIPY® FL prazosin (B7433).

Probes for Amino Acid Neurotransmitter Receptors

Caged Amino Acid Neurotransmitters

When illuminated with UV light or by multiphoton excitation, caged amino acid neurotransmitters are converted into biologically active amino acids that rapidly initiate neurotransmitter action.^{50,51} Thus, these caged probes provide a means of controlling the release—both spatially and temporally—of agonists for kinetic studies of receptor binding or channel opening.

The different caging groups confer special properties on these photoactivatable probes (Table 5.2). We synthesize two caged versions of L-glutamic acid^{52–60} (C7122, G7055), as well as caged carbachol^{61,62} (*N*-(CNB-caged) carbachol, C13654) and caged γ -aminobutyric acid^{56,63–66} (*O*-(CNB-caged) GABA, A7110), all of which are biologically inactive before photolysis.⁶⁷ *O*-(CNB-caged) GABA (A7110) and γ -(CNB-caged) L-glutamic acid (G7055), which exhibit fast uncaging rates and high photolysis quantum yields, have been used to investigate the activation kinetics of GABA receptors⁶⁶ and glutamate receptors,⁵⁵ respectively. *N*-(CNB-caged) L-glutamic acid (C7122) does not hydrolyze in aqueous solution because it is caged on the amino group, thus enabling researchers to use very high concentrations without risk of light-independent glutamic acid production.^{55,57}

Figure 16.2.7 Muscimol, BODIPY® TMR-X conjugate (M23400).

Anti-NMDA Receptor Antibodies

N-methyl-D-aspartate (NMDA) receptors constitute cation channels of the central nervous system that are gated by the excitatory neurotransmitter L-glutamate.^{68,69} We offer affinity-purified rabbit polyclonal antibodies to NMDA receptor subunits 2A, 2B and 2C (A6473, A6474, A6475). The anti-NMDA receptor subunit 2A and 2B antibodies were generated against fusion proteins containing amino acid residues 1253–1391 of subunit 2A and 984–1104 of subunit 2B, respectively. These two antibodies are active against mouse, rat and human forms of the antigens and are specific for the subunit against which they were generated. In contrast, the anti-NMDA receptor subunit 2C antibody was generated against amino acid residues 25–130 of subunit 2C and recognizes the 140,000-dalton subunit 2C, as well as the 180,000-dalton subunit 2A and subunit 2B from mouse, rat and human. These three affinity-purified antibodies are suitable for immunohistochemistry⁷⁰ (Figure 16.2.9), western blots, enzyme-linked immunosorbent assays (ELISAs) and immunoprecipitations.

Figure 16.2.8 Naloxone fluorescein (N1384).

Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit

The Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit (A12221) provides an ultrasensitive method for continuously detecting glutamic acid⁷¹ or for monitoring glutamate oxidase activity in a fluorescence microplate reader or a fluorometer.⁷² In this assay, L-glutamic acid is oxidized by glutamate oxidase to produce α -ketoglutarate, NH_3 and H_2O_2 . L-Alanine and L-glutamate-pyruvate transaminase are also included in the reaction. Thus, the L-glutamic acid is regenerated by transamination of α -ketoglutarate, resulting in multiple cycles of the initial reaction and a significant amplification of the H_2O_2 produced. Hydrogen peroxide reacts with the Amplex® Red reagent in a 1:1 stoichiometry in a reaction catalyzed by horseradish peroxidase (HRP) to generate the highly fluorescent product resorufin^{73,74} (R363, Section 10.1).

Figure 16.2.9 Rat brain cryosections labeled with anti-NMDA receptor, subunit 2A (rat), rabbit IgG fraction (A6473) and detected using Alexa Fluor® 488 goat anti-rabbit IgG antibody (A11008). The tissue was also labeled with Alexa Fluor® 594 anti-gial fibrillary acidic protein antibody (A21295) and counterstained with TOTO®-3 iodide (T3604), which was pseudocolored light blue in this image.

Figure 16.2.10 Detection of L-glutamic acid using the Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit (A12221). Each reaction contained 50 µM Amplex® Red reagent, 0.125 U/mL HRP, 0.04 U/mL L-glutamate oxidase, 0.25 U/mL L-glutamate-pyruvate transaminase, 100 µM L-alanine and the indicated amount of L-glutamic acid in 1X reaction buffer. Reactions were incubated at 37°C. After 30 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm.

Figure 16.2.11 Detection of L-glutamate oxidase using the Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit (A12221). Each reaction contained 50 µM Amplex® Red reagent, 0.125 U/mL HRP, 0.25 U/mL L-glutamate-pyruvate transaminase, 20 µM L-glutamic acid, 100 µM L-alanine and the indicated amount of *Streptomyces* L-glutamate oxidase in 1X reaction buffer. Reactions were incubated at 37°C. After 60 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. The inset represents data from a separate experiment for lower L-glutamate oxidase concentrations and incubation time of 60 minutes (0–1.25 mU/mL).

Because resorufin has absorption/emission maxima of $\sim 571/585$ nm (Figure 16.2.3), there is little interference from autofluorescence in most biological samples.

If the concentration of L-glutamic acid is limiting in this assay, then the fluorescence increase is proportional to the initial L-glutamic acid concentration. The Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit allows detection of as little as 10 nM L-glutamic acid in purified systems using a 30-minute reaction time (Figure 16.2.10). If the reaction is modified to include an excess of L-glutamic acid, then this kit can be used to continuously monitor glutamate oxidase activity. For example, purified L-glutamate oxidase from *Streptomyces* can be detected at levels as low as 40 µU/mL (Figure 16.2.11). The Amplex® Red reagent has been used to quantitate the activity of glutamate-producing enzymes in a high-throughput assay for drug discovery.⁷¹ The Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- H₂O₂
- Concentrated reaction buffer
- L-Glutamate oxidase from *Streptomyces* sp.
- L-Glutamate-pyruvate transaminase from pig heart
- L-Glutamic acid
- L-Alanine
- Detailed protocols

Each kit provides sufficient reagents for approximately 200 assays using a fluorescence microplate reader and a reaction volume of 100 µL per assay.

Probes for Other Receptors

The Molecular Probes® Handbook discusses a diverse array of receptor probes, including fluorescent derivatives of:

- Low-density lipoprotein (LDL)
- Lipopolysaccharides
- Epidermal growth factor (EGF)
- Transferrin
- Fibrinogen
- Gelatin and collagen
- Ovalbumin and bovine serum albumin
- Casein
- Histone H1
- Subunit B of cholera toxin
- Chemotactic peptide
- Insulin

These ligands are all transported into the cell by receptor-mediated endocytosis. Additional information about these probes, as well as membrane and fluid-phase markers, can be found in Section 16.1.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- All photoactivatable probes are sensitive to light. They should be protected from illumination except when photolysis is intended.
- This compound has weaker visible absorption at >300 nm but no discernible absorption peaks in this region.
- The value of EC listed for this peptide conjugate is that of the labeling dye in free solution. Use of this value for the conjugate assumes a 1:1 dye:peptide labeling ratio and no change of EC due to dye-peptide interactions.
- α -Bungarotoxin, EGF and phalloxin conjugates have approximately 1 label per peptide.
- This peptide exhibits intrinsic tryptophan fluorescence (Em ~350 nm) when excited at <300 nm.
- The value of EC listed for this α -bungarotoxin conjugate is for the labeling dye in free solution. Use of this value for the conjugate assumes a 1:1 dye:peptide labeling ratio and no change of EC due to dye-peptide interactions.

PRODUCT LIST 16.2 PROBES FOR NEUROTRANSMITTER RECEPTORS

Cat. No.	Product	Quantity
A7110	γ -aminobutyric acid, α -carboxy-2-nitrobenzyl ester, trifluoroacetic acid salt (O-(CNB-caged) GABA)	5 mg
A12217	Amplex® Red Acetylcholine/Acetylcholinesterase Assay Kit *500 assays*	1 kit
A12221	Amplex® Red Glutamic Acid/Glutamate Oxidase Assay Kit *200 assays*	1 kit
A13439	angiotensin II, Alexa Fluor® 488 conjugate	25 μ g
A13438	angiotensin II, fluorescein conjugate	25 μ g
A6473	anti-NMDA receptor, subunit 2A (rat), rabbit IgG fraction *affinity purified*	10 μ g
A6474	anti-NMDA receptor, subunit 2B (rat), rabbit IgG fraction *affinity purified*	10 μ g
A6475	anti-NMDA receptor, subunit 2C (rat), rabbit IgG fraction *affinity purified*	10 μ g
B7433	BODIPY® FL prazosin	100 μ g
B1601	α -bungarotoxin *from <i>Bungarus multicinctus</i> *	1 mg
B13422	α -bungarotoxin, Alexa Fluor® 488 conjugate	500 μ g
B35451	α -bungarotoxin, Alexa Fluor® 555 conjugate	500 μ g
B13423	α -bungarotoxin, Alexa Fluor® 594 conjugate	500 μ g
B35450	α -bungarotoxin, Alexa Fluor® 647 conjugate	500 μ g
B35452	α -bungarotoxin, Alexa Fluor® 680 conjugate	500 μ g
B1196	α -bungarotoxin, biotin-XX conjugate	500 μ g
C13654	N-(CNB-caged) carbachol (N-(α -carboxy-2-nitrobenzyl)carbamylocholine, trifluoroacetic acid salt)	5 mg
C7122	N-(CNB-caged) L-glutamic acid (N-(α -carboxy-2-nitrobenzyl)-L-glutamic acid)	5 mg
F1176	fluorescein α -bungarotoxin (α -bungarotoxin, fluorescein conjugate)	500 μ g
G7055	L-glutamic acid, γ -(α -carboxy-2-nitrobenzyl) ester, trifluoroacetic acid salt (γ -(CNB-caged) L-glutamic acid)	5 mg
M23400	muscimol, BODIPY® TMR-X conjugate	1 mg
N1384	naloxone fluorescein	5 mg
T1175	tetramethylrhodamine α -bungarotoxin (α -bungarotoxin, tetramethylrhodamine conjugate)	500 μ g

16.3 Probes for Ion Channels and Carriers

This section describes a variety of probes for Ca^{2+} , Na^+ , K^+ and Cl^- ion channels and carriers. Chapter 19 and Chapter 21 contain our extensive selection of indicators for these physiologically important ions, providing a means of correlating ion channel activation with subsequent changes in intracellular ion concentration. Ion flux also affects the cell's membrane potential, which can be measured with the probes described in Chapter 22.

Probes for Ca^{2+} Channels and Carriers

In both excitable and nonexcitable cells, intracellular Ca^{2+} levels modulate a multitude of vital cellular processes—including gene expression, cell viability, cell proliferation, cell motility and cell shape and volume regulation—and thereby play a key role in regulating cell responses to external activating agents. These dynamic changes in intracellular Ca^{2+} levels are regulated by ligand-gated and G-protein-coupled ion channels in the plasma membrane, as well as by mobilization of Ca^{2+} from intracellular stores. One of the best-studied examples of Ca^{2+} -dependent signal transduction is the depolarization of excitable cells, such as those of neuronal, cardiac, skeletal and smooth muscle tissue, which is mediated by inward Ca^{2+} and Na^+ currents. The Ca^{2+} current is attributed to the movement of ions through N-, L-, P- and T-type Ca^{2+} channels, which are defined both pharmacologically and by their biophysical properties, including conductance and voltage sensitivity. Here we describe several fluorescent ligands for imaging the spatial distribution and localization of Ca^{2+} channels in cells, as well as Premo™ Cameleon Calcium Sensor, a genetically encoded, protein-based ratiometric sensor for calcium measurements. Our complete selection of Ca^{2+} indicators is described in Chapter 19.

Fluorescent Dihydropyridine for L-Type Ca^{2+} Channels

The L-type Ca^{2+} channel is readily blocked by the binding of dihydropyridine to the channel's pore-forming α_1 -subunit. To facilitate the study of channel number and distribution in single cells, we offer fluorescent dihydropyridine derivatives. The high-affinity (–)-enantiomer of dihydropyridine is available labeled with either the green-fluorescent DM-BODIPY® (D7443, Figure 16.3.1) or the orange-fluorescent ST-BODIPY® (S7445) fluorophore. Knaus and colleagues have shown that these BODIPY® dihydropyridines bind to L-type Ca^{2+} channels with high affinity and inhibit the Ca^{2+} influx in GH_3 cells.^{1–3} For neuronal L-type Ca^{2+} channels, the (–)-enantiomers of the DM-BODIPY® dihydropyridine and ST-BODIPY® derivatives each exhibit a K_i of 0.9 nM. Their affinities for skeletal muscle L-type Ca^{2+} channels are somewhat lower. Although DM-BODIPY® dihydropyridine exhibits a more intense fluorescence, the particularly high degree of stereoselectivity retained by the ST-BODIPY® derivatives has proven useful for the *in vivo* visualization of L-type Ca^{2+} channels.⁴ DM-BODIPY® dihydropyridine has proven effective as a substrate for functional analysis of ABC drug transporters.⁵

BODIPY® FL Verapamil

Like dihydropyridine, phenylalkylamines also bind to the α_1 -subunit of L-type Ca^{2+} channels and block Ca^{2+} transport. We offer a green-fluorescent BODIPY® FL derivative (B7431, Figure 16.3.2) of verapamil, a phenylalkylamine known to inhibit P-glycoprotein-mediated drug efflux.

The 170,000-dalton P-glycoprotein is typically overexpressed in tumor cells that have acquired resistance to a variety of anticancer drugs (Section 15.6). P-glycoprotein is thought to mediate the ATP-dependent efflux or sequestration of structurally unrelated molecules, including actinomycin D, anthracyclines, colchicine, epipodophyllotoxins and vinblastine. Verapamil appears to inhibit drug efflux by acting as a substrate of P-glycoprotein, thereby overwhelming the transporter's capacity to expel the drugs. BODIPY® FL verapamil also appears to serve as a substrate for P-glycoprotein. This fluorescent verapamil derivative preferentially accumulates in the lysosomes of normal, drug-sensitive NIH 3T3 cells but is rapidly transported out of multidrug-resistant cells.^{6–9}

Eosin Derivatives: Inhibitors of the Calcium Pump

Eosin isothiocyanate (E18) is a potent reversible inhibitor of the erythrocyte plasma membrane calcium pump, with a half-maximal inhibitory concentration of $<0.2 \mu\text{M}$.¹⁰ Eosin isothiocyanate also reacts irreversibly at the ATP-binding site of this calcium pump. The succinimide ester of carboxyeosin diacetate (C22803), a cell membrane-permeant eosin derivative, also inhibits the erythrocyte plasma membrane Ca^{2+} pump.^{11,12} Fluorescein isothiocyanate (F143, Section 1.4) is a weaker inhibitor of the erythrocyte plasma membrane calcium pump.

Premo™ Cameleon Calcium Sensor

The Premo™ product line combines genetically encoded ion indicators and environmental sensors with efficient BacMam delivery (BacMam Gene Delivery and Expression Technology—Note 11.1) for intracellular measurements in mammalian cells. Premo™ Cameleon Calcium Sensor (P36207, P36208) is a ratiometric calcium-sensitive fluorescent protein that is delivered by BacMam baculovirus-mediated transduction to a variety of mammalian cell types. This content and delivery system provides an effective and robust technique for measuring Ca^{2+} mobilization in transduced cells using microplate assays or fluorescence microscopy (Figure 16.3.3).

The Premo™ Cameleon Calcium Sensor is based on the YC3.60 version of the fluorescent protein (FP)-based sensor (cameleon) family developed by Tsien, Miyawaki and co-workers, which is reported to have a Ca^{2+} dissociation constant of 240 nM.^{13,14} The sensor comprises two fluorescent proteins (Enhanced Cyan Fluorescent Protein or ECFP and Venus variant of Yellow Fluorescent Protein or YFP), linked by the calmodulin-binding peptide M13 and calmodulin. Upon binding four calcium ions, calmodulin undergoes a conformational change by wrapping itself around the M13 peptide, which changes the efficiency of the fluorescence resonance energy transfer (FRET) between the CFP donor and the YFP acceptor fluorophores (Figure 16.3.4). Following this conformational change, there is an increase in YFP emission (525–560 nm) and a simultaneous decrease in CFP emission (460–500 nm) (Figure 16.3.5), making Cameleon an effective reporter of calcium mobilization. The ratiometric readout of the Premo™ Cameleon Calcium Sensor—an increase in YFP emission (535 nm, green-yellow emission) and a decrease in CFP emission (485 nm, blue emission)—reduces assay variations due to compound or cellular autofluorescence, nonuniform cell plating, differences in expression levels between cells, instability of instrument illumination and changes in illumination pathlength.

The Premo™ Cameleon Calcium Sensor is designed to readily and accurately detect intracellular calcium flux from different receptors. Standard pharmacological assays for multiple GPCR agonists and antagonists have been tested. An example of the robustness and reproducibility and accuracy of the system is demonstrated using the endogenous histamine receptor in conjunction with histamine, pyrilamine, and thioperamide in HeLa cells (Figure 16.3.6). Expression levels will be maintained for several days, enabling iterative assays to be run, for instance, when examining agonist/antagonist relationships on the same cells.

Figure 16.3.3 Porcine left atrial appendage progenitor cells were transfected with Premo™ Cameleon calcium sensor (P36207, P36208); ATP (20 μM final concentration) was applied to the cells the following day and the cells were imaged using a Zeiss 5 Live high-speed confocal system (Carl Zeiss MicroImaging). Excitation was with a 405 nm diode laser (50 mw) operated at 50% power. Emission was collected simultaneously on two linear CCD detectors using a 490 nm dichroic mirror to split the beam through a 415–480 nm bandpass filter for CFP and a 550 nm longpass filter for YFP. Images were collected at a rate of 10 frames per second (512 x 512 pixels) using a 40x Plan-Neofluar 1.3 NA oil immersion objective lens.

Figure 16.3.5 Fluorescence emission spectra of Premo™ Cameleon Calcium Sensor (P36207, P36208). The dashed line indicates the spectra in the absence of Ca^{2+} ; the solid line shows the fluorescence resonance energy transfer (FRET)-based change upon Ca^{2+} binding.

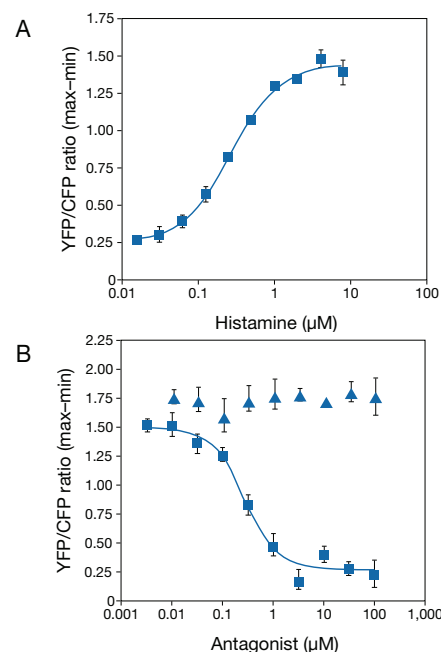

Figure 16.3.6 Agonist and antagonist dose response curves. HeLa cells were plated in a 96-well plate at a density of 15,000 cells/well, transduced with Premo™ Cameleon Calcium Sensor (P36207, P36208), and incubated overnight at 37°C. The following day, a histamine dose response was performed (A). A separate plate was used to evaluate an antagonist dose response with pyrilamine (■) and thioperamide (▲) in the presence of an EC_{80} concentration of histamine (B). Pyrilamine is a known H1 receptor antagonist that couples through G_q proteins and the second messenger Ca^{2+} . Thioperamide is a known H3 receptor antagonist that couples through G_i proteins and the second messenger cAMP.

Probes for Na⁺ Channels and Carriers

Amiloride Analogs: Probes for the Na⁺ Channel and the Na⁺/H⁺ Antiporter

Amiloride is a compound known to inhibit the Na⁺/H⁺ antiporter of vertebrate cells by acting competitively at the Na⁺-binding site.¹⁵ The antiporter extrudes protons from cells using the inward Na⁺ gradient as a driving force, resulting in intracellular alkalization. In 1967, Cragoe and co-workers reported the synthesis of amiloride and several amiloride analogs, which are pyrazine diuretics that inhibit the Na⁺ channel in urinary epithelia.¹⁶ Since then, more than 1000 different amiloride analogs have been synthesized and many of these tested for their specificity and potency in inhibiting the Na⁺ channel, Na⁺/H⁺ antiporter and Na⁺/Ca²⁺ exchanger.¹⁷ Unmodified amiloride inhibits the Na⁺ channel with an IC₅₀ of less than 1 μM. Additionally, amiloride is an important tool for studying the Na⁺/H⁺ antiporter. Structure-activity relationships have demonstrated that amiloride analogs with hydrophobic groups in the drug are the most potent and specific inhibitors for the Na⁺/H⁺ antiporter.¹⁷⁻²² For example, 5-(N-ethyl-N-isopropyl)amiloride (EIPA, E3111; Figure 16.3.7) is 200-fold more potent than amiloride for inhibiting this antiporter.

Ouabain Probes for Na⁺/K⁺-ATPase

Ouabain is a member of a class of glycosylated steroids collectively known as cardiac glycosides due to their therapeutic efficacy in the treatment of congestive heart failure. Ouabain achieves this effect by binding to the catalytic α-subunit of Na⁺/K⁺-ATPase and inhibiting its transport of Na⁺ across the plasma membrane. 9-Anthroyl ouabain (A1322) is useful for localizing Na⁺/K⁺-ATPase and for studying its membrane orientation, mobility and dynamics.²³ Anthroyl ouabain has also been employed to investigate Na⁺/K⁺-ATPase's active site, inhibition and conformational changes,²⁴⁻²⁹ as well as to investigate the kinetics of cardiac glycoside binding.³⁰⁻³⁵ BODIPY® FL ouabain (B23461, Figure 16.3.8) has been used in combination with Alexa Fluor® 555 cholera toxin B (C22843, Section 16.1) for visualizing Na⁺/K⁺-ATPase and ganglioside G_{M1} domain localization in lymphocyte plasma membranes.³⁶

Using BacMam Technology to Deliver and Express Sodium Channel cDNA

Sodium channel cDNAs that have been engineered into a baculovirus gene delivery/expression system using BacMam technology (BacMam Gene Delivery and Expression Technology—Note 11.1) are also available, including the Nav1.2 cDNA (B10341) and the Nav1.5 cDNA (B10335).

The BacMam system uses a modified insect cell baculovirus as a vehicle to efficiently deliver and express genes in mammalian cells with minimum effort and toxicity. The use of BacMam delivery in mammalian cells is relatively new, but well described, and has been used extensively in a drug discovery setting.³⁷ Furthermore, constitutively expressed ion channels and other cell surface proteins have been shown to contribute to cell toxicity in some systems, and may be subject to clonal drift and other inconsistencies that hamper successful experimentation and screening. Thus, transient expression systems such as the BacMam gene delivery and expression system are increasingly methods of choice to decrease variability of expression in such assays.

U2OS cells (ATCC number HTB-96) have been shown to demonstrate highly efficient expression of BacMam delivered targets in a null background ideal for screening in a heterologous expression system. The U2OS cell line is recommended for use if your particular cell line does not efficiently express the BacMam targets. Examples of other cell lines that are efficiently transduced by BacMam technology include HEK 293, HepG2, BHK, Cos-7 and Saos-2.

Probes for K⁺ Channels and Carriers

Glibenclamide Probes for the ATP-Dependent K⁺ Channel

Glibenclamide blocks the ATP-dependent K⁺ channel, thereby eliciting insulin secretion.³⁸ We have prepared the green-fluorescent BODIPY® FL glibenclamide (BODIPY® FL glyburide, E34251; Figure 16.3.9) and red-fluorescent BODIPY® TR glibenclamide (BODIPY® TR glyburide, E34250) as probes for the ATP-dependent K⁺ channel. BODIPY® TR glibenclamide has been used to detect sulfonylurea receptors associated with ATP-dependent K⁺ channels in bovine monocytes and in β-cells^{39,40} and to label a novel mitochondrial ATP-sensitive potassium channel in brain.⁴¹

The sulfonylurea receptors of ATP-dependent K⁺ channels are prominent on the endoplasmic reticulum (ER). Therefore, because these probes are also effective live-cell stains for ER,

BODIPY® FL glibenclamide and BODIPY® TR glibenclamide are also referred to as ER-Tracker™ Green and ER-Tracker™ Red, respectively; see Section 12.4 for a description of this application. Variable expression of sulfonylurea receptors in some specialized cell types may result in non-ER labeling with these probes.

FluxOR™ Potassium Ion Channel Assay

The FluxOR™ Potassium Ion Channel Assay Kits (F10016, F10017) provide a fluorescence-based assay for high-throughput screening of potassium ion channel and transporter activities.^{42,43} The FluxOR™ Potassium Ion Channel Assay Kits take advantage of the well-described permeability of potassium channels to thallium (Tl^+) ions. When thallium is present in the extracellular solution containing a stimulus to open potassium channels, channel activity is detected with a cell-permeant thallium indicator dye that reports large increases in fluorescence emission at 525 nm as thallium flows down its concentration gradient and into the cells (Figure 16.3.10). In this way, the fluorescence reported in the FluxOR™ system becomes a surrogate indicator of activity for any ion channel or transporter that is permeable to thallium, including the human ether-a-go-go-related (hERG) channel, one of the human cardiac potassium channels. The FluxOR™ potassium ion channel assay has been validated for homogeneous high-throughput profiling of hERG channel inhibition using BacMam-mediated transient expression of hERG.⁴² The FluxOR™ Potassium Ion Channel Assay Kits can also be used to study potassium

co-transport processes that accommodate the transport of thallium into cells.⁴⁴ Furthermore, resting potassium channels and inward rectifier potassium channels like Kir2.1 can be assayed by adding stimulus buffer with thallium alone, without any depolarization to measure the signal.

The FluxOR™ reagent, a thallium indicator dye, is loaded into cells as a membrane-permeable AM ester. Loading is assisted by the proprietary PowerLoad™ concentrate, an optimized formulation of nonionic Pluronic® surfactant polyols that act to disperse and stabilize AM ester dyes for optimal loading in aqueous solution. This PowerLoad™ concentrate is also available separately (P10020) to aid the solubilization of water-insoluble dyes and other materials in physiological media.

Once inside the cell, the nonfluorescent AM ester of the FluxOR™ dye is cleaved by endogenous esterases into a weakly fluorescent (basal fluorescence), thallium-sensitive indicator. The thallium-sensitive form is retained in the cytosol, and its extrusion is inhibited by water-soluble probenecid (P36400, Section 19.8), which blocks organic anion pumps. For most applications, cells are loaded with the dye at room temperature. For best results, the dye-loading buffer is then replaced with fresh, dye-free assay buffer (composed of physiological HBSS containing probenecid), and cells are ready for the high-throughput screening assay.

Each FluxOR™ Potassium Ion Channel Assay Kit contains:

- FluxOR™ reagent
- FluxOR™ assay buffer
- PowerLoad™ concentrate
- Probenecid
- FluxOR™ chloride-free buffer
- Potassium sulfate (K_2SO_4) concentrate
- Thallium sulfate (Tl_2SO_4) concentrate
- Dimethylsulfoxide (DMSO)
- Detailed protocols

The FluxOR™ Kits provide a concentrated thallium solution along with sufficient dye and buffers to perform ~4000 (F10016) or ~40,000 (F10017) assays in a 384-well microplate format. These kits allow maximum target flexibility and ease of operation in a homogeneous format. The FluxOR™ potassium ion channel assay has been demonstrated for use with CHO and HEK 293 cells stably expressing hERG, as well as U2OS cells transiently transduced with BacMam hERG reagent⁴² (B10019, B10033) (Figure 16.3.11). More information is available at www.invitrogen.com/handbook/fluxorpotassium.

Figure 16.3.10 Thallium redistribution in the FluxOR™ assay. Basal fluorescence from cells loaded with FluxOR™ reagent (provided in the FluxOR™ Potassium Ion Channel Assay Kits; F10016, F10017) is low when potassium channels remain unstimulated, as shown in the left panel. When thallium is added to the assay with the stimulus, the thallium flows down its concentration gradient into the cells, activating the dye as shown in the right panel.

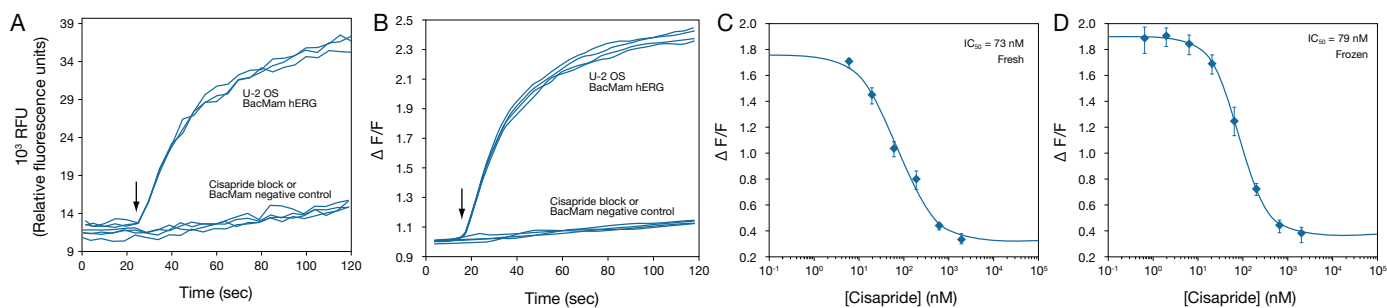

Figure 16.3.11 FluxOR™ potassium ion channel assays (F10016, F10017) performed on fresh and frozen U2OS cells transduced with the BacMam hERG reagent (B10019, B10033). **A**) Raw data obtained in the FluxOR™ assay determination of thallium flux in U2OS cells transduced with BacMam-hERG and kept frozen until the day of use. The arrow indicates the addition of the thallium/potassium stimulus, and upper and lower traces indicate data taken from the minimum and maximum doses of cisapride used in the determination of the dose-response curves. **B**) Raw pre-stimulus peak and baseline values were boxcar averaged and normalized, and indicate the fold increase in fluorescence over time. **C**) Data generated in a dose-response determination of cisapride block on BacMam hERG expressed in U2OS cells freshly prepared from overnight expression after viral transduction. **D**) Parallel data obtained from cells transduced with BacMam-hERG, stored for 2 weeks in liquid nitrogen, thawed, and plated 4 hours prior to running the assay. Error bars indicate standard deviation, $n = 4$ per determination.

Using BacMam Technology to Deliver and Express Potassium Channel cDNA

Potassium channel cDNAs that have been engineered into a baculovirus gene delivery/expression system using BacMam technology (BacMam Gene Delivery and Expression Technology—Note 11.1) are also available for use with the FluxOR™ Potassium Ion Channel Assay Kits, including the human ether-a-go-go related gene (hERG) (Figure 16.3.12), several members of the voltage-gated K⁺ channel (Kv) gene family and two members of the inwardly rectifying K⁺ channel (Kir) gene family:

- BacMam hERG⁴² (for 10 microplates, B10019; for 100 microplates, B10033)
- BacMam Kv1.1 (for 10 microplates, B10331)
- BacMam Kv1.3 (for 10 microplates, B10332)
- BacMam Kv2.1 (for 10 microplates, B10333)
- BacMam Kv7.2 and Kv7.3 (for 10 microplates, B10147)
- BacMam Kir1.1 (for 10 microplates, B10334)
- BacMam Kir2.1 (for 10 microplates, B10146)

The BacMam system uses a modified insect cell baculovirus as a vehicle to efficiently deliver and express genes in mammalian cells with minimum effort and toxicity. The use of BacMam delivery in mammalian cells is relatively new, but well described, and has been used extensively in a drug discovery setting.³⁷ Furthermore, constitutively expressed ion channels and other cell surface proteins have been shown to contribute to cell toxicity in some systems, and may be subject to clonal drift and other inconsistencies that hamper successful experimentation and screening. Thus, transient expression systems such as BacMam technology are increasingly methods of choice to decrease variability of expression in such assays.

Figure 16.3.12 BacMam-hERG gene delivery and expression. This schematic depicts the mechanism of BacMam-mediated gene delivery into a mammalian cell and expression of the hERG gene (B10019, B10033). The hERG gene resides within the baculoviral DNA, downstream of a CMV promoter that drives its expression when introduced into a mammalian target cell. BacMam viral particles are taken up by endocytic pathways into the cell, and the DNA within them is released for transcription and expression. The translated protein is then folded for insertion into the membrane, forming functional hERG ion channels. This process begins within 4–6 hours and in many cell types is completed after an overnight period.

U2OS cells (ATCC number HTB-96) have been shown to demonstrate highly efficient expression of BacMam-delivered targets in a null background ideal for screening in a heterologous expression system. The U2OS cell line is recommended for use if your particular cell line does not efficiently express the BacMam targets. Examples of other cell lines that are efficiently transduced by BacMam technology include HEK 293, HepG2, BHK, Cos-7 and Saos-2.

Probes for Anion Transporters

Stilbene Disulfonates: Anion-Transport Inhibitors

We offer three stilbene disulfonates that have been employed to inhibit (frequently irreversibly) anion transport⁴⁵ in a large number of mammalian cell types:

- DIDS (D337, Figure 16.3.13)
- H₂DIDS (D338)
- DNDS (D673)

Our stilbene disulfonate probes, which are 95–99% pure by HPLC, have significantly higher purity and more defined composition than those available from other commercial sources. DNDS was among the inhibitors used to characterize three different anion exchangers in the membranes of renal brush border cells and to compare these exchangers with the band-3 anion-transport protein of erythrocyte membranes.⁴⁶

These stilbene disulfonates can, in some cases, bind specifically to proteins that are not anion transporters. For example, DIDS and H₂DIDS complex specifically with the CD4 glycoprotein on T-helper lymphocytes and macrophages, blocking HIV type-1 growth at multiple stages of the virus life cycle.⁴⁷

Figure 16.3.13 DIDS (4,4'-diisothiocyanatostilbene-2,2'-disulfonic acid, disodium salt, D337).

Figure 16.3.14 Bis-(1,3-dibutylbarbituric acid)pentamethine oxonol (DIBAC₄(5), B436).

DiBAC₄(5)

The membrane potential-sensing dye bis-(1,3-dibutylbarbituric acid)pentamethine oxonol (DiBAC₄(5), B436; Figure 16.3.14) initially inhibits Cl⁻ exchange with an IC₅₀ of 0.146 μM. However, this inhibition increases with time to an IC₅₀ of 1.05 nM, making DiBAC₄(5) a more potent inhibitor than DIDS, which has an IC₅₀ of 31 nM under similar conditions.⁴⁸

Eosin Maleimide

Although usually selectively reactive with thiols, eosin-5-maleimide (E118, Section 2.2) is known to react with a specific lysine residue of the band-3 protein in human erythrocytes, inhibiting anion exchange in these cells and providing a convenient tag for observing band-3 behavior in the membrane.^{49–51} Eosin-5-isothiocyanate (E18) has similar reactivity with band-3 proteins.^{52,53}

Premo™ Halide Sensor

The fluorescent protein-based Premo™ Halide Sensor (P10229) is a pharmacologically relevant sensor for functional studies of ligand- and voltage-gated chloride channels and their modulators in cells. Chloride channels are involved in cellular processes as critical and diverse as transepithelial ion transport, electrical excitability, cell volume regulation and ion homeostasis. Given their physiological significance, it follows that defects in their activity can have severe implications, including such conditions as cystic fibrosis and neuronal degeneration. Thus, chloride channels represent important targets for drug discovery.⁵⁴ Other methods for detecting chloride are described in Section 21.2.

Premo™ Halide Sensor combines a Yellow Fluorescent Protein (YFP) variant sensitive to halide ions with the efficient and noncytotoxic BacMam delivery and expression technology (BacMam Gene Delivery and Expression Technology—Note 11.1). Premo™ Halide Sensor is based on the Venus variant of *Aequorea victoria* Green

Fluorescent Protein (GFP), which displays enhanced fluorescence, increased folding, and reduced maturation time when compared with YFP.⁵⁵ Additional mutations H148Q and I152L were made within the Venus sequence to increase the sensitivity of the Venus fluorescent protein to changes in local halide concentration, in particular iodide ions.⁵⁶ Because chloride channels are also permeable to the iodide ion (I⁻), iodide can be used as a surrogate for chloride. Upon stimulation, a chloride channel or transporter opens and iodide flows down the concentration gradient into the cells, where it quenches the fluorescence of the expressed Premo™ Halide Sensor protein (Figure 16.3.15). The decrease in Premo™ Halide Sensor fluorescence is directly proportional to the ion flux, and therefore the chloride channel or transporter activity. Premo™ Halide Sensor shows an excitation and emission profile similar to YFP (Figure 16.3.16) and can be detected using standard GFP/FITC or YFP filter sets. Halide-sensitive YFP-based constructs in conjunction with iodide quenching have been used in high-throughput screening (HTS) to identify modulators of calcium-activated chloride channels.⁵⁷

Premo™ Halide Sensor (P10229) is prepackaged and ready for immediate use. It contains all components required for cellular delivery and expression, including baculovirus carrying the genetically encoded biosensor, BacMam enhancer and stimulus buffer. Premo™ Halide Sensor has been demonstrated to transduce multiple cell lines including BHK, U2OS, HeLa, CHO, and primary human bronchial epithelial cells (HBEC), providing the flexibility to assay chloride-permeable channels in a wide range of cellular models. To uncouple cell maintenance and preparation from cell screening, BacMam-transduced cells can be divided into aliquots and frozen for later assay. Both stable cell lines and human primary cells can be prepared frozen and “assay-ready” and can be subsequently plated as little as 4 hours prior to screening. Screening can be conducted in complete medium and without any wash steps. Chloride channel assays with Premo™ Halide Sensor are compatible with standard fluorescence HTS platforms.

Figure 16.3.15 Principle of Premo™ Halide Sensor (P10229): Iodide redistribution upon chloride channel activation. Basal fluorescence from Premo™ Halide Sensor is high when chloride channels are closed or blocked. Upon activation (opening) of chloride channels, the iodide ions enter the cell, down its concentration gradient, and quench the fluorescence from Premo™ Halide Sensor.

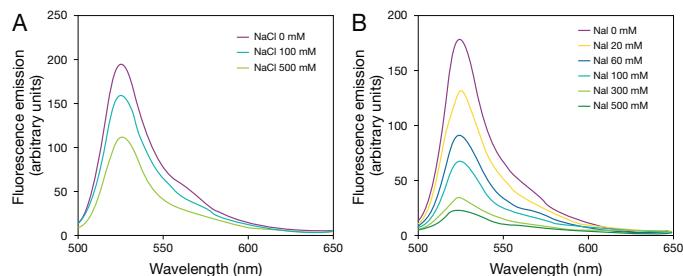

Figure 16.3.16 Quenching of Premo™ Halide Sensor fluorescence by increasing concentrations of iodide and chloride. U2OS cells were transduced with Premo™ Halide Sensor. After 24 hours, cells were trypsinized and lysed by resuspension in sterile distilled water. Fluorescence quenching of the lysate was examined using increasing concentrations of NaCl (A) and NaI (B). Iodide induces substantially greater quenching of Premo™ Halide Sensor fluorescence than chloride.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Oxonols may require addition of a base to be soluble.
- Isothiocyanates are unstable in water and should not be stored in aqueous solution.

PRODUCT LIST 16.3 PROBES FOR ION CHANNELS AND CARRIERS

Cat. No.	Product	Quantity
A1322	9-anthroyl ouabain	5 mg
B10334	BacMam Kir1.1 *for 10 microplates*	1 kit
B10146	BacMam Kir2.1 *for 10 microplates*	1 kit
B10331	BacMam Kv1.1 *for 10 microplates*	1 kit
B10332	BacMam Kv1.3 *for 10 microplates*	1 kit
B10333	BacMam Kv2.1 *for 10 microplates*	1 kit
B10147	BacMam Kv7.2 and Kv7.3 *for 10 microplates*	1 kit
B10341	BacMam Nav1.2 *for 10 microplates*	1 kit
B10335	BacMam Nav1.5 *for 10 microplates*	1 kit
B10019	BacMam-hERG *for 10 microplates*	1 kit
B10033	BacMam-hERG *for 100 microplates*	1 kit
B436	bis-(1,3-dibutylbarbituric acid)pentamethine oxonol (DiBAC ₄ (5))	25 mg
B23461	BODIPY® FL ouabain	100 µg
B7431	BODIPY® FL verapamil, hydrochloride	1 mg
C22803	CEDA, SE (5-(and-6)-carboxyeosin diacetate, succinimidyl ester) *mixed isomers*	5 mg
D337	DIDS (4,4'-diisothiocyanatostilbene-2,2'-disulfonic acid, disodium salt)	100 mg
D338	4,4'-diisothiocyanatodihydrostilbene-2,2'-disulfonic acid, disodium salt (H ₂ DIDS)	100 mg
D7443	DM-BODIPY® (-)-dihydropyridine *high affinity enantiomer*	25 µg
D673	DNDS (4,4'-dinitrostilbene-2,2'-disulfonic acid, disodium salt)	1 g
E18	eosin-5-isothiocyanate	100 mg
E34251	ER-Tracker™ Green (BODIPY® FL glibenclamide) *for live-cell imaging*	100 µg
E34250	ER-Tracker™ Red (BODIPY® TR glibenclamide) *for live-cell imaging*	100 µg
E3111	5-(N-ethyl-N-isopropyl)amiloride, hydrochloride	5 mg
F10016	FluxOR™ Potassium Ion Channel Assay *for 10 microplates*	1 kit
F10017	FluxOR™ Potassium Ion Channel Assay *for 100 microplates*	1 kit
P10020	PowerLoad™ concentrate, 100X	5 mL
P36207	Premo™ Cameleon Calcium Sensor *for 10 microplates*	1 kit
P36208	Premo™ Cameleon Calcium Sensor *for 100 microplates*	1 kit
P10229	Premo™ Halide Sensor *for 10 microplates*	1 kit
S7445	ST-BODIPY® (-)-dihydropyridine *high affinity enantiomer*	25 µg

17.1 Introduction to Signal Transduction

Cells respond to their environment through a complex and interdependent series of signal transduction pathways that frequently begin at the cell membrane. Many cellular receptors are transmembrane proteins with extracellular domains that selectively bind ligands. In response to ligand binding, the receptor's cytoplasmic domain may change conformation and transmit the signal across the membrane, or individual receptors may aggregate and interact with other membrane proteins in order to generate a response. Transmembrane signals trigger a cascade of events in the cell, which can include changes in intracellular Ca^{2+} levels, enzymatic activity and gene expression (Figure 17.1.1).

We offer several important reagents for studying signal transduction mechanisms, including Ca^{2+} regulation and second messenger activities. This chapter focuses on probes for events occurring downstream from the receptor–ligand interaction. These products complement the probes for receptors and ion channels in Chapter 16, as well as the many ion indicators discussed in Chapter 19, Chapter 20 and Chapter 21. Chapter 18 describes our selection of probes for nitric oxide research—including nitric oxide donors, nitric oxide synthase inhibitors and reagents for nitrite detection—as well as for other reactive oxygen species.

Figure 17.1.1 Neurotransmitter receptors linked to second messengers mediating growth responses in neuronal and nonneuronal cells. Abbreviations: R_{AC/Gs} = Receptors coupled to G-proteins that stimulate adenylate cyclase (AC) activity, leading to cAMP formation and enhanced activity of protein kinase A (PKA). R_{AC/Gi} = Receptors coupled to pertussis toxin (PTX)-sensitive G-proteins that inhibit adenylate cyclase activity. R_{PLC} = Receptors promoting the hydrolysis of phosphatidylinositol 4,5-diphosphate (PIP₂) to inositol 1,4,5-triphosphate (IP₃), which increases intracellular Ca²⁺, and diacylglycerol (DAG), which activates protein kinase C (PKC). R_{ION} = Receptors indirectly promoting ion fluxes due to coupling to various G-proteins. R_{LG/ION} = Receptors that promote ion fluxes directly because they are structurally linked to ion channels (members of the superfamily of ligand-gated ion channel receptors). Stimulation of proliferation is most often associated with activation of G-proteins negatively coupled to adenylate cyclase (G_i), or positively coupled to phospholipase C (G_q) or to pertussis toxin-sensitive pathways (G_o, G_i). In contrast, activation of neurotransmitter receptors positively coupled to cAMP usually inhibits cell proliferation and causes changes in cell shape indicative of differentiation. Reprinted and modified with permission from J.M. Lauder and Trends Neurosci (1993) 16:233. Learn more about gene specific products for signaling pathways at www.invitrogen.com/handbook/pathways.

17.2 Calcium Regulation

Intracellular Ca^{2+} levels modulate a multitude of vital cellular processes—including gene expression, cell viability, cell proliferation, cell motility, cell shape and volume regulation—thereby playing a key role in regulating cell responses to external signals. These dynamic changes in Ca^{2+} levels are regulated by ligand-gated and G-protein-coupled ion channels in the plasma membrane and by mobilization of Ca^{2+} from intracellular stores. The generation of cytosolic Ca^{2+} spikes and oscillations typically involves the coordinated release and uptake of Ca^{2+} from these stores, mediated by intracellular Ca^{2+} channels and their response to several second messengers such as Ca^{2+} itself, cyclic ADP ribose and inositol triphosphate.¹⁻³

This section includes several Molecular Probes® reagents for studying Ca^{2+} regulation in live cells. Fluorescent nucleotides, including analogs of ATP, ADP, AMP, GTP, and GDP, are described in Section 17.3. Our GTP analogs may be particularly useful in the assay of G-protein-coupled receptors. Section 17.4 discusses several selective phospholipase substrates, as well as labeled ceramide and sphingomyelin probes.

Inositol Triphosphate Pathway

D-*myo*-1,4,5-Inositol Triphosphate and Caged D-*myo*-1,4,5-Inositol Triphosphate

We offer the potassium salt of D-*myo*-inositol 1,4,5-triphosphate (Ins 1,4,5- P_3 , I3716) for researchers investigating inositol triphosphate-dependent Ca^{2+} mobilization and signal transduction mechanisms.¹ Cytosolic Ins 1,4,5- P_3 is a potent intracellular second messenger that induces Ca^{2+} release from membrane-bound stores in many tissues.

NPE-caged Ins 1,4,5- P_3 can be used to generate rapid and precisely controlled release of Ins 1,4,5- P_3 in intact cells and is widely employed in studies of Ins 1,4,5- P_3 -mediated second-messenger pathways.⁴⁻⁶ Our NPE-caged Ins 1,4,5- P_3 (I23580) is a mixture of the physiologically inert, singly esterified P^3 and P^5 esters (Figure 17.2.1) and does not contain the somewhat physiologically active P^1 ester. NPE-caged Ins 1,4,5- P_3 exhibits essentially no biological activity prior to photolytic release of the biologically active Ins 1,4,5- P_3 .

Figure 17.2.1 D-*myo*-inositol 1,4,5-triphosphate, P4(5)-(1-(2-nitrophenyl)ethyl) ester, tris(triethylammonium) salt (NPE-caged Ins 1,4,5- P_3) (I23580).

Fluorescent Heparin

Fluorescein-labeled heparin (H7482) is a useful tool for studying binding of this mucopolysaccharide in cells and tissues.^{7,8} In addition to its well-known anticoagulant activity,⁹ heparin binds to the Ins 1,4,5- P_3 receptor and inhibits the biological cascade of events mediated by Ins 1,4,5- P_3 .¹⁰ Heparin also binds to thrombin¹¹ and Alzheimer's tau protein,¹² as well as to blood vessel-associated proteins such as laminin and fibronectin.¹³ Fluorescence polarization assays using fluorescein-labeled heparin as a tracer provide quantitative assessments of these binding interactions.¹⁴ Fluorescein-labeled heparin has also been used to assess the efficacy of transdermal delivery of heparin by pulsed current iontophoresis as a potential alternative to conventional subcutaneous injections.¹⁵

Caged Ca^{2+} and Caged Ca^{2+} Chelators

Caged ions and caged chelators can be used to influence the ionic composition of both solutions and cells, particularly for ions such as Ca^{2+} that are present at low concentrations. The properties and uses of caged probes are described in Section 5.3.

NP-EGTA: A Caged Ca^{2+} Reagent

Developed by Ellis-Davies and Kaplan, the photolabile chelator *o*-nitrophenyl EGTA (NP-EGTA) exhibits a high selectivity for Ca^{2+} , a dramatic 12,500-fold decrease in affinity for Ca^{2+} upon UV illumination (its K_d increases from 80 nM to >1 mM) and a high photochemical quantum yield^{16,17} (~0.2). Furthermore, with a K_d for Mg^{2+} of 9 mM, NP-caged EGTA does not perturb physiological levels of Mg^{2+} . We offer both the potassium salt (N6802) and the acetoxymethyl (AM) ester (N6803) of NP-EGTA. The NP-EGTA salt can be complexed with Ca^{2+} to generate a caged calcium complex that will rapidly deliver Ca^{2+} upon photolysis (Figure 17.2.2). The cell-permeant AM ester of NP-EGTA does not bind Ca^{2+} unless the AM esters are removed. It can potentially serve as a photolabile buffer in cells because, once converted to NP-EGTA by intracellular esterases, it will bind Ca^{2+} with high affinity until photolyzed with UV light. NP-EGTA has been used to measure the calcium buffering capacity of cells.¹⁸

Figure 17.2.2 NP-EGTA (N6802) complexed with Ca^{2+} . Upon illumination, this complex is cleaved to yield free Ca^{2+} and two iminodiacetic acid photoproducts. The affinity of the photoproducts for Ca^{2+} is ~12,500-fold lower than that of NP-EGTA.

DMNP-EDTA: A Caged Ca^{2+} Reagent

The first caged Ca^{2+} reagent described by Ellis-Davies and Kaplan was 1-(4,5-dimethoxy-2-nitrophenyl) EDTA (DMNP-EDTA, D6814), which they named DM-Nitrophen™^{19,20} (now a trademark of Calbiochem-Novabiochem Corp.). Because its structure better resembles that of EDTA than EGTA, we named it as a caged EDTA derivative (Figure 17.2.3). Upon illumination, DMNP-EDTA's K_d for Ca^{2+} increases from 5 nM to 3 mM. Thus, photolysis of DMNP-EDTA complexed with Ca^{2+} results in a pulse of free Ca^{2+} . Furthermore, DMNP-EDTA has significantly higher affinity for Mg^{2+} ($K_d = 2.5 \mu\text{M}$) than does NP-EGTA¹⁹ ($K_d = 9 \text{mM}$). The photolysis product's K_d for Mg^{2+} is $\sim 3 \text{mM}$, making DMNP-EDTA an effective caged Mg^{2+} source, in addition to its applications for photolytic Ca^{2+} release.^{21,22} Photorelease of Ca^{2+} has been shown to occur in <180 microseconds, with even faster photorelease of Mg^{2+} .²³ Two reviews by Ellis-Davies discuss the uses and limitations of DMNP-EDTA.^{24,25}

Diazo-2: A Photoactivatable Ca^{2+} Knockdown Reagent

In contrast to NP-EGTA and DMNP-EDTA, diazo-2 (D3034) is a photoactivatable Ca^{2+} scavenger. Diazo-2 (Figure 17.2.4), which was introduced by Adams, Kao and Tsien,^{26,27} is a relatively weak chelator (K_d for $\text{Ca}^{2+} = 2.2 \mu\text{M}$). Following flash photolysis at $\sim 360 \text{nm}$, however, cytosolic free Ca^{2+} rapidly binds to the diazo-2 photolysis product, which has a high affinity for Ca^{2+} ($K_d = 73 \text{nM}$). Microinjecting a relatively low concentration of fluo-3, fluo-4, or one of the Calcium Green™ or Oregon Green® 488 BAPTA indicators (Section 19.3), along with a known quantity of diazo-2, permits measurement of the extent of depletion of cytosolic Ca^{2+} following photolysis.^{27–29} Intracellular loading of NP-EGTA, DMNP-EDTA and diazo-2 is best accomplished by patch pipette infusion with the carboxylate salt form of the caged compound added to the internal pipette solution at 1–10 mM. These reagents are increasingly being applied *in vivo* for controlled intervention in calcium-regulated fundamental processes in neurobiology³⁰ and developmental biology.³¹

Figure 17.2.3 DMNP-EDTA (D6814) complexed with Ca^{2+} . Upon illumination, this complex is cleaved to yield free Ca^{2+} and two iminodiacetic acid photoproducts. The affinity of the photoproducts for Ca^{2+} is $\sim 600,000$ -fold lower than that of DMNP-EDTA.

Figure 17.2.4 Diazo-2, tetrapotassium salt (D3034).

Other Probes for Calcium Regulation

Thapsigargin and Fluorescent Thapsigargin

Thapsigargin is a naturally occurring sesquiterpene lactone isolated from the umbelliferous plant *Thapsia garganica*.³² This tumor promoter releases Ca^{2+} from intracellular stores by specifically inhibiting the sarcoplasmic reticulum Ca^{2+} -ATPase^{33,34} (SERCA); it does not directly affect plasma membrane Ca^{2+} -ATPases, Ins 1,4,5- P_3 production or protein kinase C activity.^{35,36}

Thapsigargin is available in 1 mg units (T7458) and specially packaged in 20 vials containing 50 μg each (T7459). We have also prepared the green-fluorescent BODIPY® FL thapsigargin (B7487, Figure 17.2.5) and red-fluorescent BODIPY® TR-X thapsigargin (B13800, Figure 17.2.6). BODIPY® FL thapsigargin has proven useful for imaging the intracellular localization of thapsigargin during store-operated calcium entry (SOCE)³⁷ and for imaging SERCA depletion in injured sensory neurons.³⁸

Luminescent Calcium Analog

The trivalent lanthanide terbium (III), which is supplied as its chloride salt (T1247), is a luminescent analog of Ca^{2+} that can be used to study structure–function relationships in Ca^{2+} -binding proteins such as calmodulin, oncomodulin, lactalbumin and ATPases.^{39–41} The long-lived luminescence of Tb^{3+} has also been used to probe Ca^{2+} -binding sites of alkaline phosphatase,⁴² glutamine synthetase,⁴³ integrins,³⁹ protein kinase C⁴⁴ and ryanodine-sensitive Ca^{2+} channels.⁴⁵ Tb^{3+} reportedly binds most strongly to the I and II sites of calmodulin.⁴⁶

Figure 17.2.5 BODIPY® FL thapsigargin (B7487).

Figure 17.2.6 BODIPY® TR-X thapsigargin (B13800).

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- All photoactivatable probes are sensitive to light. They should be protected from illumination except when photolysis is intended.
- This compound has weaker visible absorption at >300 nm but no discernible absorption peaks in this region.
- The Ca²⁺ dissociation constant of diazo-2 is 2200 nM before photolysis and 73 nM after ultraviolet photolysis. The absorption spectrum of the photolysis product is similar to that of BAPTA. (*J Am Chem Soc* (1989) 111:7957)
- Abs and EC values determined in Ca²⁺-free solution (100 mM KCl, 10 mM EGTA, 10 mM MOPS, pH 7.2).
- K_d (Ca²⁺) increases from 5 nM to 3 mM after ultraviolet photolysis. K_d values determined in 130 mM KCl, 10 mM HEPES, pH 7.1. (*Proc Natl Acad Sci U S A* (1988) 85:6571)
- ND = not determined.
- This product is a multiply labeled bioconjugate. The number of labels per conjugate is indicated on the vial.
- Ultraviolet photolysis of I23580 generates I3716.
- K_d (Ca²⁺) increases from 80 nM to 1 mM after ultraviolet photolysis. K_d values determined in 100 mM KCl, 40 mM HEPES, pH 7.2. (*Proc Natl Acad Sci U S A* (1994) 91:187)
- This product is intrinsically a liquid or an oil at room temperature.
- N6803 is converted to N6802 via hydrolysis of its acetoxymethyl ester (AM) groups.
- Absorption and luminescence of T1247 are extremely weak unless it is chelated. Data are for dipicolinic acid (DPA) chelate. The luminescence spectrum has secondary peak at 490 nm.
- MW is for the hydrated form of this product.

PRODUCT LIST 17.2 CALCIUM REGULATION

Cat. No.	Product	Quantity
A7621	8-amino-cyclic adenosine 5'-diphosphate ribose (8-amino-cADP-ribose)	10 µg
B7487	BODIPY® FL thapsigargin	100 µg
B13800	BODIPY® TR-X thapsigargin	5 µg
C7074	cyclic adenosine 5'-diphosphate ribose, 1-(1-(2-nitrophenyl)ethyl) ester (NPE-caged cADP-ribose) *mixed isomers*	50 µg
D3034	diazo-2, tetrapotassium salt *cell impermeant*	1 mg
D6814	1-(4,5-dimethoxy-2-nitrophenyl)-1,2-diaminoethane- <i>N,N,N',N'</i> -tetraacetic acid (DMNP-EDTA) *cell impermeant*	5 mg
H7482	heparin, fluorescein conjugate	1 mg
I3716	<i>D</i> -myo-inositol 1,4,5-triphosphate, hexapotassium salt (Ins 1,4,5-P ₃)	1 mg
I23580	<i>D</i> -myo-inositol 1,4,5-triphosphate, P _{4(5)}} -(1-(2-nitrophenyl)ethyl) ester, tris(triethylammonium) salt (NPE-caged Ins 1,4,5-P ₃)	25 µg
N6803	<i>o</i> -nitrophenyl EGTA, AM (NP-EGTA, AM) *cell permeant* *special packaging*	20 x 50 µg
N6802	<i>o</i> -nitrophenyl EGTA, tetrapotassium salt (NP-EGTA) *cell impermeant*	1 mg
T1247	terbium(III) chloride, hexahydrate	1 g
T7458	thapsigargin	1 mg
T7459	thapsigargin *special packaging*	20 x 50 µg

17.3 Probes for Protein Kinases, Protein Phosphatases and Nucleotide-Binding Proteins

The cascade of cellular events in response to an internal signal or environmental stimulus requires a diversity of molecular participants, ranging from ions to enzymes. Signal transduction pathways frequently activate specific protein kinases, leading to the phosphorylation of particular cellular proteins and subsequent initiation of a multitude of cellular responses. Binding and hydrolysis of nucleotides plays a major role in these activities, and our nucleotide analogs and assays for phosphate-producing enzymes are important tools for signal transduction research and high-throughput screening of compounds that affect signal transduction.

We offer a selection of native and modified biomolecules to aid the researcher in dissecting this highly complex branch of the signal transduction process. In addition to the probes below, we have developed the *PiPer™* and *EnzChek®* assay kits for quantitation of inorganic phosphate and pyrophosphate that are extremely useful for following hydrolysis of nucleotides by various enzymes and of phosphate esters by protein phosphatases. These kits and other kits to measure ATP by chemiluminescence and protein phosphatase activity are described in Section 10.3.

Protein Kinase Probes and Assays

Protein kinases are critical players in signal transduction pathways. The fluorometric assay of kinases, however, is not straightforward because ATP-dependent phosphorylation of a fluorescent peptide substrate does not directly lead to appreciable changes in the fluorescence of the product.^{1,2} We provide an extensive range of assays for protein kinases that utilize a variety of strategies to detect phosphorylation of peptide and protein substrates (Table 17.1).

Antibody Beacon™ Tyrosine Kinase Assay Kit

The Antibody Beacon™ Tyrosine Kinase Assay Kit (A35725) provides a homogeneous solution assay for measuring the activity of tyrosine kinases and the effectiveness of potential inhibitors and modulators.³ The key to this tyrosine kinase assay is a small-molecule tracer ligand labeled with our bright green-fluorescent Oregon Green® 488 dye. When an anti-phosphotyrosine antibody binds this tracer ligand to form the Antibody Beacon™ detection complex, the fluorescence of the Oregon

Table 17.1 Invitrogen kinase assay platforms.

Assay	Principle	References
Adapta® Universal Kinase Assay	In the absence of an inhibitor, ADP formed by a kinase reaction will displace an Alexa Fluor® 647 dye-labeled ADP tracer from an Eu ³⁺ -labeled anti-ADP antibody, resulting in a decrease in the TR-FRET* signal. In the presence of an inhibitor, the amount of ADP formed by the kinase reaction is reduced, and the resulting intact antibody-tracer interaction produces a high TR-FRET signal.	
Antibody Beacon™ Tyrosine Kinase Assay	Peptide substrate phosphorylation is detected via competitive displacement of an Oregon Green® 488 dye-labeled ligand from a phosphospecific antibody.	1
LanthaScreen® Kinase Activity Assays	A terbium (Tb ³⁺)- or europium (Eu ³⁺)-labeled phosphospecific antibody binds the phosphorylated fluorescein- or Alexa Fluor® 647 dye-labeled peptide substrate, resulting in an increase in the TR-FRET signal.	2, 3
LanthaScreen® Eu Kinase Binding Assay	Binding of an Alexa Fluor® 647 tracer to a kinase is detected by addition of a Eu ³⁺ -labeled anti-epitope tag antibody. Binding of the tracer and antibody to a kinase results in a high FRET signal, whereas displacement of the tracer by a kinase inhibitor results in a loss of FRET signal.	4
LanthaScreen® Cellular Assays	Detection of phosphorylation or other protein modification event is measured on a TR-FRET-compatible plate reader. Little or no TR-FRET is observed with unstimulated or inhibited cells, whereas stimulated cell samples display high TR-FRET.	5, 6
NDP Sensor Protein	This fluorescent ADP/ATP biosensor consists of a recombinant bacterial nucleoside diphosphate kinase site-specifically labeled with an environment-sensitive coumarin dye.	7
Omnia® Kinase Assay	Fluorescence enhancement of N- or C-terminal 8-hydroxyquinoline fluorophore (Sox) upon chelation of Mg ²⁺ is coupled to phosphorylation of a peptide substrate at an adjacent Ser, Thr or Tyr residue.	8, 9
Z'-LYTE® Kinase Assay	Phosphorylation-dependent protease susceptibility of a double-labeled peptide substrate is detected using FRET.	10
CellSensor® Cell Lines	CellSensor® assays measure pathway-driven activation of transcription factors using GeneBLAzer® β-lactamase reporter technology. Minimal amounts of β-lactamase are expressed in untreated cells or cells treated with a pathway-specific inhibitor. Stimulation of the pathway with a ligand or with a constitutively active mutation in a pathway component leads to activation of downstream transcription factor(s), resulting in β-lactamase reporter gene expression. Cells are loaded with a cell-permeable β-lactamase substrate, and β-lactamase reporter activity is measured on a fluorescence plate reader.	11–13

* TR-FRET = Time-resolved fluorescence resonance energy transfer. For further information on these assay technologies and other kinase biology products and services, visit www.invitrogen.com/handbook/kinase.

Green® 488 dye is efficiently quenched. In the presence of a phosphotyrosine-containing peptide, however, this Antibody Beacon™ detection complex is rapidly disrupted, releasing the tracer ligand and relieving its antibody-induced quenching (Figure 17.3.1). Upon its displacement by a phosphotyrosine residue, the Oregon Green® 488 dye–labeled tracer ligand exhibits an approximately 4-fold fluorescence enhancement, enabling the detection of as little as 50 nM phosphotyrosine-containing peptide with excellent signal-to-background discrimination. Key benefits of the Antibody Beacon™ Tyrosine Kinase Assay Kit include:

- Real-time measurements. Unlike many other commercially available tyrosine kinase assays, the Antibody Beacon™ Tyrosine Kinase Assay Kit permits real-time monitoring of kinase activity (Figure 17.3.2). Not only is the Antibody Beacon™ detection complex rapidly dissociated in the presence of phosphotyrosine residues, but the assay components have been designed to be simultaneously combined, reducing any delay in the measurements.
- Simple detection protocol. Tyrosine kinase activity is measured by a simple increase in fluorescence intensity; no special equipment, additional reagents, or extra steps are required. This assay is readily compatible with any fluorescence microplate reader.
- Use of natural substrates. The Antibody Beacon™ tyrosine kinase assay utilizes unlabeled peptide or protein substrates, is compatible with substrates that are pre-phosphorylated at serine or threonine (but *not* at tyrosine) residues and is applicable to the assay of a wide variety of kinases.

Figure 17.3.1 Reaction scheme for the tyrosine kinase assay used in the Antibody Beacon™ Tyrosine Kinase Assay Kit (A35725). The unlabeled natural substrate (AIYAE) is phosphorylated by the tyrosine kinase to AIY(P)AE, which displaces the quenched Oregon Green® 488 dye–labeled peptide from the anti-phosphotyrosine antibody, resulting in a large increase in its fluorescence that is proportional to the amount of AIY(P)AE formed in the reaction.

Figure 17.3.2 Real-time detection capability of the Antibody Beacon™ Tyrosine Kinase Assay Kit (A35725). Fluorescence of the Antibody Beacon™ detection complex in tyrosine kinase assay buffer was monitored over time. After ~15 seconds, an excess of phosphotyrosine-containing peptide was added to the Antibody Beacon™ detection complex and the off-rate was calculated.

- Compatibility. The anti-phosphotyrosine antibody provided in the Antibody Beacon™ Tyrosine Kinase Assay Kit is specific for phosphotyrosine residues; assay components such as ATP (up to 1 mM) and reducing agents such as dithiothreitol (DTT, up to 1 mM) do not interfere with this assay. This anti-phosphotyrosine antibody was selected from among several clones to produce the greatest fluorescence enhancement by the kinase-phosphorylated product.
- Reliability. This tyrosine kinase assay has a broad signal window,⁴ indicated by a Z' factor of >0.85.

The Antibody Beacon™ Tyrosine Kinase Assay Kit comes with all the reagents needed to perform this assay, including:

- Oregon Green® 488 dye–labeled tracer ligand
- Anti-phosphotyrosine antibody
- Concentrated tyrosine kinase reaction buffer
- Two generic tyrosine kinase substrate solutions: a poly(Glu:Tyr) solution and a poly(Glu:Ala:Tyr) solution
- Dithiothreitol (DTT)
- Adenosine triphosphate (ATP)
- Phosphotyrosine-containing peptide, phospho-pp60 c-src (521–533), for use as a reference
- Detailed protocols

Each kit provides sufficient reagents to perform ~400 assays using a 50 µL assay volume in a fluorescence microplate reader.

Fluorescent Polymyxin B Analogs

Polymyxin B is a cyclic polycationic peptide antibiotic (Figure 17.3.3) that binds to lipopolysaccharides and anionic lipids.⁵ Polymyxin B is also a selective inhibitor of protein kinase C, with an IC₅₀ of ~35 µM,^{6–9} as well as a potent inhibitor of calmodulin, with an IC₅₀ of 80 nM in the presence of 500 µM Ca²⁺.¹⁰ Our fluorescent polymyxin B analogs include those of the green-fluorescent BODIPY® FL¹¹ and Oregon Green® 514 fluorophores (P13235, P13236), as well as the ultra-violet light–excitable dansyl polymyxin⁵ (P13238).

Hypericin

Hypericin (H7476, Figure 17.3.4), an anthraquinone derivative isolated from plants of the genus *Hypericum*,^{12,13} is a potent, selective inhibitor of PKC (IC₅₀ = 1.7 µg/mL = 3.4 µM) useful for probing and manipulating PKC in live cells.¹⁴ Hypericin has a variety of pharmacological properties, from antibacterial and antineoplastic activities to antiviral activities^{15–18} and induction of apoptosis.¹⁹ Hypericin is also a potent photosensitizer, with a quantum yield of 0.75 for the generation of singlet oxygen.²⁰

Figure 17.3.3 Polymyxin B.

Protein Phosphatase Assay Kits

RediPlate™ 96 EnzChek® Tyrosine Phosphatase Assay Kits

Protein tyrosine phosphatases (PTP) represent a large family of enzymes that play a very important role in intra- and intercellular signaling. PTPs work antagonistically with protein tyrosine kinases to regulate signal transduction pathways in response to a variety of signals, including hormones and mitogens.³ Our RediPlate™ 96 EnzChek® Tyrosine Phosphatase Assay Kit (R22067) provides researchers with a sensitive and convenient method to monitor PTP and screen PTP inhibitors in a variety of research areas.^{21–24}

The EnzChek® tyrosine phosphatase assay is based on 6,8-difluoro-4-methylumbellifer-yl phosphate²⁵ (DiFMUP, D6567, D22065; Section 10.3). Unlike other end-point tyrosine phosphatase assay kits, the EnzChek® tyrosine phosphatase assay is continuous, allowing researchers to easily measure fluorescence at various time points in order to follow the kinetics of the reaction. Furthermore, the assay is not affected by free phosphate and is compatible with most nonionic detergents, resulting in minimal sample processing before analysis. Most importantly, each assay well contains inhibitors to help ensure that the assay is selective for tyrosine phosphatases; other phosphatases, including serine/threonine phosphatases, will not hydrolyze DiFMUP under our assay conditions (Figure 17.3.5). Unlike phosphopeptide-based assays, this DiFMUP-based assay can be used to monitor a variety of tyrosine phosphatases, including PTP-1B and CD-45 (Figure 17.3.5). Tyrosine phosphatase inhibitors can be evaluated quantitatively in the assay for their effect on tyrosine phosphatase activity.

Each RediPlate™ 96 EnzChek® Tyrosine Phosphatase Assay Kit (R22067) includes:

- One RediPlate™ 96 EnzChek® tyrosine phosphatase assay 96-well microplate
- Reaction buffer
- Detailed assay protocols

RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit

The majority of protein phosphorylation occurs on serine and threonine residues, with <0.01–0.05% on tyrosine residues. Serine/threonine phosphatases represent a large family of enzymes that have been implicated in the regulation of metabolism, transcription, translation, differentiation, cell cycle, cytoskeletal dynamics, oncogenesis and signal transduction. The RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit (R33700) provides a fast, simple and direct fluorescence-based assay for detecting serine/threonine phosphatases and their corresponding modulators and inhibitors²⁵ (Figure 17.3.6).

As with the RediPlate™ 96 EnzChek® Tyrosine Phosphatase Kit, the substrate incorporated in the RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit is DiFMUP. Inhibitors are included in each assay well to help ensure that the assay is selective for serine/threonine phosphatases; under the prescribed assay conditions, other phosphatases, including tyrosine phosphatases, do not significantly react with the substrate (Figure 17.3.7). Furthermore, unlike phosphopeptide-based assays, this DiFMUP-based assay can be used to monitor a variety of serine/threonine phosphatases including PP-1, PP-2A and PP-2B (Figure 17.3.7). Serine/threonine phosphatase inhibitors can be evaluated quantitatively in the assay for their effect on serine/

threonine phosphatase activity (Figure 17.3.8). Additional advantages of this RediPlate™ assay include compatibility with nonionic detergents and insensitivity to free phosphate, minimizing sample processing before analysis.

Each RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit includes:

- One RediPlate™ 96 EnzChek® serine/threonine phosphatase assay 96-well microplate
- Concentrated reaction buffer
- NiCl₂
- MnCl₂
- Dithiothreitol
- Detailed assay protocols

To ensure the integrity of the predispensed reagents, the 96-well microplate provided in both RediPlate™ Protein Phosphatase Assay Kits is packaged in a resealable foil pouch and consists of twelve removable strips, each with eight wells (Figure 17.3.9). Eleven of the strips (88 wells) are preloaded with the fluorogenic substrate DiFMUP; the remaining strip, marked with black tabs, contains a dilution series of the DiFMU reference standard for generating a standard curve.

Pro-Q® Diamond Phosphoprotein/Phosphopeptide Microarray Stain Kit

The Pro-Q® Diamond Phosphoprotein/Phosphopeptide Microarray Stain Kit (P33706) provides a method for selectively staining phosphoproteins or phosphopeptides on microarrays without the use of antibodies or radioactivity. This kit permits direct detection of phosphate groups

NOTE 17.1

G-Proteins and GTP Analogs for Binding Studies

We prepare a wide variety of nucleotide analogs for protein-binding studies; their chemical and spectral properties are described in Section 17.3. These include various fluorescent, photoaffinity and caged versions of adenosine and guanosine triphosphates, diphosphates and cyclic monophosphates. The GTP analogs are among the most important probes for the study of G-proteins and G protein-coupled receptors (GPCR). Heterotrimeric guanine nucleotide-binding regulatory proteins transmit a variety of receptor signals to modulate diverse cellular responses,^{1,2} including apoptosis.³

G-proteins are composed of α -, β - and γ -subunits. Upon receptor stimulus, the α -subunit of the heterotrimeric G-proteins exchanges GDP for GTP and dissociates from the β - γ -subunit complex. The GTP-bound G protein will interact with various second-messenger systems, either inhibiting (G_i) or stimulating (G_s) their activity. Stimulatory G-proteins are permanently activated by cholera toxin, inhibitory G-proteins by pertussis toxin. The α -subunit has a slow intrinsic rate of GTP hydrolysis, and once the GTP is hydrolyzed it reassociates with the β - γ -subunit complex. The GTP hydrolysis by G-proteins is regulated by interactions with GTPase-activating proteins, or GAPs. There is a large family of GAPs for G-proteins known as regulators of G protein signaling or, RGS proteins.⁴ G-proteins are turned off when the α -subunit hydrolyzes the GTP, either spontaneously or upon interaction with a GTPase-activating protein, permitting the heterotrimeric α - β - γ -complex to reassociate.

The GAPs are a diverse group of monomeric GTPases, including ARF, Ran, Ras, Rab, Rac, Rho and Sar, which play an important part in regulating many intracellular processes, such as cytoskeletal organization and secretion. There is less diversity among the β - and γ -subunits, but they may have direct activating effects in their own right. Most β - and γ -subunits are posttranslationally modified by myristoylation or isoprenylation, which may alter their association with membranes.

Our fluorescent GTP analogs include:

- Blue-fluorescent MANT-GTP (M12415) and nonhydrolyzable MANT-GMPPNP (M22353)
- Green-fluorescent BODIPY® FL guanosine 5'-triphosphate (BODIPY® FL GTP, G12411)
- Red-fluorescent BODIPY® TR guanosine 5'-triphosphate (BODIPY® TR GTP, G22351)
- Nonhydrolyzable green-fluorescent BODIPY® FL GTP- γ -S thioester (G22183)

1. Annu Rev Biochem (2008) 77:1; 2. Physiol Rev (1999) 79:1373; 3. J Biol Chem (2000) 275:20726; 4. J Biol Chem (1998) 273:1269.

attached to tyrosine, serine or threonine residues in a microarray environment and has been optimized for microarrays with acrylamide gel surfaces. Each Pro-Q® Diamond Phosphoprotein/Phosphopeptide Microarray Stain Kit provides:

- Pro-Q® Diamond phosphoprotein/phosphopeptide microarray stain
- Pro-Q® Diamond microarray destain solution
- Microarray staining gasket with seal tabs, 10 chambers
- Slide holder tube, 20 tubes
- Detailed protocols

The Pro-Q® Diamond Phosphoprotein/Phosphopeptide Microarray Stain Kit is ideal for identifying kinase targets in signal transduction pathways and for phosphoproteomics studies.²⁶

Adenylate Cyclase Assays

3',5'-Cyclic AMP (cAMP) is an important second messenger in many signal transduction pathways, linking activation of cell-surface membrane receptors to intracellular responses, and, ultimately, to changes in gene expression. cAMP is synthesized by plasma membrane-bound adenylate cyclase, which is coupled to transmembrane receptors for hormones, neurotransmitters and other signaling molecules by heterotrimeric G-proteins. Upon ligand binding, the intracellular receptor domain of a G-protein-coupled receptor (GPCR) interacts with a G-protein, which then dissociates and activates adenylate cyclase, resulting in an increase in the concentration of intracellular cAMP. Subsequently, cAMP activates cAMP-dependent protein kinases (protein kinase A), which phosphorylate specific substrate proteins, including enzymes, structural proteins, transcription factors and ion channels.

Adenylate Cyclase Probe: BODIPY® FL Forskolin

Forskolin, isolated from *Coleus forskohlii*, is a potent activator of adenylate cyclase, the enzyme that catalyzes the formation of cAMP from ATP. Green-fluorescent BODIPY® FL forskolin (B7469, Figure 17.3.10) has been used to visualize adenylyl cyclase internalization and subcellular distribution,²⁷ as well as for the pharmacological characterization of adenylyl cyclase catalytic subunits.²⁸

cAMP Chemiluminescent Immunoassay Kit

The cAMP Chemiluminescent Immunoassay Kit enables ultrasensitive determination of 3',5'-cyclic AMP (cAMP) levels in cell lysates, providing the highest sensitivity of any commercially available cAMP assay. As few as 60 femtomoles of cAMP can be detected. Furthermore, this assay has a wide dynamic range, detecting from 0.06 to 6000 picomoles without the need for sample dilution or manipulations such as acetylation. This extensive dynamic range is especially important in cell-based assays designed to measure G_s- or G_i-coupled agonist stimulation or inhibition. Intra-assay precision for duplicate samples is typically 5% or less.

This competitive immunoassay is formatted with maximum flexibility to permit either manual assay or automated high-throughput screening. The cAMP immunoassay is based on the highly sensitive CSPD® alkaline phosphate substrate, a chemiluminescent 1,2-dioxetane, with Sapphire-II™ luminescence enhancer. The ready-to-use

substrate/enhancer reagent generates sustained glow light emission that is measured 30 minutes after addition. Once the substrate/enhancer reaches the glow signal, the plate can be read for hours with little or no degradation of the signal, facilitating screening protocols in which several plates are compared to each other. In addition, the assay exhibits exceptionally low cross-reactivity with other adenosine-containing or cyclic nucleotides.

The cAMP Chemiluminescent Immunoassay Kit (2-plate size, C10557; 10-plate size, C10558) is designed for the rapid and sensitive quantitation of cAMP in extracts prepared from mammalian cells cultured in microwell plates. Each kit provides all required reagents, including:

- Alkaline phosphate conjugate of cAMP
- Anti-cAMP antibody
- cAMP standard
- CSPD® substrate and Sapphire™-II luminescence enhancer
- Assay and lysis buffer
- Conjugate dilution buffer
- Wash buffer
- Precoated microplates
- Detailed protocols

The cAMP Chemiluminescent Immunoassay Kit is designed for quantitating cellular cAMP for functional assays of receptor activation. It has been used with established cell lines for functional measurements with endogenous receptors,^{29–32} with cell lines containing exogenously expressed ligand receptors,^{33,34} with primary cells^{35,36} and with tissues.³⁷ It has also been used for receptor characterization,³⁸ orphan receptor ligand identification³⁹ and the characterization of novel chimeric receptors.⁴⁰ In addition, this assay can be used for high-throughput screening assays⁴¹ of compounds that stimulate or interfere with these signal transduction pathways.

Nucleotide Analogs

Nucleotide analogs that serve as substrates or inhibitors of enzymes, as well as nucleotide derivatives that selectively bind to regulatory sites of nucleotide-binding proteins, have been used as structural and mechanistic probes for isolated proteins, reconstituted membrane-bound enzymes, organelles such as mitochondria, and tissues such as skinned muscle fibers.⁴² More recently, however, these analogs have also been employed to study the effects of nucleotides on signal transduction and to screen for compounds that may affect signal transduction, such as G protein inhibitors and activators (G-Proteins and GTP Analogs for Binding Studies—Note 17.1).

Figure 17.3.10 BODIPY® FL forskolin (B7469).

Figure 17.3.12 Adenosine 5'-triphosphate, BODIPY® FL 2'-(*or*-3')-*O*-(*N*-(2-aminoethyl)urethane), trisodium salt (BODIPY® FL ATP) (A12410).

Figure 17.3.13 Fluorescence emission spectra of (1) free BODIPY® FL dye in phosphate-buffered saline, pH 7.2; (2) BODIPY® FL ATP (A12410); and (3) BODIPY® FL GTP (G12411). Samples were prepared with equal absorbance at the excitation wavelength (488 nm). The areas under the curves are therefore proportional to the relative fluorescence quantum yields, clearly showing the quenching effect caused by interaction of the BODIPY® FL fluorophore with the guanine base of GTP.

Figure 17.3.14 Adenosine 5'-*O*-(3-thiotriphosphate), BODIPY® FL thioester, sodium salt (BODIPY® FL ATP-γ-S, thioester) (A22184).

Figure 17.3.11 Alexa Fluor® 488 8-(6-aminohexyl)aminoadenosine 3',5'-cyclicmonophosphate, bis(triethylammonium) salt (Alexa Fluor® 488 cAMP) (A35775).

We prepare a variety of nucleotide analogs, including:

- Alexa Fluor® derivatives of cAMP for use as probes of type I cAMP-dependent protein kinases (PKA I) and Alexa Fluor® 647 ATP (A22362)
- BODIPY® dye-labeled nucleotides for use as enzyme substrates and as long-wavelength probes of nucleotide-binding sites
- Environment-sensitive, blue-fluorescent *N*-methylanthraniloyl (MANT) nucleotides
- Blue-fluorescent ethenoadenosine triphosphate (ϵ -ATP, E23691)
- Environment-sensitive trinitrophenyl (TNP) nucleotides
- Caged nucleotides, which are important probes for studying the kinetics and mechanism of nucleotide-binding proteins because they allow spatial and temporal control of the release of active nucleotide
- Photoaffinity nucleotides for site-selective covalent labeling
- Fluorescent ChromaTide® nucleotides and aha-dUTP nucleotides, which are primarily used for biosynthetic incorporation into DNA or RNA (Section 8.2)

Alexa Fluor® cAMP and Alexa Fluor® ATP

Our Alexa Fluor® cAMP analogs are 8-(6-aminohexyl)amino derivatives; similar analogs have been shown to exhibit a marked preference for binding to type I cAMP-dependent protein kinases (PKA I). We offer the green-fluorescent Alexa Fluor® 488 cAMP (A35775, Figure 17.3.11) and far-red-fluorescent Alexa Fluor® 647 cAMP (A35777). Alexa Fluor® 488 cAMP was loaded into cells by electroporation and then used to measure intercellular diffusion of cAMP from regulatory to responder T cells via gap junctions.⁴³

The Alexa Fluor® 647 conjugate of ATP (A22362) comprises the long-wavelength Alexa Fluor® 647 fluorophore linked to the ribose of ATP by a urethane bridge. Validated applications of this probe include fluorescence resonance energy transfer (FRET) analysis (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2) of nucleotide association with Na^+/K^+ -ATPase⁴⁴ and measurements of the catalytic activity of heavy meromyosin.⁴⁵

BODIPY® Ribonucleotide Di- and Triphosphates

Our selection of BODIPY® dye-modified ribonucleotides includes:

- BODIPY® FL adenosine 5'-triphosphate (BODIPY® FL ATP, A12410)
- BODIPY® TR adenosine 5'-triphosphate (BODIPY® TR ATP, A22352)
- BODIPY® TR adenosine 5'-diphosphate (BODIPY® TR ADP, A22359)
- BODIPY® FL guanosine 5'-triphosphate (BODIPY® FL GTP, G12411)
- BODIPY® TR guanosine 5'-triphosphate (BODIPY® TR GTP, G22351)
- BODIPY® FL guanosine 5'-diphosphate (BODIPY® FL GDP, G22360)

These mixed-isomer analogs comprise a BODIPY® fluorophore attached to the 2' or 3' position of the ribose ring via an aminoethylcarbamoyl linker (Figure 17.3.12). Interactions between the fluorophore and the purine base are evident from the spectroscopic properties of these nucleotide analogs. The fluorescence quantum yield of BODIPY® FL GTP and BODIPY® FL ATP is significantly quenched in solution (Figure 17.3.13) and increases upon binding to at least some GTP-binding proteins.^{46,47} Similar nucleotide analogs incorporating fluorophores such as fluorescein, tetramethylrhodamine and Cy*3 dye have been primarily used for biophysical studies of nucleotide-binding proteins.⁴⁸ The BODIPY® dye-labeled nucleotides may be particularly useful for fluorescence polarization-based assays of ATP- or GTP-binding proteins.

Nonhydrolyzable BODIPY® ATP and GTP Analogs

Among the most useful fluorescent nucleotides for protein-binding studies are those that stoichiometrically bind to ATP- or GTP-binding sites but are not metabolized. We offer the following nonhydrolyzable BODIPY® nucleotides:

- BODIPY® FL AMPPNP⁴⁹ (B22356)
- BODIPY® FL ATP- γ -S (A22184, Figure 17.3.14)
- BODIPY® FL GTP- γ -S⁴⁶ (G22183)
- BODIPY® 515/530 GTP- γ -S (G35779)
- BODIPY® TR GTP- γ -S (G35780)
- BODIPY® FL GTP- γ -NH amide (G35778)

The fluorescence of the BODIPY® GTP- γ -S thioesters is quenched ~90% relative to that of the free dye but is recovered upon protein binding to G-proteins.⁴⁶ The green-fluorescent BODIPY® FL GTP- γ -S has been used to detect GTP-binding proteins separated by capillary electrophoresis.⁵⁰ As compared with BODIPY® FL GTP- γ -S thioester, the green-fluorescent BODIPY® 515/530 GTP- γ -S thioester has a greater fluorescence increase upon protein binding. The BODIPY® TR GTP- γ -S thioester is a red-fluorescent analog with spectral properties similar to the Texas Red® dye.

Although BODIPY® FL GTP- γ -NH amide exhibits less fluorescence enhancement upon protein binding, it is reportedly the best of the three green-fluorescent GTP- γ analogs for directly monitoring nucleotide exchange.⁵¹ The different linker lengths of the green-fluorescent GTP- γ analogs (six-carbon for BODIPY® FL GTP- γ -NH amide, four-carbon for BODIPY® FL GTP- γ -S and one-carbon for BODIPY® 515/530 GTP- γ -S) may be useful for understanding protein active-site geometries.

In addition to their potential use for binding studies, BODIPY® FL ATP- γ -S and BODIPY® FL GTP- γ -S thioesters are important substrates for Fhit (Figure 17.3.15), a member of the histidine triad superfamily of nucleotide-binding proteins that bind and cleave diadenosine polyphosphates.^{52–54} Fhit, one of the most frequently inactivated proteins in lung cancer, functions as a tumor suppressor by inducing apoptosis.^{53,55,56} These BODIPY® nucleotides should be especially useful for screening potential Fhit inhibitors and activators.

N-Methylantraniloyl (MANT) Nucleotides

The blue-fluorescent MANT nucleotide analogs of ATP (Figure 17.3.16), AMPPNP, GTP, GMPPNP, ADP and GDP are modified on the ribose moiety, making these probes particularly useful for studying nucleotide-binding proteins that are sensitive to modifications of the

Figure 17.3.15 Principle of fluorescence-based detection of the diadenosine triphosphate hydrolase activity of Fhit using BODIPY® FL GTP- γ -S thioester (G22183) as a substrate analog.

Figure 17.3.16 2'-(or-3')-O-(N-methylantraniloyl)adenosine 5'-triphosphate, trisodium salt (MANT-ATP) (M12417).

Figure 17.3.17 1,*N*⁶-ethenoadenosine 5'-triphosphate (ε-ATP) (E23691).

Figure 17.3.18 2'-(or-3')-O-(trinitrophenyl)adenosine 5'-triphosphate, trisodium salt (TNP-ATP) (T7602).

purine base.^{57,58} The compact nature of the MANT fluorophore and its attachment position on the ribose ring results in nucleotide analogs that induce minimal perturbation of nucleotide-protein interactions, as confirmed by X-ray crystal structures of MANT nucleotides bound to myosin⁵⁹ and H^{-ras} p21.⁶⁰ Furthermore, because MANT fluorescence is sensitive to the environment of the fluorophore, nucleotide-protein interactions may be directly detectable. These properties (Table 17.2) make MANT nucleotides valuable probes of the structure and enzymatic activity of nucleotide-binding proteins.⁴⁸

Applications for MANT-ATP (M12417), MANT-ADP (M12416) and MANT-AMPPNP (M22354) include analysis of:

- ATPase kinetics of kinesin^{61–63} and other microtubule motor-proteins^{64,65} using stopped-flow fluorescence measurements
- Conformation of the myosin subfragment-1 nucleotide-binding site, as indicated by fluorescence quencher accessibility^{66,67}
- Interaction of P-glycoprotein ATP-binding sites with drug efflux-modulating steroids⁶⁸
- Myosin ATPase activity in rabbit skeletal muscle⁶⁹
- Structural characteristics of the nucleotide-binding site of *Escherichia coli* DnaB helicase^{70,71}

Applications for MANT-GTP (M12415), MANT-GDP (M12414) and MANT-GMPPNP (M22353) include analysis of:

- Activation of protein kinases by Rho subfamily GTP-binding proteins⁷²
- Conformational changes during activation of heterotrimeric G-proteins⁷³
- Effects of nucleotide structural modifications on binding to H^{-ras} p21⁷⁴
- Nucleotide hydrolysis and dissociation kinetics of H^{-ras} p21 and other low molecular weight GTP-binding proteins^{57,75–78}
- GTP-binding proteins Rab5 and Rab7,⁷⁹ Raf-1,⁸⁰ Rho^{81,82} and Rac,^{83,84} as well as Ras-related proteins^{57,75}

Ethenoadenosine Nucleotide

The ethenoadenosine nucleotides—developed in 1972 by Leonard and collaborators^{85,86}—bind like endogenous nucleotides to several proteins. The properties and applications of ethenoadenosine and MANT nucleotides have been comprehensively reviewed.⁴⁸ The etheno ATP analog (ε-ATP, E23691; Figure 17.3.17) can often mimic ATP in both binding and function. This probe has been used to replace ATP in actin polymerization reactions⁸⁷ and is frequently incorporated in place of the tightly bound actin nucleotide.^{88,89} It also supports contraction of actomyosin, facilitates the measurement of nucleotide-exchange kinetics in actin⁹⁰ and serves as a substrate for myosin, which converts it to ε-ADP.⁹¹ Sensitized luminescence of Tb³⁺ (T1247, Section 14.3) coordinated to ε-ATP is a sensitive probe of binding to the catalytic site of protein disulfide isomerase.⁹²

Trinitrophenyl (TNP) Nucleotides

Unlike the etheno derivatives, the free trinitrophenyl (TNP) nucleotides are essentially non-fluorescent in water. The TNP nucleotides undergo an equilibrium transition to a semiquinoid structure that has relatively long-wavelength spectral properties;^{93–95} this form is only fluorescent when bound to the nucleotide-binding site of some proteins. The TNP derivative of ATP frequently exhibits a spectral shift and fluorescence enhancement upon protein binding and actually binds with higher affinity than ATP to some proteins. The broad, long-wavelength absorption of TNP nucleotides makes them useful for FRET studies^{96–98} (Fluorescence Resonance

Table 17.2 Spectroscopic properties of MANT-nucleotides in aqueous solution (pH 8).

Parameter	Value	Notes
Absorption maximum	356 nm	Stronger absorption at shorter wavelengths ($\lambda_{\max} = 255$ nm)
Molar extinction coefficient (EC_{\max})	$5800 \text{ cm}^{-1}\text{M}^{-1}$	$23,000 \text{ cm}^{-1}\text{M}^{-1}$ at 255 nm
Fluorescence emission maximum	448 nm	Shifts 10–20 nm shorter in nonpolar solvents and upon binding to most proteins
Fluorescence quantum yield	0.22	Increases in nonpolar solvents and upon binding to most proteins

Energy Transfer (FRET)—Note 1.2). The TNP derivatives of ATP (TNP-ATP, T7602; Figure 17.3.18), ADP (TNP-ADP, T7601) and AMP (TNP-AMP, T7624) have been used as structural probes for a wide variety of nucleotide-binding proteins.^{99–101} We have found that chromatographically purified TNP nucleotides are unstable during lyophilization. Consequently, these derivatives are sold in aqueous solution and should be frozen immediately upon arrival.

Caged Nucleotides

Caged nucleotides are nucleotide analogs in which the terminal phosphate is esterified with a blocking group, rendering the molecule biologically inactive. Photolytic removal of the caging group by UV illumination results in a pulse of the nucleotide—often on a microsecond to millisecond time scale—at the site of illumination. Because photolysis (“uncaging”) can be temporally controlled and confined to the area of illumination, the popularity of this technique is growing. We are supporting this development by synthesizing a variety of caged nucleotides, neurotransmitters and Ca²⁺ chelators. Our current selection of caged nucleotides includes:

- NPE-caged ATP (A1048)
- DMNPE-caged ATP (A1049)
- NPE-caged ADP (A7056)
- DMNB-caged c-AMP (D1037)

Section 5.3 discusses our selection of caged probes and the properties of the different caging groups that we use (Table 5.2).

Researchers investigating the cytoskeleton have benefited greatly from advances in caging technology, primarily originating from the work of Trentham, Kaplan and their colleagues.¹⁰² NPE-caged ADP (A7056) is a useful probe for studying the effect of photolytic release of ADP in muscle fibers^{103,104} and isolated sarcoplasmic reticulum.¹⁰⁵ Although it is

sometimes difficult to properly abstract papers that describe experiments with caged ATP because they could be referring to either NPE-caged ATP (A1048), DMNPE-caged ATP (A1049) or earlier caged versions of this nucleotide, most researchers have used NPE-caged ATP.

Because the caged nucleotides may be added to an experimental system at relatively high concentrations, use of the enzyme apyrase was recommended by Sleep and Burton¹⁰⁶ to eliminate any traces of ATP that may be present in the caged ATP probes.^{107–110} Once the caged ATP solutions have been preincubated with apyrase, the enzyme can be removed by centrifugal filtration.^{107,109}

These caged nucleotides are generally cell impermeant and must be microinjected into cells or loaded by other techniques (Table 14.1). Permeabilization of cells with staphylococcal α -toxin or the saponin ester β -escin is reported to make the membrane of smooth muscle cells permeable to low molecular weight (<1000 daltons) molecules, while retaining high molecular weight compounds.¹¹¹ α -Toxin permeabilization has permitted the introduction of caged nucleotides, including caged ATP (A1048) and caged GTP- γ -S, as well as of caged inositol 1,4,5-triphosphate (NPE-caged Ins 1,4,5; I23580; Section 17.2) into smooth muscle cells.¹¹² Caged inositol 1,4,5-triphosphate has also been successfully loaded in ECV304 cells using electroporation.¹¹³

BzBzATP

Functional ion channels can be assembled from both homomeric and heteromeric combinations of the seven P2X receptor subunits so far identified (P2X_{1–7}). Due to the lack of specific agonists or antagonists for P2X receptors, it is difficult to determine which receptor subtypes mediate particular cellular responses. We offer one of the most potent and widely used P2X receptor agonists, BzBzATP^{114,115} (2′-(or 3′)-O-(4-benzoylbenzoyl)adenosine 5′-triphosphate, B22358). BzBzATP has more general applications for site-directed irreversible modification of nucleotide-binding proteins via photoaffinity labeling.^{116,117}

DATA TABLE 17.3 PROBES FOR PROTEIN KINASES, PROTEIN PHOSPHATASES AND NUCLEOTIDE-BINDING PROTEINS

Cat. No.	MW	Storage	Soluble	Abs	EC	Em	Solvent	Notes
A1048	700.30	FF,D,LL	H ₂ O	259	18,000	none	MeOH	1, 2, 3
A1049	760.35	FF,D,LL	H ₂ O	351	4400	none	H ₂ O	1, 2
A7056	614.44	FF,D,LL	H ₂ O	259	15,000	none	MeOH	1, 2, 3
A12410	933.30	FF,L	H ₂ O	505	54,000	514	H ₂ O	4, 5
A12412	1117.18	FF,L	H ₂ O	323	4200	461	pH 7	4, 5, 6
A22184	878.28	FF,L	H ₂ O	504	68,000	514	pH 7	4, 5
A22352	1065.43	FF,L	H ₂ O	591	55,000	620	pH 7	4, 5
A22359	963.47	FF,L	H ₂ O	592	57,000	621	pH 7	4, 5
A22362	~2050	FF,L	H ₂ O	648	246,000	667	pH 7	4, 5
A35775	1162.23	FF,L	H ₂ O	493	71,000	517	pH 7	4, 5
A35777	~1700	FF,L	H ₂ O	649	246,000	666	pH 7	4, 5
B7469	784.70	F,D,L	DMSO	504	79,000	511	MeOH	
B22356	932.31	FF,L	H ₂ O	504	68,000	514	H ₂ O	4, 5
B22358	1018.97	FF,L	H ₂ O	260	27,000	none	pH 7	
D1037	524.38	F,D,LL	DMSO	338	6100	none	MeOH	1, 2
E23691	619.13	FF	H ₂ O	265	5000	411	pH 7	5
G12411	949.30	FF,L	H ₂ O	504	68,000	511	H ₂ O	4, 5, 7
G22183	894.28	FF,L	H ₂ O	504	68,000	510	pH 7	4, 5, 7
G22351	1081.43	FF,L	H ₂ O	591	56,000	620	pH 7	4, 5, 7
G22360	1005.75	FF,L	H ₂ O	504	68,000	508	pH 7	4, 5, 7
G35778	905.29	FF,L	H ₂ O	505	68,000	512	pH 7	4, 5, 7
G35779	865.28	FF,L	H ₂ O	511		520	pH 7	4, 5, 7
G35780	1153.60	FF,L	H ₂ O	591		621	pH 7	4, 5, 7
H7476	504.45	F,D,L	DMSO, DMF	591	37,000	594	EtOH	
M12414	620.32	FF,L	H ₂ O	356	5700	447	pH 8	4, 5, 8
M12415	722.28	FF,L	H ₂ O	356	5700	448	pH 7	4, 5, 8
M12416	604.32	FF,L	H ₂ O	356	5800	448	pH 7	4, 5, 8
M12417	706.28	FF,L	H ₂ O	356	5800	447	pH 7	4, 5, 8
M22353	721.29	FF,L	H ₂ O	357	5700	447	pH 8	4, 5, 8
M22354	705.29	FF,L	H ₂ O	357	5800	447	pH 8	4, 5, 9
T7601	682.26	FF,L	H ₂ O	408	26,000	none	pH 8	4, 5, 9
T7602	784.22	FF,L	H ₂ O	408	26,000	none	pH 8	4, 5, 9
T7624	579.29	F,L	H ₂ O	408	26,000	none	pH 8	4, 5, 9

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. Caged nucleotide esters are free of contaminating free nucleotides when initially prepared. However, some decomposition may occur during storage.
2. All photoactivatable probes are sensitive to light. They should be protected from illumination except when photolysis is intended.
3. This compound has weaker visible absorption at >300 nm but no discernible absorption peaks in this region.
4. The molecular weight (MW) of this product is approximate because the degree of hydration and/or salt form has not been conclusively established.
5. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
6. QY = 0.63 in 50 mM Tris, pH 8.0. Fluorescence shifts to longer wavelengths (Em ~475 nm) on enzymatic cleavage of the α-β phosphoryl bond. (Biochem Biophys Res Commun (1978) 81:35, J Biol Chem (1979) 254:12069)
7. Fluorescence of BODIPY® dye-labeled guanosine derivatives is generally weak due to base-specific intramolecular quenching. (Anal Biochem (2001) 291:109)
8. Fluorescence quantum yields of MANT nucleotides are environment-dependent. In H₂O, QY is ~0.2. (Biochim Biophys Acta (1983) 742:496)
9. Trinitrophenyl nucleotides are in fact very weakly fluorescent in water (Em ~560 nm). Fluorescence is blue-shifted and more intense in organic solvents (DMSO, EtOH) and when bound to proteins (Em ~540 nm). Absorption spectrum also has a second, less intense peak at about 470 nm. (Biochim Biophys Acta (1982) 719:509)

PRODUCT LIST 17.3 PROBES FOR PROTEIN KINASES, PROTEIN PHOSPHATASES AND NUCLEOTIDE-BINDING PROTEINS

Cat. No.	Product	Quantity
A22359	adenosine 5'-diphosphate, BODIPY® TR 2'-(or-3')-O-(N-(2-aminoethyl)urethane), disodium salt (BODIPY® TR ADP) *5 mM in buffer*	100 µL
A7056	adenosine 5'-diphosphate, P ² -(1-(2-nitrophenyl)ethyl) ester, monopotassium salt (NPE-caged ADP)	5 mg
A22184	adenosine 5'-O-(3-thiotriphosphate), BODIPY® FL thioester, sodium salt (BODIPY® FL ATP-γ-S, thioester) *5 mM in buffer*	50 µL
A22362	adenosine 5'-triphosphate, Alexa Fluor® 647 2'-(or-3')-O-(N-(2-aminoethyl)urethane), hexa(triethylammonium) salt (Alexa Fluor® 647 ATP) *5 mM in buffer*	100 µL
A12410	adenosine 5'-triphosphate, BODIPY® FL 2'-(or-3')-O-(N-(2-aminoethyl)urethane), trisodium salt (BODIPY® FL ATP) *5 mM in buffer*	100 µL
A22352	adenosine 5'-triphosphate, BODIPY® TR 2'-(or-3')-O-(N-(2-aminoethyl)urethane), trisodium salt (BODIPY® TR ATP) *5 mM in buffer*	100 µL
A1048	adenosine 5'-triphosphate, P ³ -(1-(2-nitrophenyl)ethyl) ester, disodium salt (NPE-caged ATP)	5 mg
A1049	adenosine 5'-triphosphate, P ³ -(1-(4,5-dimethoxy-2-nitrophenyl)ethyl) ester, disodium salt (DMNPE-caged ATP)	5 mg
A12412	adenosine 5'-triphosphate, P ³ -(5-sulfo-1-naphthylamide), tetra(triethylammonium) salt (ATP γ-AmNS) *5 mM in buffer*	400 µL
A35775	Alexa Fluor® 488 8-(6-aminohexyl)aminoadenosine 3',5'-cyclicmonophosphate, bis(triethylammonium) salt (Alexa Fluor® 488 cAMP) *5 mM in buffer*	100 µL
A35777	Alexa Fluor® 647 8-(6-aminohexyl)aminoadenosine 3',5'-cyclicmonophosphate, tetra(triethylammonium) salt (Alexa Fluor® 647 cAMP) *5 mM in buffer*	100 µL
A35725	Antibody Beacon™ Tyrosine Kinase Assay Kit *400 assays*	1 kit
A6442	anti-synapsin I (bovine), rabbit IgG fraction *affinity purified*	10 µg
B22358	2'-(or-3')-O-(4-benzoylbenzoyl)adenosine 5'-triphosphate, tris(triethylammonium) salt (BzBzATP) *5 mM in buffer*	2 mL
B7469	BODIPY® FL forskolin	100 µg
B22356	2'-(or-3')-O-(BODIPY® FL)-β-γ-imidoadenosine 5'-triphosphate, trisodium salt (BODIPY® FL AMPNP) *5 mM in buffer*	50 µL
C10558	cAMP Chemiluminescent Immunoassay Kit *10-plate size*	1 kit
C10557	cAMP Chemiluminescent Immunoassay Kit *2-plate size*	1 kit
D1037	4,5-dimethoxy-2-nitrobenzyl adenosine 3',5'-cyclicmonophosphate (DMNB-caged cAMP)	5 mg
E23691	1,N ⁶ -ethenoadenosine 5'-triphosphate (ε-ATP) *5 mM in buffer*	2 mL
G22360	guanosine 5'-diphosphate, BODIPY® FL 2'-(or-3')-O-(N-(2-aminoethyl)urethane), bis(triethylammonium) salt (BODIPY® FL GDP) *5 mM in buffer*	100 µL
G35778	guanosine 5'-O-(3-iminotriphosphate), BODIPY® FL ethylamide, sodium salt (BODIPY® FL GTP-γ-NH, amide) *1 mM in buffer*	100 µL
G35779	guanosine 5'-O-(3-thiotriphosphate), BODIPY® 515/530 thioester, sodium salt (BODIPY® 515/530 GTP-γ-S, thioester) *1 mM in buffer*	100 µL
G22183	guanosine 5'-O-(3-thiotriphosphate), BODIPY® FL thioester, sodium salt (BODIPY® FL GTP-γ-S, thioester) *5 mM in buffer*	50 µL
G35780	guanosine 5'-O-(3-thiotriphosphate), BODIPY® TR thioester, sodium salt (BODIPY® TR GTP-γ-S, thioester) *1 mM in buffer*	100 µL
G12411	guanosine 5'-triphosphate, BODIPY® FL 2'-(or-3')-O-(N-(2-aminoethyl)urethane), trisodium salt (BODIPY® FL GTP) *5 mM in water*	100 µL
G22351	guanosine 5'-triphosphate, BODIPY® TR 2'-(or-3')-O-(N-(2-aminoethyl)urethane), trisodium salt (BODIPY® TR GTP) *5 mM in water*	100 µL
H7476	hypericin	1 mg
M12416	2'-(or-3')-O-(N-methylanthraniloyl)adenosine 5'-diphosphate, disodium salt (MANT-ADP) *5 mM in buffer*	400 µL
M12417	2'-(or-3')-O-(N-methylanthraniloyl)adenosine 5'-triphosphate, trisodium salt (MANT-ATP) *5 mM in buffer*	400 µL
M12414	2'-(or-3')-O-(N-methylanthraniloyl)guanosine 5'-diphosphate, disodium salt (MANT-GDP) *5 mM in buffer*	400 µL
M12415	2'-(or-3')-O-(N-methylanthraniloyl)guanosine 5'-triphosphate, trisodium salt (MANT-GTP) *5 mM in buffer*	400 µL
M22354	2'-(or-3')-O-(N-methylanthraniloyl)-β-γ-imidoadenosine 5'-triphosphate, trisodium salt (MANT-AMPNP) *5 mM in buffer*	50 µL
M22353	2'-(or-3')-O-(N-methylanthraniloyl)-β-γ-imidoguanosine 5'-triphosphate, trisodium salt (MANT-GMPPNP) *5 mM in buffer*	50 µL
P13235	polymyxin B, BODIPY® FL conjugate, trifluoroacetic acid salt *mixed species*	100 µg
P13238	polymyxin B, dansyl conjugate, trifluoroacetic acid salt *mixed species*	100 µg
P13236	polymyxin B, Oregon Green® 514 conjugate, trifluoroacetic acid salt *mixed species*	100 µg
P33706	Pro-Q® Diamond Phosphoprotein/Phosphopeptide Microarray Stain Kit	1 kit
R33700	RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit *one 96-well microplate*	1 kit
R22067	RediPlate™ 96 EnzChek® Tyrosine Phosphatase Assay Kit *one 96-well microplate*	1 kit
T7601	2'-(or-3')-O-(trinitrophenyl)adenosine 5'-diphosphate, disodium salt (TNP-ADP) *5 mg/mL in water*	2 mL
T7624	2'-(or-3')-O-(trinitrophenyl)adenosine 5'-monophosphate, sodium salt (TNP-AMP) *5 mg/mL in buffer*	2 mL
T7602	2'-(or-3')-O-(trinitrophenyl)adenosine 5'-triphosphate, trisodium salt (TNP-ATP) *5 mg/mL in buffer*	2 mL

17.4 Probes for Lipid Metabolism and Signaling

Figure 17.4.1 Cleavage specificities of phospholipases. R¹ and R² are typically saturated or unsaturated aliphatic groups. The polar head group R³ can be choline, ethanolamine, glycerol, inositol, inositol phosphate, serine or other alcohols.

Lipids and lipid metabolites are abundant in cells and have both a structural function and a role in cell regulation. Phospholipases, in particular, play an important part in cellular signaling processes via the generation of second messengers such as diacylglycerols, arachidonate and inositol 1,4,5-triphosphate¹⁻⁴ (Ins 1,4,5-P₃, I3716; Section 17.2). In addition, phospholipase A₂ activation is a key step in inflammation processes, and phospholipase A₂ plays major roles in bacterial virulence and in the pathogenesis of acute respiratory distress syndrome⁵⁻⁷ (ARDS), making this class of enzymes important therapeutic targets.^{8,9}

Phospholipases are classified according to the cleavage site on the phospholipid substrate (Figure 17.4.1). There are at least three types of fluorescence-based phospholipase detection methods:¹⁰

- Continuous methods, which permit direct fluorometric monitoring of enzymatic activity using self-quenching or excimer-forming probes
- Methods that continuously detect nonfluorescent product formation from natural phospholipids, such as detection of fatty acids with our ADIFAB reagent or enzyme-coupled detection of choline with our Amplex® Red Phospholipase Assay Kits
- Discontinuous methods, which require resolution of fluorescent substrates and products by TLC, HPLC or other separation techniques

Table 17.3 summarizes Molecular Probes® products for fluorescence-based phospholipase assays. Other applications for our wide range of fluorescent phospholipids are described in Chapter 13.

Table 17.3 Fluorescence-based phospholipase assays.

Phospholipase*	Probes	Assay Principle	Detection Method
A ₁	A10070, E10219, E10221	Intramolecular self-quenching	Fluorescence increase at ~530 nm
A ₁ , A ₂	B7701	Intramolecular self-quenching	Fluorescence increase at ~515 nm ¹
A ₁ , A ₂	B3781, B3782	Intramolecular excimer formation	Emission ratio 380/470 nm ²⁻⁴
A ₁ , A ₂	A3880	Free fatty acid sensor	Emission ratio 432/v505 nm ⁵⁻⁷
A ₂	A10072, E10217, E10218	Intramolecular fluorescence resonance energy transfer (FRET)	Fluorescence increase at ~515 nm or increase in emission ratio at 515/575 nm
A ₂	D23739	Intramolecular self-quenching	Fluorescence increase at ~515 nm ⁸
A ₂	N3786, N3787	Intermolecular self-quenching	Fluorescence increase at ~530 nm ^{9,10}
A ₂	H361, H3809	Intermolecular excimer formation	Emission ratio 380/470 nm ¹¹⁻¹³
A ₂	D3803	Release of a fluorescent fatty acid	TLC or fluorescence image scanner ¹⁴
A ₂ , C, D	D3771	Formation of a fluorescent O-alkylglycerol derivative	TLC or HPLC ¹⁵⁻¹⁷
A ₂ , C, D	H361	Quenching by a disulfide-polymerized lipid matrix	Fluorescence increase at ~380 nm ^{18,19}
C	A12218	Peroxidase-linked detection of phosphocholine	Conversion of the nonfluorescent Amplex® Red reagent to fluorescent resorufin ²⁰⁻²²
C	E10215, E10216	Release of dye-labeled diacylglycerol	Fluorescence increase at 516 nm, with potential interference from phospholipase A ₂ and phospholipase D activity

Phospholipase A₁ and A₂ Assays

The importance of phospholipases in cellular signaling, lipid metabolism, inflammatory responses and pathological disorders related to these processes has stimulated demand for fluorescence-based enzyme activity monitoring methods. Several of the fluorogenic phospholipase A substrates described here are designed to provide continuous monitoring of phospholipase A activity in purified enzyme preparations, cell lysates and live cells; applications of some of these substrates extend as far as *in vivo* small animal imaging.^{11–13} The phospholipase A substrates are generally dye-labeled phospholipids of two types—glycerophosphocholines with BODIPY® dye-labeled *sn*-1 or *sn*-2 (or both) acyl or alkyl chains and glycerophosphoethanolamines with BODIPY® dye-labeled acyl chains and dinitrophenyl quencher-modified head groups (Figure 17.4.2). These structural variations determine specificity for phospholipase A₁ (which hydrolyzes the *sn*-1 ester linkage between phospholipids and fatty acids) versus phospholipase A₂ (which hydrolyzes the *sn*-2

ester linkage between phospholipids and fatty acids, Figure 17.4.1), and the fluorescence response associated with enzymatic cleavage of the substrate (Table 17.3).

PED-A1 Phospholipase A₁ Substrate

PED-A1 (A10070, Figure 17.4.3) is a fluorogenic substrate designed to provide specific, real-time monitoring of phospholipase A₁ activity in purified enzyme preparations, cell lysates and live cells.^{14,15} PED-A1 is comprised of a dinitrophenyl quencher-modified glycerophosphoethanolamine head group and a green-fluorescent BODIPY® FL dye-labeled acyl chain at the *sn*-1 position. Upon cleavage by phospholipase A₁, PED-A1 exhibits an increase in green fluorescence (measured at excitation/emission = 488/530 nm). Phospholipase A₁ specificity is imparted by the placement of the BODIPY® FL acyl chain in the *sn*-1 position and by incorporation of an acyl group with an enzyme-resistant (noncleavable) ether linkage in the *sn*-2 position.

Figure 17.4.2 Mechanism of phospholipase activity-linked fluorescence enhancement responses of bis-BODIPY® FL C₁₁-PC (B7701) and PED6 (D23739). Note that enzymatic cleavage of bis-BODIPY® FL C₁₁-PC yields two fluorescent products, whereas cleavage of PED6 yields only one.

Figure 17.4.3 PED-A1 (N-(6-(2,4-DNP)amino)hexanoyl)-1-(BODIPY® FL C₅)-2-hexyl-*sn*-glycero-3-phosphoethanolamine, A10070).

Figure 17.4.4 Detection of phospholipase A₁ (PLA₁) using the EnzChek® Phospholipase A₁ Assay Kit (E10219, E10221). PLA₁ reactions were run at ambient temperature with liposomes for 30 minutes according to the assay protocol provided, and fluorescence emission was measured using 460 nm excitation on a Spectra Max M5 (Molecular Devices). Background fluorescence determined for the no-enzyme control reaction has been subtracted.

Figure 17.4.6 Fluorescence emission spectra (excitation at 480 nm) of Red/Green BODIPY® PC-A2 phospholipase A₂ substrate (A10072) incorporated in liposomes with addition of bee venom phospholipase A₂ at ambient temperature.

EnzChek® Phospholipase A₁ Assay Kit

The EnzChek® Phospholipase A₁ Assay Kit (E10219, E10221) provides a simple, fluorometric method for continuous monitoring of phospholipase A₁ activity based on the phospholipase A₁-specific PED-A1 substrate (A10070, described above). The EnzChek® Phospholipase A₁ Assay Kit can detect phospholipase A₁ activity at 0.04 U/mL or lower (Figure 17.4.4). This microplate-based assay is well suited for rapid and direct analysis of phospholipase A₁ in purified enzyme preparations and cell lysates using automated instrumentation, as well as for characterizing phospholipase A₁ inhibitors.

Each EnzChek® Phospholipase A₁ Assay Kit (2-plate size, E10219; 10-plate size, E10221) provides:

- PED-A1 phospholipase A₁ substrate
- Phospholipase A₁ (Lecitase Ultra)
- Concentrated phospholipase A₁ reaction buffer
- Dioleoylphosphatidylcholine (DOPC)
- Dioleoylphosphatidylglycerol (DOPG)
- Dimethylsulfoxide (DMSO)
- Detailed assay protocols

The 2-plate assay kit provides sufficient reagents for 200 reactions in 96-well microplates at a volume of 100 μ L per well or 800 reactions using low-volume 384-well microplates at a volume of \leq 25 μ L per well. The 10-plate assay kit provides sufficient reagents for 1000 reactions in 96-well microplates at a volume of 100 μ L per well or 4000 reactions using low-volume 384-well microplates at a volume of \leq 25 μ L per well.

Red/Green BODIPY® PC-A2 Ratiometric Phospholipase A₂ Substrate

Red/Green BODIPY® PC-A2 (A10072, Figure 17.4.5) is a ratiometric fluorogenic substrate designed to provide selective, real-time monitoring of phospholipase A₂ activity in purified enzyme preparations, cell lysates and live cells. Cleavage of the BODIPY® FL pentanoic acid substituent at the *sn*-2 position results in decreased quenching by fluorescence resonance energy transfer (FRET) of the BODIPY® 558/568 dye attached at the *sn*-1 position. Thus, upon cleavage by phospholipase A₂, Red/Green BODIPY® PC-A2 exhibits an increase in BODIPY® FL fluorescence, detected from 515–545 nm (Figure 17.4.6). The FRET-sensitized BODIPY® 558/568 fluorescence signal is expected to show a reciprocal decrease; in practice, however, this longer-wavelength fluorescence may show a decrease or a slight increase, depending on the formulation of the substrate and the instrument wavelength settings. The ratiometric detection mode of this substrate (emission intensity ratio at 515/575 nm with excitation at \sim 460 nm) allows measurements of phospholipase A₂ activity that are essentially independent of instrumentation and assay conditions. The dual-emission properties of this substrate also provide the capacity to localize the lysophospholipid and fatty acid products of the phospholipase A₂ cleavage via their distinct spectroscopic signatures in imaging experiments.

EnzChek® Phospholipase A₂ Assay Kit

The EnzChek® Phospholipase A₂ Assay Kit (E10217, E10218) provides a simple, fluorometric method for continuous monitoring of phospholipase A₂ activity based on the phospholipase A₂-selective Red/Green BODIPY® PC-A2 (A10072, described above). This phospholipase A₂ assay can be used in an intensity-based detection mode, by following the fluorescence increase at

Figure 17.4.5 Red/Green BODIPY® PC-A2 (1-O-(6-BODIPY® 558/568-aminohexyl)-2-BODIPY® FL C₅-*sn*-glycero-3-phosphocholine, A10072).

~515 nm, or in a ratiometric-based detection mode, by following the changes in the emission intensity ratio at 515/575 nm with excitation at ~460 nm (Figure 17.4.7). The EnzChek® Phospholipase A₂ Assay Kit can detect bee venom phospholipase A₂ activity at 0.05 U/mL or lower (Figure 17.4.7). This microplate-based assay is well suited for rapid and direct analysis of phospholipase A₂ in purified enzyme preparations and cell lysates using automated instrumentation, as well as for characterizing phospholipase A₂ inhibitors.

Each EnzChek® Phospholipase A₂ Assay Kit (2-plate size, E10217; 10-plate size, E10218) provides:

- Red/Green BODIPY® PC-A2 phospholipase A₂ substrate
- Phospholipase A₂ from honey bee venom
- Concentrated phospholipase A₂ reaction buffer
- Dioleoylphosphatidylcholine (DOPC)
- Dioleoylphosphatidylglycerol (DOPG)
- Dimethylsulfoxide (DMSO)
- Detailed assay protocols

The 2-plate assay kit provides sufficient reagents for 200 reactions in 96-well microplates at a volume of 100 µL per well or 800 reactions using low-volume 384-well microplates at a volume of ≤25 µL per well. The 10-plate assay kit provides sufficient reagents for 1000 reactions in 96-well microplates at a volume of 100 µL per well or 4000 reactions using low-volume 384-well microplates at a volume of ≤25 µL per well.

PED6 Phospholipase A₂ Substrate

PED6 (D23739, Figure 17.4.8) is a fluorogenic substrate for phospholipase A₂ incorporating a BODIPY® FL dye-labeled *sn*-2 acyl chain and a dinitrophenyl quencher-labeled head group¹⁶ (Figure 17.4.2). Cleavage of the dye-labeled acyl chain by phospholipase A₂ eliminates the intramolecular quenching effect of the dinitrophenyl group, resulting in a corresponding fluorescence increase. Continuous kinetic assays show PED6 to be a good substrate for both secreted and cytosolic phospholipase A₂ and platelet-activating factor acetylhydrolase.¹⁶ PED6 has been used by Steven Farber and co-workers for *in vivo* analysis of intestinal lipid metabolism in zebrafish larvae as a basis for identifying and screening mutant phenotypes^{12,13,17} (Figure 17.4.9). PED6 is also useful for high-throughput screening of potential phospholipase A₂ inhibitors or activators.

Other BODIPY® Dye Phospholipase A Substrates

The bis-BODIPY® phospholipase A substrate—bis-BODIPY® FL glycerophosphocholine (bis-BODIPY® FL C₁₁-PC, B7701)—has been specifically designed to allow continuous monitoring of phospholipase A action and to be spectrally compatible with argon-ion laser excitation sources.¹⁸ When this probe is incorporated into cell membranes, the proximity of the BODIPY® FL fluorophores on adjacent phospholipid acyl chains causes fluorescence self-quenching (Figure 17.4.2). Separation of the fluorophores upon hydrolytic cleavage of one of the acyl chains by either phospholipase A₁ or A₂ results in increased fluorescence. Bis-BODIPY® FL C₁₁-PC has been developed in collaboration with Elizabeth Simons, who has successfully employed it for flow cytometric detection of phospholipase A activity in neutrophils.¹⁹ More recently, bis-BODIPY® FL C₁₁-PC has been used to detect phospholipase A₂ activation induced by tumor necrosis factor (TNF)²⁰ and for high-throughput assays of endothelial lipase, a critical determinant of HDL cholesterol levels.^{21,22}

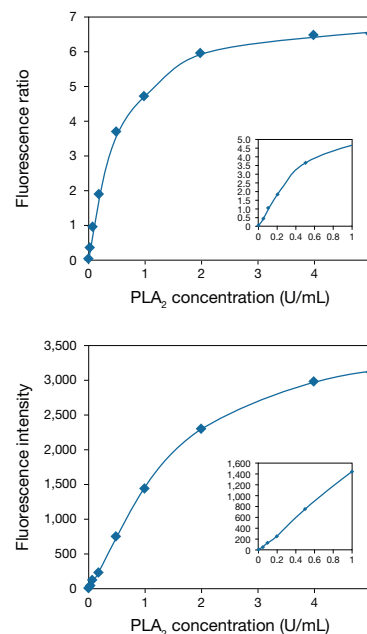

Figure 17.4.7 Detection of phospholipase A₂ (PLA₂) using the EnzChek® Phospholipase A₂ Assay Kit (E10217, E10218). PLA₂ reactions were run at ambient temperature with liposomes for 10 minutes according to the assay protocol provided, and fluorescence emission was measured using 460 nm excitation on a Spectra Max® M5 (Molecular Devices). Background fluorescence determined for the no-enzyme control reaction has been subtracted. Top panel shows ratiometric-based (515/575 nm) detection mode; bottom panel shows intensity-based (515 nm channel) detection mode. Background fluorescence determined for the no-enzyme control reaction has been subtracted for each value.

Figure 17.4.8 *N*-((6-(2,4-dinitrophenyl)amino)hexanoyl)-2-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-pentanoyl)-1-hexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt (PED6) (D23739).

Figure 17.4.9 Imaging of lipid digestion pathways in zebrafish (*Danio rerio*) using the fluorogenic phospholipase A₂ substrate PED6 (D23739). A zebrafish larva (5 days post-fertilization) was incubated with PED6 for 2 hours. Localized fluorescence in the gallbladder and intestinal lumen results from endogenous lipase activity and rapid transport of the substrate cleavage products through the intestinal and hepatobiliary systems. The image was provided by Steven A. Farber, Thomas Jefferson University.

Figure 17.4.10 2-decanoyl-1-(O-(11-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-propionyl)amino)undecyl)-sn-glycero-3-phosphocholine (D3771).

Figure 17.4.11 Assay of cytoplasmic phospholipase A₂ (cPLA₂) using β-BODIPY® FL C₅-HPC (D3803) as a substrate. The substrate was incubated in enzyme-free assay buffer (lane 1), with secreted PLA₂ (from *Naja mossambica*; lane 2) or with purified human recombinant cPLA₂ (lane 3). Cleavage products were separated by thin-layer chromatography in chloroform/methanol/acetic acid/water (50:30:8:4) and were subsequently analyzed using a fluorescence image scanner. Both phospholipases liberated fluorescent BODIPY® FL dye-labeled fatty acids (FFA) by cleavage of the substrate at the *sn*-2 acyl bond. Figure reproduced with permission from *J Biol Chem* (1999) 274:19338.

Figure 17.4.12 1,2-bis-(1-pyrenebutanoyl)-sn-glycero-3-phosphocholine (B3781).

Figure 17.4.13 Excimer formation by pyrene in ethanol. Spectra are normalized to the 371.5 nm peak of the monomer. All spectra are essentially identical below 400 nm after normalization. Spectra are as follows: 1) 2 mM pyrene, purged with argon to remove oxygen; 2) 2 mM pyrene, air-equilibrated; 3) 0.5 mM pyrene (argon-purged); and 4) 2 μM pyrene (argon-purged). The monomer-to-excimer ratio (371.5 nm/470 nm) is dependent on both pyrene concentration and the excited-state lifetime, which is variable because of quenching by oxygen.

Figure 17.4.14 1-hexadecanoyl-2-(1-pyrenedecanoyl)-sn-glycero-3-phosphocholine (β-py-C10-HPC) (H361).

Figure 17.4.15 1-hexadecanoyl-2-(1-pyrenedecanoyl)-sn-glycero-3-phosphoglycerol, ammonium salt (β-py-C10-PG) (H3809).

Specificity for phospholipase A₂ versus phospholipase A₁ can be obtained using phospholipids with nonhydrolyzable, ether-linked alkyl chains in the *sn*-1 position. A 1-*O*-alkyl-substituted phospholipid containing the BODIPY® FL fluorophore (D3771, Figure 17.4.10) is a useful substrate for a phospholipase A₂-specific chromatographic assay.²³

The singly labeled BODIPY® phospholipase A₂ substrate—β-BODIPY® FL C₅-HPC (D3803)—has been used to quantitatively delineate a discontinuous increase of Ca²⁺-dependent cytosolic phospholipase A₂ (cPLA₂) activity during zebrafish embryogenesis. The analytical method developed for this study uses a fluorescence image scanner to quantitatively detect the free BODIPY® FL dye-labeled fatty acid generated by the action of cPLA₂²⁴ (Figure 17.4.11).

Bis-Pyrenyl Phospholipase A Substrates

Our bis-pyrenyl phospholipase A probes (B3781, B3782) both emit at ~470 nm, indicating that their adjacent pyrene fluorophores (Figure 17.4.12) form excited-state dimers (Figure 17.4.13). Phospholipase A-mediated hydrolysis separates the fluorophores, which then emit as monomers at ~380 nm.²⁵ These substrates have proven to be effective phospholipase A₂ substrates in model membrane systems (Table 17.3); however, it has been reported that 1,2-bis-(1-pyrenebutanoyl)-*sn*-glycero-3-phosphocholine (B3781) is highly resistant to degradation by phospholipases in human skin fibroblasts.²⁶ 1,2-bis-(1-pyrenebutanoyl)-*sn*-glycero-3-phosphocholine has been used in a sensitive, continuous assay for lecithin:cholesterol acyltransferase^{27,28} (LCAT).

Singly Labeled Pyrenyl and NBD Phospholipase A₂ Substrates

Phospholipase A₂ activity has also been measured using phospholipids labeled with a single pyrene (H361, Figure 17.4.14; H3809, Figure 17.4.15) or NBD (N3786; N3787, Figure 17.4.16) fluorophore (Table 17.3). Because only the *sn*-2 phospholipid acyl chain is labeled, these probes can discriminate between phospholipase A₂ and phospholipase A₁ activity. To obtain a direct fluorescence response to enzymatic cleavage, sufficient phospholipid must be loaded into membranes to cause either intermolecular self-quenching (NBD-acyl phospholipids) or excimer formation²⁹ (pyreneacyl phospholipids). Pyrene-labeled acidic phospholipids—particularly the phosphoglycerol derivative^{30,31} (H3809)—are preferred as substrates by pancreatic and intestinal phospholipase A₂, whereas labeled phosphocholine (H361, Figure 17.4.14) is preferred by phospholipase A₂ from snake venom.³²

ADIFAB Indicator: A Different View of Phospholipase A Activity

The ADIFAB fatty acid indicator (A3880, Figure 17.4.17) functions as a fluorescent sensor for the free fatty acid cleavage products of phospholipases.^{33–36} It does not require membrane loading

and can be used to monitor hydrolysis of natural (rather than synthetic) substrates. Assaying lysophospholipase activity with ADIFAB yields sensitivity comparable to radioisotopic methods.³⁷ Richieri and Kleinfeld have described a methodology for using the ADIFAB reagent to measure the activity of phospholipase A₂ on cell and lipid-vesicle membranes; their assay is capable of detecting hydrolysis rates as low as 10⁻¹² mole/minute.³⁶

Phospholipase C Assays

EnzChek® Direct Phospholipase C Assay Kit

The EnzChek® Direct Phospholipase C Assay Kit (E10215, E10216) provides a simple and robust microplate-based method for monitoring phosphatidylcholine-specific phospholipase C (PC-PLC) activity in purified enzyme preparations. PC-PLC plays a crucial role in many cell signaling pathways involved in apoptosis and cell survival, as well as in diseases as diverse as cancer and HIV. This assay uses a proprietary substrate (glycerophosphoethanolamine with a dye-labeled *sn*-2 acyl chain) to detect PC-PLC activity. Substrate cleavage by PC-PLC releases dye-labeled diacylglycerol, which produces a positive fluorescence signal that can be measured continuously using a fluorescence microplate reader. The reaction product has fluorescence excitation and emission maxima of 509 nm and 516 nm, respectively.

The EnzChek® Direct Phospholipase C Assay Kit has been optimized using purified PC-PLC from *Bacillus cereus*. This assay may be amenable for use with cells and cell lysates, although the presence of phospholipase A₂ or phospholipase D activity can potentially result in confounding signal enhancement. Using the EnzChek® Direct Phospholipase C Assay Kit with purified enzyme from *Bacillus cereus*, we can typically detect as little as 10 mU/mL PC-PLC after one hour incubation at room temperature (Figure 17.4.18). This kit is also useful for characterizing PC-PLC inhibition, and because it offers a direct measurement, the potential for false positives in a compound screen is reduced.

Each EnzChek® Direct Phospholipase C Assay Kit (2-plate size, E10215; 10-plate size, E10216) provides:

- Phosphatidylcholine-specific phospholipase C (PC-PLC) substrate
- Phospholipase C from *Bacillus cereus*
- Concentrated phospholipase C reaction buffer
- Phosphatidylcholine (lecithin)
- Dimethylsulfoxide (DMSO)
- Detailed assay protocols

The 2-plate assay kit provides sufficient reagents for 200 reactions in 96-well microplates at a volume of 200 µL per well or 2000 reactions using low-volume 384-well microplates at a volume of 20 µL per well. The 10-plate assay kit provides sufficient reagents for 1000 reactions in 96-well microplates at a volume of 200 µL per well or 10,000 reactions using low-volume 384-well microplates at a volume of 20 µL per well.

Amplex® Red Phosphatidylcholine-Specific Phospholipase C Assay Kit

The Amplex® Red Phosphatidylcholine-Specific Phospholipase C Assay Kit (A12218) provides a sensitive method for continuously monitoring phosphatidylcholine-specific phospholipase C (PC-PLC) activity *in vitro* using a fluorescence microplate reader or fluorometer.^{38–40} In this enzyme-coupled assay, PC-PLC activity is monitored indirectly using the Amplex® Red reagent, a sensitive fluorogenic probe for H₂O₂ (Section 10.5). First, PC-PLC converts the phosphatidylcholine (lecithin) substrate to form phosphocholine and diacylglycerol. After the action of alkaline phosphatase, which hydrolyzes phosphocholine to inorganic phosphate and choline, choline is oxidized by choline oxidase to betaine and H₂O₂. Finally, H₂O₂, in the presence of horseradish peroxidase, reacts with the Amplex® Red reagent in a 1:1 stoichiometry to generate the highly fluorescent product, resorufin. Because resorufin has absorption and fluorescence emission maxima of approximately 571 nm and 585 nm, respectively, there is little interference from autofluorescence in most biological samples.

The Amplex® Red Phosphatidylcholine-Specific Phospholipase C Assay Kit is potentially useful for detecting PC-PLC activity in cell extracts and for screening PC-PLC inhibitors. Experiments

Figure 17.4.16 2-(12-(7-nitrobenzyl-2-oxa-1,3-diazol-4-yl)amino)dodecanoyl-1-hexadecanoyl-*sn*-glycero-3-phosphocholine (NBD C12-HPC) (N3787).

Figure 17.4.17 Ribbon representation of the ADIFAB free fatty acid indicator (A3880). In the left-hand image, the fatty acid binding site of intestinal fatty acid-binding protein (yellow) is occupied by a covalently attached acrylodan fluorophore (blue). In the right-hand image, a fatty acid molecule (gray) binds to the protein, displacing the fluorophore (green) and producing a shift of its fluorescence emission spectrum. Image contributed by Alan Kleinfeld, FFA Sciences LLC, San Diego.

Figure 17.4.18 Detection of phosphatidylcholine-specific phospholipase C (PC-PLC) using the EnzChek® Direct Phospholipase C Assay Kit (E10215, E10216). Triplicate samples of PC-PLC from *Bacillus cereus* were assayed at concentration of 7.8 mU/mL to 500 mU/mL per well in the presence of 1X PLC substrate and 200 µM lecithin in 1X PLC reaction buffer. Reactions were incubated at room temperature for 60 minutes and fluorescence was measured using excitation/emission wavelengths of 490/520 nm. The inset represents a separate experiment and illustrates the linearity of fluorescence response at low levels of PC-PLC. The average variation of replicates (CV) was less than 3%. Background fluorescence determined for the no-enzyme control reaction has been subtracted.

Figure 17.4.19 Detection of phosphatidylcholine-specific phospholipase C using the Amplex® Red Phosphatidylcholine-Specific Phospholipase C Assay Kit (A12218). Fluorescence was measured in a fluorescence microplate reader using excitation at 560 ± 10 nm and fluorescence detection at 590 ± 10 nm. The inset shows the sensitivity at very low enzyme concentrations.

Figure 17.4.20 Quantitation of phospholipase D from *Streptomyces chromofuscus* using the Amplex® Red Phospholipase D Assay Kit (A12219). Fluorescence was measured with a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. The inset shows the sensitivity at very low enzyme concentrations (0–25 mU/mL).

Figure 17.4.21 EnzChek® lipase substrate (E33955).

with purified PC-PLC from *Bacillus cereus* indicate that the Amplex® Red Phosphatidylcholine-Specific Phospholipase C Assay Kit can detect PC-PLC levels as low as 0.2 mU/mL using a reaction time of one hour (Figure 17.4.19). One unit of PC-PLC is defined as the amount of enzyme that will liberate 1.0 micromole of water-soluble organic phosphorus from L- α -phosphatidylcholine per minute at pH 7.3 at 37°C.

Each Amplex® Red Phosphatidylcholine-Specific Phospholipase C Assay Kit includes:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- H₂O₂ for use as a positive control
- Concentrated reaction buffer
- Choline oxidase from *Alcaligenes* sp.
- Alkaline phosphatase from calf intestine
- L- α -Phosphatidylcholine (lecithin)
- Phosphatidylcholine-specific phospholipase C from *Bacillus cereus*
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using a fluorescence microplate reader and a reaction volume of 200 μ L per assay.

Bacillus cereus PI-PLC

Phosphatidylinositol-specific phospholipase C (PI-PLC, EC 3.1.4.10) from *Bacillus cereus* cleaves phosphatidylinositol (PI), yielding water-soluble D-*myo*-inositol 1,2-cyclic monophosphate and lipid-soluble diacylglycerol.⁴¹ This enzyme also functions to release enzymes that are linked to glycosylphosphatidylinositol (GPI) membrane anchors. We offer highly purified *B. cereus* PI-PLC (P6466), which has been used in studies of PI synthesis and export across the plasma membrane.⁴² PI-PLC generates diacylglycerols for PKC-linked signal transduction studies⁴³ and provides an efficient means of releasing most GPI-anchored proteins from cell surfaces under conditions in which the cells remain viable.^{44,45}

Phospholipase D Assays

Amplex® Red Phospholipase D Assay Kit

The Amplex® Red Phospholipase D Assay Kit (A12219) provides a sensitive method for measuring phospholipase D (PLD) activity *in vitro* using a fluorescence microplate reader or fluorometer.^{38,40,46} In this enzyme-coupled assay, PLD activity is monitored indirectly using the Amplex® Red reagent (Section 10.5). First, PLD cleaves the phosphatidylcholine (lecithin) substrate to yield choline and phosphatidic acid. Second, choline is oxidized by choline oxidase to betaine and H₂O₂. Finally, H₂O₂, in the presence of horseradish peroxidase, reacts with the Amplex® Red reagent to generate the highly fluorescent product, resorufin (excitation/emission maxima ~571/585 nm).

The Amplex® Red Phospholipase D Assay Kit is designed for detecting PLD activity in cell extracts and for screening PLD inhibitors. This kit can be used to continuously assay PLD enzymes with near-neutral pH optima, whereas PLD enzymes with acidic pH optima can be assayed in a simple two-step procedure. Experiments with purified PLD from *Streptomyces chromofuscus* indicate that the Amplex® Red Phospholipase D Assay Kit can detect PLD levels as low as 10 mU/mL using a reaction time of one hour (Figure 17.4.20). One unit of PLD is defined as the amount of enzyme that will liberate 1.0 micromole of choline from L- α -phosphatidylcholine per minute at pH 8.0 at 30°C. Each Amplex® Red Phospholipase D Assay Kit includes:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- H₂O₂ for use as a positive control
- Concentrated reaction buffer
- Choline oxidase from *Alcaligenes* sp.
- L- α -Phosphatidylcholine (lecithin)
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using a fluorescence microplate reader and a reaction volume of 200 μL per assay.

Fluorescent Substrates for Phospholipase D

The products of phospholipase A₂, C and D cleavage of 1-*O*-alkyl-2-decanoyl-*sn*-glycero-3-phosphocholine labeled with the BODIPY® FL fluorophore (D3771, Figure 17.4.10) can be separated and independently quantitated based on their differential migration on TLC or HPLC.^{23,47,48} Our BODIPY® FL analog is preferred for this application because it is relatively photostable and the fluorescence properties of its different enzymatic products are all very similar.⁴⁹ Researchers have taken advantage of these features to detect and quantitate phospholipase D activity in vascular smooth muscle cells,^{49,50} cultured mammalian cells⁵¹ and yeast.^{52–54}

EnzChek® Lipase Substrate

The triacylglycerol-based EnzChek® lipase substrate (E33955, Figure 17.4.21) offers higher throughput and better sensitivity than chromogenic (TLC or HPLC) assays, and a visible light-excitabile alternative to 6,8-difluoro-4-methylumbelliferyl octanoate (DiFMU octanoate, D12200; Section 10.6). In the presence of lipases, the nonfluorescent EnzChek® lipase substrate produces a bright, green-fluorescent product (excitation/emission maxima of ~505/515 nm) for the accurate and sensitive detection of lipase activity in solution.

Anti-Phosphoinositide Monoclonal Antibodies

Phosphatidylinositol (PI or PtdIns) and its phosphorylated derivatives represent only a small fraction of eukaryotic cellular phospholipids but are functionally significant in a disproportionately large number of regulatory and signal transduction processes.^{55–60} The most familiar of these processes is the phospholipase C-mediated generation of the ubiquitous second messengers inositol 1,4,5-triphosphate (InsP₃) and diacylglycerol (DAG) from phosphatidylinositol 4,5-diphosphate (PtdIns(4,5)P₂; Section 17.2). Research has revealed the direct action of phosphatidylinositol 4,5-diphosphate (PtdIns(4,5)P₂) and phosphatidylinositol 3,4,5-triphosphate (PtdIns(3,4,5)P₃) on a diverse array of cellular functions, including actin assembly and cytoskeletal dynamics, vesicular protein trafficking, protein kinase localization and activation, cell proliferation and apoptosis. We offer mouse monoclonal IgM antibodies to PtdIns(4,5)P₂ (A21327) and PtdIns(3,4,5)P₃ (A21328) for immunocytochemical localization of these important lipid metabolites.⁶¹ Both antibodies have been shown to recognize their cognate phosphoinositides in murine and human cells with only slight cross-reactivity with other phosphoinositides or phospholipids.

Sphingolipids

Sphingolipids include sphingomyelins, which are phospholipid analogs, as well as ceramides, glycosyl ceramides (cerebrosides), gangliosides and other derivatives (Figure 17.4.22). Several excellent reviews of the chemistry and biology of sphingolipids and glycosphingolipids and their role in the process of signal transduction are available.^{62,63}

Figure 17.4.22 A) Phosphatidylcholines, phosphatidylinositols and phosphatidic acids are examples of glycerolipids derived from glycerol. B) Sphingomyelins, ceramides and cerebrosides are examples of sphingolipids derived from sphingosine. In all the structures shown, R represents the hydrocarbon tail portion of a fatty acid residue.

Figure 17.4.23 *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-pentanoyl)sphingosine (BODIPY[®] FL C₅-ceramide) (D3521).

Figure 17.4.24 *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-pentanoyl)sphingosyl phosphocholine (BODIPY[®] FL C₅-sphingomyelin) (D3522).

Figure 17.4.25 Nucleus and Golgi apparatus of a bovine pulmonary artery endothelial cell (BPAEC) labeled with Hoechst 33342 (H1399, H3569, H21492) and the BSA complex of BODIPY[®] FL C₅-ceramide (B22650), respectively.

Figure 17.4.26 Cells in the notochord rudiment of a zebrafish embryo undergoing mediolateral intercalation to lengthen the forming notochord. BODIPY[®] FL C₅-ceramide (D3521) localizes in the interstitial fluid of the zebrafish embryo and freely diffuses between cells, illuminating cell boundaries. This confocal image was obtained using a Bio-Rad[®] MRC-600 microscope. Image contributed by Mark Cooper, University of Washington.

Figure 17.4.27 BODIPY[®] TR ceramide (*N*-((4-(4,4-difluoro-5-(2-thienyl)-4-bora-3a,4a-diaza-*s*-indacene-3-yl)phenoxy)acetyl)sphingosine) (D7540).

BODIPY[®] Sphingolipids

Ceramides (*N*-acylsphingosines), like diacylglycerols, are lipid second messengers that function in signal transduction processes.^{63–65} The concentration-dependent spectral properties of BODIPY[®] FL C₅-ceramide (D3521, B22650; Figure 17.4.23), BODIPY[®] FL C₅-sphingomyelin^{66–68} (D3522, Figure 17.4.24) and BODIPY[®] FL C₁₂-sphingomyelin⁶⁹ (D7711) make them particularly suitable for investigating sphingolipid transport and metabolism,^{68,70–73} in addition to their applications as structural markers for the Golgi complex⁷⁴ (Section 12.4). BODIPY[®] FL C₅-ceramide can be visualized by fluorescence microscopy^{75,76} (Figure 17.4.25, Figure 17.4.26) or by electron microscopy following diaminobenzidine (DAB) photoconversion to an electron-dense product.⁷⁷ (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2).

Our range of BODIPY[®] sphingolipids also includes the long-wavelength light-excitable BODIPY[®] TR ceramide^{78,79} (D7540, Figure 17.4.27), as well as BODIPY[®] FL C₅-lactosylceramide^{80–85} (D13951), BODIPY[®] FL C₅-ganglioside G_{M1}⁸⁶ (B13950, Figure 17.4.28) and BODIPY[®] FL C₁₂-galactocerebroside (D7519). All of our sphingolipids are prepared from *D*-erythro-sphingosine and therefore have the same stereochemical conformation as natural biologically active sphingolipids.⁸⁷

Complexing fluorescent lipids with defatted bovine serum albumin (BSA) facilitates cell labeling by eliminating the need for organic solvents to dissolve the lipophilic probe; the

Figure 17.4.28 BODIPY[®] FL C₅-ganglioside GM1 (B13950).

Figure 17.4.29 Selective staining of the Golgi apparatus using the green-fluorescent BODIPY[®] FL C₅-ceramide (D3521) (top panel). At high concentrations, the BODIPY[®] FL fluorophore forms excimers that can be visualized using a red longpass optical filter (bottom panel). The BODIPY[®] FL C₅-ceramide accumulation in the trans-Golgi is sufficient for excimer formation (J Cell Biol (1991) 113:1267). Images contributed by Richard Pagano, Mayo Foundation.

Figure 17.4.30 Live J774 macrophage cells labeled with BODIPY[®] FL C₅-ganglioside G_{M1} (B13950) and then with Alexa Fluor[®] 555 cholera toxin subunit B conjugate (C22843). Cells were then treated with anti-CT-B antibody to induce crosslinking. Yellow fluorescence indicates colocalization of the two dyes. Nuclei were stained with the blue fluorescent Hoechst 33342 dye (H1399, H3570, H21492).

BSA-complexed probe can be directly dissolved in water.⁸⁸ We offer four BODIPY® sphingolipid-BSA complexes for the study of lipid metabolism and trafficking, including:

- BODIPY® FL C₅-ceramide (B22650)
- BODIPY® TR ceramide (B34400)
- BODIPY® FL C₅-lactosylceramide (B34401)
- BODIPY® FL C₅-ganglioside G_{M1} (B34402)

BODIPY® FL C₅-ceramide has been used to investigate the linkage of sphingolipid metabolism to protein secretory pathways⁸⁹⁻⁹¹ and neuronal growth.^{83,92} Internalization of BODIPY® FL C₅-sphingomyelin (D3522) from the plasma membrane of human skin fibroblasts results in a mixed population of labeled endosomes that can be distinguished based on the concentration-dependent green (~515 nm) or red (~620 nm) emission of the probe⁶⁸ (Figure 17.4.29). BODIPY® C₅-sphingomyelin has also been used to assess sphingomyelinase gene transfer and expression in hematopoietic stem and progenitor cells.⁹³ BODIPY® FL C₅-lactosylceramide, BODIPY® FL C₅-ganglioside G_{M1} and BODIPY® FL cerebrosides are useful tools for the study of glycosphingolipid transport and signaling pathways in cells.⁹⁴⁻⁹⁷ BODIPY® FL C₅-ganglioside G_{M1} has been shown to form cholesterol-enhanced clusters in membrane complexes with amyloid β-protein in a model of Alzheimer disease amyloid fibrils.⁹⁸ Colocalization of fluorescent cholera toxin B conjugates (Section 7.7) and BODIPY® FL C₅-ganglioside G_{M1} observed by fluorescence microscopy provides a direct indication of the association of these molecules in lipid rafts^{99,100} (Figure 17.4.30, Figure 17.4.31).

NBD Sphingolipids

NBD C₆-ceramide (N1154, Figure 17.4.32) and NBD C₆-sphingomyelin (N3524) analogs predate their BODIPY® counterparts and have been extensively used for following sphingolipid metabolism in cells¹⁰¹⁻¹⁰³ and in multicellular organisms.¹⁰⁴ As with BODIPY® FL C₅-ceramide, we also offer NBD C₆-ceramide complexed with defatted BSA (N22651) to facilitate cell loading without the use of organic solvents to dissolve the probe.⁸⁸ Elimination of NBD fluorescence at the extracellular surface by dithionite reduction (Figure 17.4.33) can be used to assess endocytosis and recycling of NBD sphingolipids.

Amplex® Red Sphingomyelinase Assay Kit

The Amplex® Red Sphingomyelinase Assay Kit (A12220) is designed for measuring sphingomyelinase activity in solution using a fluorescence microplate reader or fluorometer (Figure 17.4.34). This assay should be useful for screening sphingomyelinase activators or inhibitors or for detecting sphingomyelinase activity in cell and tissue extracts. The assay, which uses natural sphingomyelin as the principal substrate, employs an enzyme-coupled detection scheme in which phosphocholine liberated by the action of sphingomyelinase is cleaved by alkaline phosphatase to generate choline. Choline is, in turn, oxidized to betaine by choline oxidase, generating H₂O₂, which drives the conversion of the Amplex® Red reagent (A12222, A22177; Section 10.5) to red-fluorescent resorufin (Figure 17.4.35). This sensitive assay technique has been employed to detect activation of acid sphingomyelinase associated with ultraviolet radiation-induced apoptosis¹⁰⁵ and to characterize an insecticidal sphingomyelinase C produced by *Bacillus cereus*.¹⁰⁶

Figure 17.4.31. A J774 mouse macrophage cell sequentially stained with BODIPY® FL ganglioside G_{M1} (B13950) and then with Alexa Fluor® 555 dye-labeled cholera toxin subunit B (C22843, C34776). The cell was then treated with an anti-CT-B antibody to induce crosslinking. Alexa Fluor® 555 dye fluorescence (left panel, red) and BODIPY® FL dye fluorescence (middle panel, green) were imaged separately and overlaid to emphasize the coincident staining (right panel, yellow). Nuclei were stained with blue-fluorescent Hoechst 33258 (H1398, H3569, H21491).

Figure 17.4.32 NBD C₆-ceramide (6-(N-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoyl)sphingosine (N1154).

Fluorescent

Nonfluorescent

Figure 17.4.33 Dithionite reduction of 6-(N-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoic acid (NBD-X, N1316). The elimination of fluorescence associated with this reaction, coupled with the fact that extraneously added dithionite is not membrane permeant, can be used to determine whether the NBD fluorophore is located in the external or internal monolayer of lipid bilayer membranes.

Figure 17.4.34 Measurement of sphingomyelinase activity using the Amplex® Red Sphingomyelinase Assay Kit (A12220). Each reaction contained 50 μM Amplex® Red reagent, 1 U/mL horseradish peroxidase (HRP), 0.1 U/mL choline oxidase, 4 U/mL of alkaline phosphatase, 0.25 mM sphingomyelin and the indicated amount of *Staphylococcus aureus* sphingomyelinase in 1X reaction buffer. Reactions were incubated at 37°C for 1 hour. Fluorescence was measured with a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm.

Figure 17.4.35 Absorption and fluorescence emission spectra of resorufin in pH 9.0 buffer.

Figure 17.4.36 The free fatty acid-dependent spectral shift of ADIFAB reagent (A3880). Spectra shown represent 0.2 μM ADIFAB in pH 8.0 buffer with (+OA) and without (-OA) addition of 4.7 μM *cis*-9-octadecenoic (oleic) acid (OA). The ratio of fluorescence emission intensities at 505 nm and 432 nm can be quantitatively related to free fatty acid concentrations.

The Amplex® Red Sphingomyelinase Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- H_2O_2 for use as a positive control
- Concentrated reaction buffer
- Choline oxidase from *Alcaligenes* sp.
- Alkaline phosphatase from calf intestine
- Sphingomyelin
- Triton X-100
- Sphingomyelinase from *Bacillus* sp.
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using a fluorescence microplate reader and a reaction volume of 200 μL per assay.

ADIFAB Reagent: A Unique Free Fatty Acid Indicator

Elevated levels of free fatty acids (FFA)—which are associated with multiple pathological states, including cancer, diabetes and cardiac ischemia¹⁰⁷—are generated by inflammatory responses, phospholipase A activity and cytotoxic phenomena.¹⁰⁸ Sensitive techniques are required to detect and quantitate free fatty acids because these important metabolites have low aqueous solubility and are usually found complexed to carriers. ADIFAB (A3880) is a dual-wavelength fluorescent FFA indicator that consists of a polarity-sensitive fluorescent probe (acrylodan, A433; Section 2.3) conjugated to I-FABP, a rat intestinal fatty acid-binding protein with a low molecular weight (15,000 daltons) and a high binding affinity for FFA^{109–111} (Figure 17.4.17).

As shown in Figure 17.4.36, titration of the ADIFAB reagent with oleic acid results in a shift of its fluorescence maximum from ~432 nm to ~505 nm. The ratio (R) of these signals (505 nm/432 nm) can be converted to an FFA concentration by using the FFA dissociation constant (K_d) and employing analysis procedures similar to those developed for Ca^{2+} indicators¹¹² (Chapter 19). Values of K_d vary considerably for different fatty acids; a typical value is 0.28 μM for oleic acid¹¹¹ (determined at 37°C). There is little, if any, interference from bile acids, glycerides, sterols or bilirubin. With appropriate precautions, which are described in the product information sheet accompanying this product, ADIFAB can be used to determine FFA concentrations in the range 1 nM to >20 μM .

ADIFAB was used to investigate the physical basis of *cis*-unsaturated fatty acid inhibition of cytotoxic T cells.¹¹³ This effect is due to inhibition of a specific tyrosine phosphorylation event that normally accompanies antigen stimulation.^{114,115} Measurements using ADIFAB have also revealed previously undetected differences in FFA binding affinities among fatty acid-binding proteins from different tissues^{116,117} and have enabled quantitation of FFA levels in human serum as a potential diagnostic tool.^{107,118}

Notes

- ADIFAB fatty acid indicator is a protein conjugate with a molecular weight of approximately 15,350. Em shifts from about 432 nm to 505 nm upon binding of fatty acids. (*Mol Cell Biochem* (1999) 192:87)
- Chloroform is the most generally useful solvent for preparing stock solutions of phospholipids (including sphingomyelins). Glycerophosphocholines are usually freely soluble in ethanol. Most other glycerophospholipids (phosphoethanolamines, phosphatidic acids and phosphoglycerols) are less soluble in ethanol, but solutions up to 1–2 mg/mL should be obtainable, using sonication to aid dispersion if necessary. Labeling of cells with fluorescent phospholipids can be enhanced by addition of cyclodextrins during incubation. (*J Biol Chem* (1999) 274:35359)
- Phospholipase A cleavage generates a fluorescent fatty acid (P1903MP (Section 13.2)) and a fluorescent lysophospholipid.
- Phospholipase A cleavage generates a fluorescent fatty acid (P31 (Section 13.2)) and a fluorescent lysophospholipid.
- Phospholipase A cleavage results in increased fluorescence with essentially no wavelength shift. The cleavage products are D3862 (Section 13.2) and a fluorescent lysophospholipid.
- Em for BODIPY® FL sphingolipids shifts to ~620 nm when high concentrations of the probe (>5 mol %) are incorporated in lipid mixtures. (*J Cell Biol* (1991) 113:1267)
- This product is a lipid complexed with bovine serum albumin (BSA). Spectroscopic data are for the free lipid in MeOH.
- Phospholipase A₂ cleavage generates a fluorescent fatty acid (D3834 (Section 13.2)) and a nonfluorescent lysophospholipid.
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- Phospholipase A₂ cleavage results in increased fluorescence with essentially no wavelength shift. The cleavage products are D3834 (Section 13.2) and a dinitrophenylated lysophospholipid.
- Fluorescence of the intact substrate is weak. Lipase hydrolysis releases a highly fluorescent fatty acid (D3823, Section 13.2).
- Pyrene derivatives exhibit structured spectra. The absorption maximum is usually about 340 nm with a subsidiary peak at about 325 nm. There are also strong absorption peaks below 300 nm. The emission maximum is usually about 376 nm with a subsidiary peak at 396 nm. Excimer emission at about 470 nm may be observed at high concentrations.
- Phospholipase A₂ hydrolysis releases a fluorescent fatty acid; P31 (Section 13.2).
- Fluorescence of NBD and its derivatives in water is relatively weak. QY and τ increase and Em decreases in aprotic solvents and other nonpolar environments relative to water. (*Biochemistry* (1977) 16:5150, *Photochem Photobiol* (1991) 54:361)
- Phospholipase A₂ hydrolysis releases a fluorescent fatty acid; N316 (Section 13.2) from N3786 or N678 (Section 13.2) from N3787.
- Phospholipase A₁ cleavage results in increased fluorescence with essentially no wavelength shift. The cleavage products are D3834 (Section 13.2) and a dinitrophenylated lysophospholipid.
- A10072 exhibits dual emission (Em = 510 nm and 567 nm in MeOH, 513 nm and 575 nm when incorporated in phospholipid bilayer membranes). Phospholipase A₂ cleavage results in increased 510–513 nm emission and reciprocally diminished 567–575 nm emission.
- A10072 is also soluble at 2 mM in 2-methoxyethanol.

PRODUCT LIST 17.4 PROBES FOR LIPID METABOLISM AND SIGNALING

Cat. No.	Product	Quantity
A3880	ADIFAB fatty acid indicator	200 µg
A12218	Amplex® Red Phosphatidylcholine-Specific Phospholipase C Assay Kit *500 assays*	1 kit
A12219	Amplex® Red Phospholipase D Assay Kit *500 assays*	1 kit
A12220	Amplex® Red Sphingomyelinase Assay Kit *500 assays*	1 kit
A21328	anti-phosphatidylinositol 3,4,5-triphosphate, mouse IgM, monoclonal RC6F8 (anti-PtdIns(3,4,5)P ₃) *1 mg/mL*	100 µL
A21327	anti-phosphatidylinositol 4,5-diphosphate, mouse IgM, monoclonal 2C11 (anti-PtdIns(4,5)P ₂) *1 mg/mL*	100 µL
B3781	1,2-bis-(1-pyrenebutanoyl)-sn-glycero-3-phosphocholine	1 mg
B3782	1,2-bis-(1-pyrenedecanoyl)-sn-glycero-3-phosphocholine	1 mg
B7701	1,2-bis-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-undecanoyl)-sn-glycero-3-phosphocholine (bis-BODIPY® FL C ₁₁ -PC)	100 µg
B22650	BODIPY® FL C ₅ -ceramide complexed to BSA	5 mg
B13950	BODIPY® FL C ₅ -ganglioside G _{M1}	25 µg
B34401	BODIPY® FL C ₅ -ganglioside G _{M1} complexed to BSA	1 mg
B34402	BODIPY® FL C ₅ -lactosylceramide complexed to BSA	1 mg
B34353	BODIPY® FL phosphatidylinositol(4,5) bisphosphate (BODIPY® FL PtdIns(4,5)P ₂)	50 µg
D7540	BODIPY® TR ceramide (N-((4-(4,4-difluoro-5-(2-thienyl)-4-bora-3a,4a-diaza-s-indacene-3-yl)phenoxy)acetyl)sphingosine)	250 µg
B34400	BODIPY® TR ceramide complexed to BSA	5 mg
D3771	2-decanoyl-1-(O-(11-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-propionyl)amino)undecyl)-sn-glycero-3-phosphocholine	1 mg
D7519	N-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-dodecanoyl)sphingosyl 1-β-D-galactopyranoside (BODIPY® FL C ₁₂ -galactocerebroside)	25 µg
D7711	N-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-dodecanoyl)sphingosyl phosphocholine (BODIPY® FL C ₁₂ -sphingomyelin) *1 mg/mL in DMSO*	250 µL
D3803	2-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-pentanoyl)-1-hexadecanoyl-sn-glycero-3-phosphocholine (β-BODIPY® FL C ₅ -HPC)	100 µg
D3521	N-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-pentanoyl)sphingosine (BODIPY® FL C ₅ -ceramide)	250 µg
D13951	N-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-pentanoyl)sphingosyl 1-β-D-lactoside (BODIPY® FL C ₅ -lactosylceramide)	25 µg
D3522	N-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-pentanoyl)sphingosyl phosphocholine (BODIPY® FL C ₅ -sphingomyelin)	250 µg
D23739	N-((6-(2,4-dinitrophenyl)amino)hexanoyl)-2-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-pentanoyl)-1-hexadecanoyl-sn-glycero-3-phosphoethanolamine, triethylammonium salt (PED6)	1 mg
E10215	EnzChek® Direct Phospholipase C Assay Kit *phosphatidylcholine specific* *2-plate size*	1 kit
E10216	EnzChek® Direct Phospholipase C Assay Kit *phosphatidylcholine specific* *10-plate size*	1 kit
E33955	EnzChek® lipase substrate *green fluorescent, 505/515*	100 µg
E10219	EnzChek® Phospholipase A ₁ Assay Kit *2-plate size*	1 kit
E10221	EnzChek® Phospholipase A ₁ Assay Kit *10-plate size*	1 kit
E10217	EnzChek® Phospholipase A ₂ Assay Kit *2-plate size*	1 kit
E10218	EnzChek® Phospholipase A ₂ Assay Kit *10-plate size*	1 kit
H361	1-hexadecanoyl-2-(1-pyrenedecanoyl)-sn-glycero-3-phosphocholine (β-py-C ₁₀ -HPC)	1 mg
H3809	1-hexadecanoyl-2-(1-pyrenedecanoyl)-sn-glycero-3-phosphoglycerol, ammonium salt (β-py-C ₁₀ -PG)	1 mg
N1154	NBD C ₆ -ceramide (6-((N-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoyl)sphingosine)	1 mg
N22651	NBD C ₆ -ceramide complexed to BSA	5 mg
N3524	NBD C ₆ -sphingomyelin (6-((N-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoyl)sphingosyl phosphocholine)	1 mg
N3787	2-(12-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)dodecanoyl-1-hexadecanoyl-sn-glycero-3-phosphocholine (NBD C ₁₂ -HPC)	5 mg
N3786	2-(6-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoyl-1-hexadecanoyl-sn-glycero-3-phosphocholine (NBD C ₆ -HPC)	5 mg
A10070	PED-A1 (N-((6-(2,4-DNP)amino)hexanoyl)-1-(BODIPY® FL C ₅)-2-hexyl-sn-glycero-3-phosphoethanolamine) *phospholipase A ₁ selective substrate*	100 µg
P6466	phospholipase C, phosphatidylinositol-specific *from <i>Bacillus cereus</i> * *100 U/mL*	50 µL
A10072	Red/Green BODIPY® PC-A2 (1-O-(6-BODIPY® 558/568-aminohexyl)-2-BODIPY® FL C ₅ -sn-glycero-3-phosphocholine) *ratiometric phospholipase A ₂ substrate*	100 µg

CHAPTER 18

Probes for Reactive Oxygen Species,
Including Nitric Oxide

18.1 Introduction to Reactive Oxygen Species	805
18.2 Generating and Detecting Reactive Oxygen Species	806
Generating Singlet Oxygen	806
Hypericin	806
Rose Bengal Diacetate	806
Merocyanine 540	806
Detecting Singlet Oxygen	807
Singlet Oxygen Sensor Green Reagent	807
<i>trans</i> -1-(2'-Methoxyvinyl)pyrene	807
Generating Hydroxyl and Superoxide Radicals	807
Malachite Green	807
1,10-Phenanthroline Iodoacetamide	807
Detecting Hydroxyl and Superoxide Radicals	808
MitoSOX™ Red Mitochondrial Superoxide Indicator	808
Dihydroethidium (Hydroethidine)	808
Fluorogenic Spin Traps	809
Chemiluminescent and Chromogenic Reagents for Detecting Superoxide	809
Detecting Peroxides, Peroxyl Radicals and Lipid Peroxidation	810
<i>cis</i> -Parinaric Acid	810
Diphenyl-1-Pyrenylphosphine	810
BODIPY® 581/591 C: A Ratiometric Lipid Peroxidation Sensor	811
Other Scavengers for Peroxyl Radicals	811
Luminol	811
Detecting 4-Hydroxy-2-Nonenal	811
Detecting Peroxides and Peroxidases with Amplex® Red Reagents	811
Amplex® Red Reagent: Stable Substrate for Peroxidase Detection	811
Amplex® UltraRed Reagent: Brighter and More Sensitive than the Amplex® Red Reagent	812
Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit	812
Amplex® Red Xanthine/Xanthine Oxidase Assay Kit	812
EnzChek® Myeloperoxidase (MPO) Activity Assay Kit	813
Zen™ Myeloperoxidase (MPO) ELISA Kit	814
Assaying Oxidative Activity in Live Cells	815
Dichlorodihydrofluorescein Diacetate	815
Improved Versions of H ₂ DCFDA	816
Image-iT® LIVE Green Reactive Oxygen Species Detection Kit	817
Aminophenyl Fluorescein and Hydroxyphenyl Fluorescein	817
Dihydrocalcein AM	818
OxyBURST® Green Reagents	818
Amine-Reactive OxyBURST® Green Reagent	818

Dihydrorhodamine 123	818
A Longer-Wavelength Reduced Rhodamine	819
Reduced MitoTracker® Probes	819
RedoxSensor™ Red CC-1 Stain	819
Glutathiolation Detection with BioGEE	819
Tetrazolium Salts: Chromogenic Redox Indicators	820
Data Table 18.2 Generating and Detecting Reactive Oxygen Species	821
Product List 18.2 Generating and Detecting Reactive Oxygen Species	823
18.3 Probes for Nitric Oxide Research	824
Spontaneous Nitric Oxide Donors and Antagonist	824
Spermine NONOate	824
SNAP and SIN-1	824
Carboxy-PTIO: A Nitric Oxide Antagonist	824
SNAP: A Photoactivatable Nitric Oxide Donor	824
Detecting Nitric Oxide, Nitrite and Nitrate	824
DAF-FM Nitric Oxide Indicator	824
2,3-Diaminonaphthalene	825
1,2-Diaminoanthraquinone	826
NBD Methylhydrazine	826
Dichlorodihydrofluorescein Diacetate and Dihydrorhodamine 123	826
Anti-Nitrotyrosine Antibody	826
S-Nitrosothiol Detection	826
Griess Reagent Kit	827
Measure-iT™ High-Sensitivity Nitrite Assay Kit	827
Data Table 18.3 Probes for Nitric Oxide Research	828
Product List 18.3 Probes for Nitric Oxide Research	828

18.1 Introduction to Reactive Oxygen Species

Activated oxygen species are produced during a number of physiological¹⁻³ and pathological⁴⁻⁷ processes. Their effects are through reactions with a large variety of easily oxidizable cellular components, including NADH, NADPH, ascorbic acid, histidine, tryptophan, tyrosine, cysteine, glutathione, proteins and nucleic acids.⁸⁻¹² Reactive oxygen species can also oxidize cholesterol and unsaturated fatty acids, causing membrane lipid peroxidation.^{7,13,14} Several reviews discuss the chemistry of the different reactive oxygen species and their detection.¹⁵⁻¹⁹

Molecular Probes® products include probes that either generate or detect various reactive oxygen species (Table 18.1), including singlet oxygen (¹O₂), superoxide anion (•O₂⁻), hydroxyl radical (HO•) and various peroxides (ROOR') and hydroperoxides (ROOH). Section 18.2 describes these probes and their applications *in vitro* and *in vivo*.

The importance of the nitric oxide radical (abbreviated NO) and other reactive oxygen species as biological messengers is the focus of intense research.²⁰⁻²² Section 18.3 is devoted to our probes for promoting, inhibiting or detecting nitric oxide production in a variety of experimental systems.

Table 18.1 Reactive oxygen species.

Reactive Oxygen Species	Structure	Detection Reagents
Hydrogen peroxide	H ₂ O ₂	<ul style="list-style-type: none"> Carboxy-H₂DCFDA (C400)¹⁻³ CM-H₂DCFDA (C6827)^{4,5} Dihydrocalcein AM (D23805) Dihydrorhodamine 123 (D632, D23806)⁶ Dihydrorhodamine 6G (D633)⁷

18.2 Generating and Detecting Reactive Oxygen Species

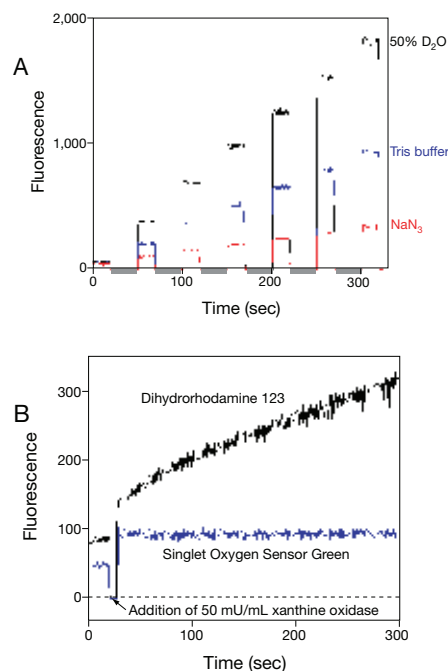

Figure 18.2.1 Fluorescence response and specificity of Singlet Oxygen Sensor Green reagent (S36002) to $^1\text{O}_2$. **A**) Fluorescence measurements were made in a spectrofluorometer using excitation/emission wavelengths of 488/525 nm for solutions containing: 1 μM Singlet Oxygen Sensor Green reagent and 10 μM methylene blue in 100 mM pH 7.5 Tris buffer alone, the singlet oxygen scavenger sodium azide (NaN_3 , 1 mM), or 50% D_2O , which increases the lifetime of $^1\text{O}_2$. Measurements were made for 20-second periods, with 30-second intervals (indicated by grey bars) between each measurement. During the 30-second intervals, the samples were exposed to laser radiation (630–680 nm, <5 mW), resulting in methylene blue–photosensitized generation of $^1\text{O}_2$. **B**) Fluorescence measurements were made in a spectrofluorometer using excitation/emission wavelengths of 488/525 nm for solutions of 50 mM pH 7 Tris buffer with 1 mM xanthine containing either 1 μM Singlet Oxygen Sensor Green reagent or dihydrorhodamine 123 (D632, D23806). After ~20 seconds, 50 mU/mL of xanthine oxidase (XO) was added. XO catalyzes the oxidation of xanthine, producing uric acid and superoxide. Superoxide can spontaneously degrade to H_2O_2 .

We offer an assortment of Molecular Probes® products for the generation of reactive oxygen species (ROS), including singlet oxygen ($^1\text{O}_2$), superoxide ($\bullet\text{O}_2^-$), hydroxyl radical ($\text{HO}\bullet$) and various peroxides (ROOR') and hydroperoxides (ROOH) (Table 18.1), as well as for their fluorometric detection in solution. Although there are no sensors that reversibly monitor the level of reactive oxygen species, this section discusses a number of probes that trap or otherwise react with singlet oxygen, hydroxyl radicals or superoxide. The optical or electron spin properties of the resulting products can be used as a measure of the presence or quantity of the reactive oxygen species and, in certain cases, can report the kinetics and location of their formation.

Generating Singlet Oxygen

Singlet oxygen is responsible for much of the physiological damage caused by reactive oxygen species, including nucleic acid modification through selective reaction with deoxyguanosine to form 8-hydroxydeoxyguanosine^{1,2} (8-OHdG). The lifetime of singlet oxygen is sufficiently long (4.4 microseconds in water³) to permit significant diffusion in cells and tissues.⁴ In the laboratory, singlet oxygen is usually generated in one of three ways: photochemically from dioxygen ($^3\text{O}_2$) using a photosensitizing dye (Figure 18.2.1), chemically by thermal decomposition of a peroxide or dioxetane, or by microwave discharge through an oxygen stream. Singlet oxygen can be directly detected by its characteristic weak chemiluminescence at 1270 nm.^{4,5}

Hypericin

Among the most efficient reagents for generating singlet oxygen is the photosensitizer hypericin (H7476, Figure 18.2.2), a natural pigment isolated from plants of the genus *Hypericum*. This heat-stable dye exhibits a quantum yield for singlet oxygen generation in excess of 0.7, as well as high photostability, making it an important agent for both anticancer and antiviral research.^{6,7}

Rose Bengal Diacetate

Rose bengal diacetate (R14000) is an efficient, cell-permeant generator of singlet oxygen.^{8–10} It is an iodinated xanthene derivative that has been chemically modified by the introduction of acetate groups (Figure 18.2.3). These modifications inactivate both its fluorescence and photosensitization properties, while increasing its ability to cross cell membranes. Once inside a live cell, esterases remove the acetate groups, restoring rose bengal to its native structure. Its intracellular localization allows rose bengal diacetate to be a very effective photosensitizer.

Merocyanine 540

Photoirradiation of merocyanine 540 (M24571) produces both singlet oxygen and other reactive oxygen species, including oxygen radicals.^{11–14} Merocyanine 540 is often used as a photosensitizer in photodynamic therapy.¹⁵

Detecting Singlet Oxygen

Singlet Oxygen Sensor Green Reagent

Unlike other fluorescent and chemiluminescent singlet oxygen detection reagents, the Singlet Oxygen Sensor Green reagent (S36002) is highly selective for singlet oxygen ($^1\text{O}_2$); it shows no appreciable response to other reactive oxygen species, including hydroxyl radical ($\text{HO}\cdot$), superoxide ($\cdot\text{O}_2^-$) and nitric oxide (NO) (Figure 18.2.1). Before reaction with singlet oxygen, this probe initially exhibits weak blue fluorescence with excitation peaks at 372 and 393 nm and emission peaks at 395 and 416 nm. In the presence of singlet oxygen, however, it emits a green fluorescence similar to that of fluorescein (excitation/emission maxima $\sim 504/525$ nm).

We have observed that the fluorescent product of Singlet Oxygen Sensor Green reagent can degrade with time in some solutions and that Singlet Oxygen Sensor Green reagent can become fluorescent at alkaline pH in the absence of singlet oxygen. Nevertheless, with the proper controls the intensity of the green-fluorescent signal can be correlated with singlet oxygen concentration, without significant interference from other reactive oxygen species. The Singlet Oxygen Sensor Green reagent has demonstrated utility for detecting singlet oxygen in solution^{16,17} and in plant tissues.^{18,19}

trans-1-(2'-Methoxyvinyl)pyrene

trans-1-(2'-Methoxyvinyl)pyrene (M7913) can be used to detect picomole quantities of singlet oxygen in chemical and biological systems (Figure 18.2.4), making this compound one of the most sensitive singlet oxygen probes currently available.^{20–22} Furthermore, this highly selective chemiluminescent probe does not react with other activated oxygen species such as hydroxyl radical, superoxide or hydrogen peroxide.

Generating Hydroxyl and Superoxide Radicals

Hydroxyl and superoxide radicals have been implicated in a number of pathological conditions, including ischemia, reperfusion and aging. The superoxide anion (Table 18.1) may also play a role in regulating normal vascular function. The hydroxyl radical is a very reactive oxygen species²³ that has a lifetime of about 2 nanoseconds in aqueous solution and a radius of diffusion of about 20 Å. Thus, it induces peroxidation only when it is generated in close proximity to its target. The hydroxyl radical can be derived from superoxide in a Fenton reaction catalyzed by Fe^{2+} or other transition metals, as well as by the effect of ionizing radiation on dioxygen. Superoxide is most effectively generated from a hypoxanthine–xanthine oxidase generating system^{24–26} (Figure 18.2.1).

Malachite Green

Malachite green is a nonfluorescent photosensitizer that absorbs at long wavelengths (~ 630 nm). Its photosensitizing action can be targeted to particular cellular sites by conjugating malachite green isothiocyanate (M689, Figure 18.2.5) to specific antibodies.^{27,28} Enzymes and other proteins within ~ 10 Å of the binding site of the malachite green–labeled antibody can then be selectively destroyed upon irradiation with long-wavelength light. Studies by Jay and colleagues have demonstrated that this photoinduced destruction of enzymes in the immediate vicinity of the chromophore is apparently the result of localized production of hydroxyl radicals, which have short lifetimes that limit their diffusion from the site of their generation.²⁹

1,10-Phenanthroline Iodoacetamide

Conjugation of the iodoacetamide of 1,10-phenanthroline (P6879, Figure 18.2.6) to thiol-containing ligands confers the metal-binding properties of this important complexing agent on the ligand. For example, the covalent copper–phenanthroline complex of oligonucleotides or nucleic acid–binding molecules in combination with hydrogen peroxide acts as a chemical nuclease to selectively cleave DNA or RNA.^{30,31} Hydroxyl radicals or other reactive oxygen species appear to be involved in this cleavage.^{32,33}

Figure 18.2.4 Reaction of *trans*-1-(2'-methoxyvinyl)pyrene (M7913) with singlet oxygen ($^1\text{O}_2$), yielding a dioxetane intermediate that generates chemiluminescence (CL) upon decomposition to 1-pyrenecarboxaldehyde.

Figure 18.2.5 Malachite green isothiocyanate (M689).

Figure 18.2.6 *N*-(1,10-phenanthroline-5-yl)iodoacetamide (P6879).

Figure 18.2.7 Detection of superoxide in live cells using MitoSOX™ Red superoxide indicator (M36008). Live 3T3 cells were treated with FeTCPP, a superoxide scavenger (right), or left untreated (left). Cells were then labeled with MitoSOX™ Red reagent, which fluoresces when oxidized by superoxide, and nuclei were stained with blue-fluorescent Hoechst 33342. The mitochondria of untreated cells exhibited red fluorescence, indicating the presence of superoxide, whereas the mitochondria of treated cells showed minimal fluorescence.

Figure 18.2.8 Oxidation of MitoSOX™ Red mitochondrial superoxide indicator to 2-hydroxy-5-(triphenylphosphonium)hexylethidium by superoxide ($\text{O}_2^{\cdot-}$).

Figure 18.2.9 Selectivity of the MitoSOX™ Red mitochondrial superoxide indicator (M36008). Cell-free systems were used to generate a variety of reactive oxygen species (ROS) and reactive nitrogen species (RNS); each oxidant was then added to a separate 10 μM solution of MitoSOX™ Red reagent and incubated at 37°C for 10 minutes. Excess DNA was added (unless otherwise noted) and the samples were incubated for an additional 15 minutes at 37°C before fluorescence was measured. The Griess Reagent Kit (G7921) (for nitric oxide, peroxynitrite, and nitrite standards only; blue bars) and dihydrorhodamine 123 (DHR 123 (D632); green bars) were employed as positive controls for oxidant generation. Superoxide dismutase (SOD), a superoxide scavenger, was used as a negative control for superoxide. The results show that the MitoSOX™ Red probe (red bars) is readily oxidized by superoxide but not by the other oxidants.

Figure 18.2.10 Dihydroethidium (hydroethidine, D1168).

Detecting Hydroxyl and Superoxide Radicals

MitoSOX™ Red Mitochondrial Superoxide Indicator

Mitochondrial superoxide is generated as a by-product of oxidative phosphorylation. In an otherwise tightly coupled electron transport chain, approximately 1–3% of mitochondrial oxygen consumed is incompletely reduced; these "leaky" electrons can quickly interact with molecular oxygen to form superoxide anion, the predominant reactive oxygen species in mitochondria.^{34,35} Increases in cellular superoxide production have been implicated in cardiovascular diseases, including hypertension, atherosclerosis and diabetes-associated vascular injuries,³⁶ as well as in neurodegenerative diseases such as Parkinson disease, Alzheimer disease and amyotrophic lateral sclerosis (ALS).³⁵

MitoSOX™ Red mitochondrial superoxide indicator (M36008) is a cationic derivative of dihydroethidium (also known as hydroethidine; see below) designed for highly selective detection of superoxide in the mitochondria of live cells (Figure 18.2.7). The cationic triphenylphosphonium substituent of MitoSOX™ Red indicator is responsible for the electrophoretically driven uptake of the probe in actively respiring mitochondria. Oxidation of MitoSOX™ Red indicator (or dihydroethidium) by superoxide results in hydroxylation at the 2-position (Figure 18.2.8). 2-hydroxyethidium (and the corresponding derivative of MitoSOX™ Red indicator) exhibits a fluorescence excitation peak at $\sim 400\text{ nm}$ ³⁷ that is absent in the excitation spectrum of the ethidium oxidation product generated by reactive oxygen species other than superoxide. Thus, fluorescence excitation at 400 nm with emission detection at $\sim 590\text{ nm}$ provides optimum discrimination of superoxide from other reactive oxygen species^{37–39} (Figure 18.2.9).

Measurements of mitochondrial superoxide generation using MitoSOX™ Red indicator in mouse cortical neurons expressing caspase-cleaved tau microtubule-associated protein have been correlated with readouts from fluorescent indicators of cytosolic and mitochondrial calcium and mitochondrial membrane potential.⁴⁰ The relationship of mitochondrial superoxide generation to dopamine transporter activity, measured using the aminostyryl dye substrate 4-Di-1-ASP (D288, Section 12.2), has been investigated in mouse brain astrocytes.⁴¹ MitoSOX™ Red indicator has been used for confocal microscopy analysis of reactive oxygen species (ROS) production by mitochondrial NO synthase (mtNOS) in permeabilized cat ventricular myocytes⁴² and, in combination with Amplex® Red reagent, for measurement of mitochondrial superoxide and hydrogen peroxide production in rat vascular endothelial cells.⁴³ In addition to imaging and microscope photometry measurements, several flow cytometry applications of MitoSOX™ Red indicator have also been reported. Detailed protocols for simultaneous measurements of mitochondrial superoxide generation and apoptotic markers APC annexin V (A35110, Section 15.5) and SYTOX® Green (S7020, Section 8.1) in human coronary artery endothelial cells by flow cytometry have been published by Mukhopadhyay and co-workers.⁴⁴

Dihydroethidium (Hydroethidine)

Although dihydroethidium (Figure 18.2.10), which is also called hydroethidine, is commonly used to analyze respiratory bursts in phagocytes,⁴⁵ it has been reported that this probe undergoes significant

oxidation in resting leukocytes, possibly through the uncoupling of mitochondrial oxidative phosphorylation.⁴⁶ Cytosolic dihydroethidium exhibits blue fluorescence; however, once this probe is oxidized to ethidium it intercalates within DNA, staining the cell nucleus a bright fluorescent red^{47–49} (Figure 18.2.11). The mechanism of dihydroethidium's interaction with lysosomes and DNA has been described.⁵⁰ Similar to MitoSOX™ Red mitochondrial superoxide indicator (Figure 18.2.8), dihydroethidium is oxidized by superoxide to 2-hydroxyethidium.³⁷ It is frequently used for mitochondrial superoxide detection,^{51–54} although MitoSOX™ Red indicator provides more specific mitochondrial localization. Indeed, in some cases researchers have used dihydroethidium and MitoSOX™ Red indicator to provide discrete indications of cytosolic and mitochondrial superoxide production, respectively.⁵⁵

Dihydroethidium (hydroethidine) is available in a 25 mg vial (D1168), as a stabilized 5 mM solution in DMSO (D23107) or specially packaged in 10 vials of 1 mg each (D11347); the stabilized DMSO solution or special packaging is recommended when small quantities of the dye will be used over a long period of time.

Fluorogenic Spin Traps

Hydroxyl radicals have usually been detected after reaction with spin traps. We offer TEMPO-9-AC (A7923, Figure 18.2.12) and proxyl fluorescamine^{56–59} (C7924, Figure 18.2.13), two fluorogenic probes for detecting hydroxyl radicals⁶⁰ and superoxide. Each of these molecules contains a nitroxide moiety that effectively quenches its fluorescence. However, once TEMPO-9-AC or proxyl fluorescamine traps a hydroxyl radical or superoxide, its fluorescence is restored and the radical's electron spin resonance signal is destroyed, making these probes useful for detecting radicals either by fluorescence or by electron spin resonance spectroscopy. TEMPO-9-AC has been reported to detect glutathionyl radicals but not phenoxyl radicals.⁶¹ Proxyl fluorescamine can be used to detect the methyl radicals that are formed by reacting hydroxyl radicals with DMSO.⁵⁹ Radical-specific scavengers (Table 18.2)—such as the superoxide-specific *p*-benzoquinone and superoxide dismutase⁶² or the hydroxyl radical-specific mannitol and dimethylsulfoxide (DMSO)^{56,63,64}—can be used to identify the detected species.

Chemiluminescent and Chromogenic Reagents for Detecting Superoxide

In the absence of apoaquorin, the luminophore coelenterazine (C2944) produces chemiluminescence in response to superoxide generation in cells, organelles, bacteria⁶⁵ and tissues.⁶⁶ Unlike luminol, coelenterazine exhibits luminescence that does not depend on the activity of cell-derived myeloperoxidase and is not inhibited by azide.⁶⁷

In addition to coelenterazine, we offer MCLA (M23800, Figure 18.2.14) for detecting superoxide.⁶⁸ MCLA and coelenterazine are superior alternatives to lucigenin⁶⁵ (L6868) for this application because lucigenin can reportedly sensitize superoxide production, leading to false-positive results.^{69–73} An additional advantage of MCLA is that its pH optimum for luminescence generation is closer to the physiological near-neutral range than are the pH optima of luminol and lucigenin.⁷⁴

Nitro blue tetrazolium salt (NBT, N6495; Table 18.3) and other tetrazolium salts are chromogenic probes useful for superoxide determination.^{75,76} The superoxide sensitivity of tetrazolium salts can be a confounding factor in their more common applications for cell viability and proliferation assays.⁷⁷

Detecting Peroxides, Peroxyl Radicals and Lipid Peroxidation

In peroxisomes, H₂O₂ is produced by several enzymes that use molecular oxygen to oxidize organic compounds. This H₂O₂ is then used by catalase to oxidize other substrates, including phenols, formic acid, formaldehyde and alcohol. In liver and kidney cells, these oxidation reactions are important for detoxifying a variety of compounds in the bloodstream.^{78–81} However, H₂O₂ also plays a role in neurodegenerative and other disorders through induction of apoptosis⁸² and DNA strand breaks,⁸³ modification of intracellular Ca²⁺ levels and mitochondrial potential, and oxidation of glutathione. In addition, H₂O₂ is released from cells during hypoxia.⁸⁴

Peroxidation of unsaturated lipids affects cell membrane properties,⁸⁵ signal transduction pathways,^{86,87} apoptosis and the deterioration of foods and other biological compounds.⁸⁸ Lipid hydroperoxides have been reported to accumulate in oxidatively stressed individuals, including HIV-infected patients.⁸⁹ Lipid peroxidation may also be responsible for aging, as well as for pathological processes such as drug-induced phototoxicity and atherosclerosis,⁹⁰ and is often the cause of

free radical-mediated damage in cells. To directly assess the extent of lipid peroxidation, researchers either measure the amount of lipid hydroperoxides directly or detect the presence of secondary reaction products^{91–93} (e.g., 4-hydroxy-2-nonenal or malonaldehyde; see below).

Peroxyl radicals are formed by the decomposition of various peroxides and hydroperoxides, including lipid hydroperoxides. The hydroperoxyl radical is also the protonated form of superoxide, and approximately 0.3% of the superoxide in the cytosol is present as this protonated radical.⁹⁴ Experimentally, peroxyl radicals, including alkylperoxyl (ROO•) and hydroperoxyl (HOO•) radicals, are generated from compounds such as 2,2'-azobis(2-amidinopropane) and from hydroperoxides such as cumene hydroperoxide.

cis-Parinaric Acid

Fluorescence quenching of the fatty acid analog *cis*-parinaric acid (P36005) has been used in several lipid peroxidation assays,^{95–97} including quantitative determinations in live cells.^{98,99} Parinaric acid's extensive unsaturation (Figure 18.2.15) makes it quite susceptible to oxidation if not rigorously protected from air.¹⁰⁰ Consequently, we offer *cis*-parinaric acid in a 10 mL unit size of a 3 mM solution in deoxygenated ethanol (P36005); if stored protected from light under an inert argon atmosphere at –20°C, this stock solution should be stable for at least 6 months. During experiments, we advise handling parinaric acid samples under inert gas and preparing solutions using degassed buffers and solvents. Parinaric acid is also somewhat photolabile and undergoes photodimerization when exposed to intense illumination, resulting in loss of fluorescence.¹⁰¹

Diphenyl-1-Pyrenylphosphine

Hydroperoxides in lipids, serum, tissues and foodstuffs can be directly detected using the fluorogenic reagent diphenyl-1-pyrenylphosphine^{102,103} (DPPP, D7894). DPPP is essentially nonfluorescent until oxidized to a phosphine oxide by peroxides; *in vitro*, DPPP remains nonfluorescent in the presence of hydroxyl radicals generated by the Cu²⁺-ascorbate method.¹⁰⁴ DPPP has previously been used to detect

Figure 18.2.15 *cis*-parinaric acid (P36005).

picomole levels of hydroperoxides by HPLC.^{105,106} Its solubility in lipids makes DPPP quite useful for detecting hydroperoxides in the membranes of live cells^{104,107,108} and in low-density lipoprotein particles.¹⁰⁹

BODIPY® 581/591 C: A Ratiometric Lipid Peroxidation Sensor

The BODIPY® 581/591 C₁₁ fatty acid (D3861, Figure 18.2.16) is a sensitive fluorescent reporter for lipid peroxidation, undergoing a shift from red to green fluorescence emission upon oxidation of the phenylbutadiene segment of the fluorophore.¹¹⁰ This oxidation-dependent emission shift enables fluorescence ratio imaging of lipid peroxidation in live cells.^{111–113} Other common applications of BODIPY® 581/591 C₁₁ include fluorometric assays of antioxidant efficacy in plasma^{114,115} and in lipid vesicles.¹¹⁶ The oxidation and nitroxidation products of this BODIPY® fatty acid have been characterized by mass spectrometry.^{117,118} Based on mass spectrometry analysis of oxidation products, MacDonald and co-workers report that BODIPY® 581/591 C₁₁ is more sensitive to oxidation than endogenous lipids, and therefore tends to overestimate oxidative damage and underestimate antioxidant protection effects.¹¹⁹

Peroxyl radicals have also been detected in erythrocyte and red blood cell membranes using BODIPY® FL EDA¹²⁰ (D2390, Section 3.4), a water-soluble BODIPY® dye, or BODIPY® FL hexadecanoic acid (D3821, Section 13.2). BODIPY® FL hexadecanoic acid exhibits the red shift common to the fluorescence of lipophilic BODIPY® dyes when they are concentrated, permitting ratiometric measurements of hydroxyl radical production and allowing the onset of lipid peroxidation in live cells to be monitored.¹²¹

Other Scavengers for Peroxyl Radicals

The fluorescence of several other probes is lost following interaction with peroxyl radicals. Lipophilic fluorescein dyes such as hexadecanoylamino fluorescein¹²² (H110, Section 13.5) and fluorescein-labeled phosphatidylethanolamine (F362, Section 13.2) have been useful for detecting peroxyl radical formation in membranes and in solution. Phycobiliproteins, such as B-phycoerythrin, R-phycoerythrin and allophycocyanin (P800, P801, A803, A819; Section 6.4), and phenolic dyes such as fluorescein (F1300, F36915; Section 10.1) are extensively used as substrates in total antioxidant capacity assays of plasma and foods.^{115,123,124}

Luminol

Although luminol (L8455) is not useful for detecting superoxide in live cells,¹²⁵ it is commonly employed to detect peroxidase- or metal ion-mediated oxidative events.^{126–128} Used alone, luminol can detect oxidative events in cells rich in peroxidases, including granulocytes^{129–132} and spermatozoa.¹³³ This probe has also been used in conjunction with

Figure 18.2.16 4,4-difluoro-5-(4-phenyl-1,3-butadienyl)-4-bora-3a,4a-diaza-5-indacene-3-undecanoic acid (BODIPY® 581/591 C₁₁, D3861).

horseradish peroxidase (HRP) to investigate reoxygenation injury in rat hepatocytes.^{134,135} In these experiments, it is thought that the primary species being detected is hydrogen peroxide. In addition, luminol has been employed to detect peroxynitrite generated from the reaction of nitric oxide and superoxide.^{136–138}

Detecting 4-Hydroxy-2-Nonenal

Formation of 4-hydroxy-2-nonenal (HNE) from linoleic acid is a major cause of lipid peroxidation-induced toxicity. Several reagents for the direct fluorometric detection of aldehydes are described in Section 3.3. The biotinylated hydroxylamine ARP (A10550, Section 4.2) is particularly useful for this purpose.¹³⁹ Biotinylation using click chemistry coupling (Section 3.1) enables affinity purification of HNE-modified proteins.¹⁴⁰

Detecting Peroxides and Peroxidases with Amplex® Red Reagents

Amplex® Red Reagent: Stable Substrate for Peroxidase Detection

In the presence of horseradish peroxidase (HRP), Amplex® Red reagent (10-acetyl-3,7-dihydroxyphenoxazine, A12222, A22177; Figure 18.2.17) reacts with H₂O₂ in a 1:1 stoichiometry to produce highly fluorescent resorufin¹⁴¹ (R363, Section 10.1, Figure 18.2.18). Amplex® Red reagent has greater stability, yields less background and produces a red-fluorescent product that is more readily detected than the similar reduced methylene blue derivatives commonly used for colorimetric determination of lipid peroxides in plasma, sera, cell extracts and a variety of membrane systems.^{142–144}

Figure 18.2.17 Amplex® Red reagent (A12222).

Figure 18.2.18 Principle of coupled enzymatic assays using Amplex® Red reagent. Oxidation of glucose by glucose oxidase results in generation of H₂O₂, which is coupled to conversion of the Amplex® Red reagent to fluorescent resorufin by HRP. The detection scheme shown here is used in the Amplex® Red Glucose/Glucose Oxidase Assay Kit (A22189).

Figure 18.2.19 Detection of H_2O_2 using Amplex® UltraRed reagent (red squares) or Amplex® Red reagent (blue triangles). Reactions containing 50 μM Amplex® UltraRed or Amplex® Red reagent, 1 U/mL HRP and the indicated amount of H_2O_2 in 50 mM sodium phosphate buffer, pH 7.4, were incubated for 30 minutes at room temperature. The inset shows the sensitivity and linearity of the Amplex® UltraRed assay at low levels of H_2O_2 .

Figure 18.2.20 Comparison of pH-dependent fluorescence of the products derived from oxidation of Amplex® UltraRed reagent (solid blue circles) and Amplex® Red reagent (open blue squares). Fluorescence intensities were measured using excitation/emission of $\sim 570/585$ nm.

Figure 18.2.21 Absorption and fluorescence emission spectra of the product generated by horseradish peroxidase-mediated oxidation of the Amplex® UltraRed reagent in pH 7.5 buffer.

Amplex® Red reagent has been used to detect the release of H_2O_2 from activated human leukocytes,^{141,145} to measure the activity of monoamine oxidase in bovine brain tissue,¹⁴⁶ to demonstrate the extracellular production of H_2O_2 produced by UV light stimulation of human keratinocytes^{147–149} and for microplate assays of H_2O_2 and lipid hydroperoxide generation by isolated mitochondria.^{51,68,150} Amplex® Red reagent is available in a single 5 mg vial (A12222) or packaged as a set of 10 vials, each containing 10 mg of the substrate, for high-throughput screening applications (A22177).

Amplex® UltraRed Reagent: Brighter and More Sensitive than the Amplex® Red Reagent

Amplex® UltraRed reagent (A36006) improves upon the performance of Amplex® Red reagent, offering brighter fluorescence and enhanced sensitivity on a per-mole basis in horseradish peroxidase or horseradish peroxidase-coupled enzyme assays (Figure 18.2.19). Fluorescence of oxidized Amplex® UltraRed reagent is also less sensitive to pH (Figure 18.2.20), and the substrate and its oxidation product exhibit greater stability than Amplex® Red reagent in the presence of H_2O_2 or thiols such as dithiothreitol (DTT). Like Amplex® Red reagent, nonfluorescent Amplex® UltraRed reagent reacts with H_2O_2 in a 1:1 stoichiometric ratio to produce a brightly fluorescent and strongly absorbing reaction product (excitation/emission maxima $\sim 568/581$ nm) (Figure 18.2.21). Although the primary applications of the Amplex® UltraRed reagent are enzyme-linked immunosorbent assays (ELISAs; see Zen™ Myeloperoxidase ELISA Kit below) and *in vitro* antioxidant capacity assays,¹⁵¹ it is also frequently used (in combination with HRP) to detect H_2O_2 production by isolated mitochondria¹⁵² and cell cultures.^{153,154}

Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit

The Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit (A22188) provides a simple, sensitive, one-step assay for detecting H_2O_2 or the activity of horseradish peroxidase either by measuring fluorescence with a fluorescence-based microplate reader or a fluorometer (Figure 18.2.22) or by measuring absorption with an absorption-based microplate reader or a spectrophotometer. The Amplex® Red peroxidase substrate can detect the presence of active peroxidases and the release of H_2O_2 from biological samples, including cells and cell extracts.^{51,141,155,156}

The Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish (HRP)
- H_2O_2 for use as a positive control
- Concentrated reaction buffer
- Detailed protocols

Each kit provides sufficient reagents for approximately 500 assays using a fluorescence- or absorption-based microplate reader and a reaction volume of 100 μL per assay. Several additional kits that utilize the Amplex® Red peroxidase substrate to detect H_2O_2 in coupled enzymatic reactions are described in Section 10.5.

Amplex® Red Xanthine/Xanthine Oxidase Assay Kit

Xanthine oxidase (E.C. 1.2.3.2) plays a key role in the production of free radicals, including superoxide, in the body. The Amplex® Red Xanthine/Xanthine Oxidase Assay Kit (A22182) provides an ultrasensitive method for detecting xanthine or hypoxanthine or for monitoring xanthine oxidase activity. In the assay, xanthine oxidase catalyzes the oxidation of purine nucleotides, hypoxanthine or xanthine, to uric acid and superoxide. In the reaction mixture, the superoxide spontaneously degrades to H_2O_2 , which in the presence of HRP reacts stoichiometrically with Amplex® Red reagent to generate the red-fluorescent oxidation product, resorufin. Resorufin has absorption and fluorescence emission maxima of approximately 571 nm and 585 nm (Figure 18.2.23), respectively, and because the extinction coefficient is high ($54,000 \text{ cm}^{-1}\text{M}^{-1}$), the assay can be performed either fluorometrically or spectrophotometrically.

The Amplex® Red Xanthine/Xanthine Oxidase Assay Kit (A22182) contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- H₂O₂
- Concentrated reaction buffer
- Xanthine oxidase from buttermilk
- Hypoxanthine
- Xanthine
- Detailed protocols

Each kit provides sufficient reagents for approximately 400 assays using either a fluorescence- or absorption-based microplate reader and a reaction volume of 100 μ L per assay.

In healthy individuals, xanthine oxidase is present in appreciable amounts only in the liver and jejunum. In various liver disorders, however, the enzyme is released into circulation. Therefore, determination of serum xanthine oxidase levels serves as a sensitive indicator of acute liver damage such as jaundice. The Amplex® Red xanthine/xanthine oxidase assay has been used as a marker of recovery from exercise stress.¹⁵⁷ Previously, researchers have utilized chemiluminescence or absorbance to monitor xanthine oxidase activity. The Amplex® Red Xanthine/Xanthine Oxidase Assay Kit permits the detection of xanthine oxidase in a purified system at levels as low as 0.1 mU/mL by fluorescence (Figure 18.2.24). This kit can also be used to detect as little as 200 nM hypoxanthine or xanthine (Figure 18.2.25), and, when coupled to the purine nucleotide phosphorylase enzyme, to detect inorganic phosphate.¹⁵⁸

EnzChek® Myeloperoxidase (MPO) Activity Assay Kit

Myeloperoxidase (MPO, EC 1.11.1.7) is a lysosomal hemoprotein located in the azurophilic granules of polymorphonuclear (PMN) leukocytes and monocytes. It is a dimeric protein composed of two 59 kD and two 13.5 kD subunits. MPO is a unique peroxidase that catalyzes the conversion of hydrogen peroxide (H₂O₂) and chloride to hypochlorous acid, a strong oxidant with powerful antimicrobial activity and broad-spectrum reactivity with biomolecules. MPO is considered an important marker for inflammatory diseases, autoimmune diseases and cancer. MPO is also experimentally and clinically important for distinguishing myeloid from lymphoid leukemia and, due to its role in the pathology of atherogenesis, has been advocated as a prognostic marker of cardiovascular disease.

The ferric, or native, MPO reacts with hydrogen H₂O₂ to form the active intermediate MPO-I, which oxidizes chloride (Cl⁻) to HOCl; these reactions make up the chlorination cycle (Figure 18.2.26). MPO also oxidizes a variety of substrates, including phenols and anilines, via the classic peroxidation cycle. The relative concentrations of chloride and the reducing substrate determine whether MPO uses hydrogen peroxide for chlorination or peroxidation. Assays based on measurement of chlorination activity are more specific for MPO than those based on peroxidase substrates such as tetramethylbenzidine (TMB).

Figure 18.2.22 Detection of HRP using the Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit (A22188). Reactions containing 50 μ M Amplex® Red reagent, 1 mM H₂O₂ and the indicated amount of HRP in 50 mM sodium phosphate buffer, pH 7.4, were incubated for 30 minutes at room temperature. Fluorescence was measured with a fluorescence microplate reader using excitation at 530 \pm 12.5 nm and fluorescence detection at 590 \pm 17.5 nm. Background fluorescence (3 units), determined for a no-HRP control reaction, was subtracted from each value. The inset shows the sensitivity of the assay at very low levels of HRP.

Figure 18.2.23 Absorption and fluorescence emission spectra of resorufin in pH 9.0 buffer.

Figure 18.2.24 Detection of xanthine oxidase using the Amplex® Red Xanthine/Xanthine Oxidase Assay Kit (A22182). Each reaction contained 50 μ M Amplex® Red reagent, 0.2 U/mL horseradish peroxidase, 0.1 mM hypoxanthine and the indicated amount of xanthine oxidase in 1X reaction buffer. After 30 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 \pm 12.5 nm and detection at 590 \pm 17.5 nm. A background of 65 fluorescence units was subtracted from each data point. The inset shows the assay's sensitivity and linearity at low hypoxanthine concentrations.

Figure 18.2.25 Detection of hypoxanthine using the Amplex® Red Xanthine/Xanthine Oxidase Assay Kit (A22182). Each reaction contained 50 μ M Amplex® Red reagent, 0.2 U/mL horseradish peroxidase, 20 mU/mL xanthine oxidase and the indicated amount of hypoxanthine in 1X reaction buffer. Reactions were incubated at 37°C. After 30 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 \pm 12.5 nm and detection at 590 \pm 17.5 nm. A background of 54 fluorescence units was subtracted from each data point. The inset shows the assay's sensitivity and linearity at low enzyme concentrations.

Figure 18.2.26 Schematic diagram for detection of chlorination and peroxidation activity of MPO using the EnzChek® Myeloperoxidase (MPO) Activity Assay Kit (E33856). AH_2 represents the nonfluorescent Amplex® UltraRed substrate, and A represents its fluorescent oxidation product.

The EnzChek® Myeloperoxidase (MPO) Activity Assay Kit (E33856) provides assays for rapid and sensitive determination of both chlorination and peroxidation activities of MPO in solution and in cell lysates^{159–161} (Figure 18.2.26). For detection of chlorination, the kit provides nonfluorescent 3'-(*p*-aminophenyl) fluorescein (APF), which is selectively cleaved by hypochlorite (OCl^-) to yield fluorescein. Peroxidation is detected using nonfluorescent Amplex® UltraRed reagent, which is oxidized by the H_2O_2 -generated redox intermediates MPO-I and MPO-II to form a fluorescent product. The EnzChek® Myeloperoxidase Activity Assay Kit can be used to continuously detect these activities at room temperature over a broad dynamic range (1.5 to 200 ng/mL) (Figure 18.2.27). The speed (30 minutes), sensitivity and mix-and-read convenience make this kit ideal for measuring MPO activities and for high-throughput screening for MPO-specific inhibitors.

Each EnzChek® Myeloperoxidase (MPO) Activity Assay Kit contains:

- 3'-(*p*-aminophenyl) fluorescein (APF)
- Amplex® UltraRed reagent
- Human myeloperoxidase (MPO) standard
- Chlorination inhibitor
- Peroxidation inhibitor
- Hydrogen peroxide (H_2O_2)
- Phosphate-buffered saline (PBS)
- Dimethylsulfoxide (DMSO)
- Detailed protocols

Sufficient reagents are provided to perform 200 assays for chlorination and 200 assays for peroxidation activity in a 96-well fluorescence microplate format (100 μL per assay).

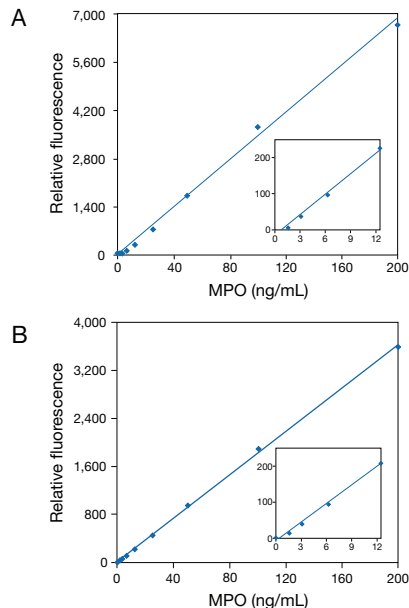

Figure 18.2.27 Typical standard curves for detection of MPO using the APF-based chlorination assay (A) and Amplex® UltraRed-based peroxidation assay (B) provided in the EnzChek® Myeloperoxidase (MPO) Activity Assay Kit (E33856). Reactions were incubated at room temperature for 30 minutes. Values on the x-axes are concentrations of MPO in the standards prior to adding the detection reagent. Fluorescence was measured with a fluorescence microplate reader using fluorescence excitation and emission at 485 and 530 nm, respectively, for the APF assay, or excitation and emission at 530 and 590 nm, respectively, for the Amplex® UltraRed assay. The background fluorescence measured for each zero-MPO control reaction was subtracted from each fluorescence measurement before plotting.

Zen™ Myeloperoxidase (MPO) ELISA Kit

The Zen™ Myeloperoxidase (MPO) ELISA Kit (Z33857) provides a comprehensive set of components for accurate and sensitive quantitation of human MPO in a variety of biological samples, including human serum. This sandwich immunoassay utilizes the Amplex® UltraRed reagent, a fluorogenic substrate for horseradish peroxidase (HRP) that reacts with H_2O_2 in a 1:1 stoichiometric ratio to produce the brightly fluorescent and strongly absorbing Amplex® UltraRed oxidation product (excitation/emission maxima ~568/581 nm). Because the Amplex® UltraRed product has long-wavelength emission, there is little interference from the blue or green autofluorescence found in most biological samples. With a high extinction coefficient, good quantum efficiency and resistance to autooxidation, the fluorescence-based Amplex® UltraRed reagent delivers better sensitivity and a broader assay range than colorimetric reagents.

Each Zen™ Myeloperoxidase (MPO) ELISA Kit contains:

- Amplex® UltraRed reagent
- Dimethylsulfoxide (DMSO)
- Concentrated phosphate-buffered saline (PBS)
- Horseradish peroxidase (HRP) labeled goat anti-rabbit IgG antibody
- Amplex® stop reagent
- Hydrogen peroxide (H_2O_2)
- MPO standard
- Bovine serum albumin (BSA)
- Tween® 20
- Mouse anti-MPO antibody (capture antibody)
- Rabbit anti-MPO antibody (detection antibody)
- Zen™ microplates for oriented capture antibody coating
- Detailed protocols

Sufficient reagents are provided for 200 assays in a microplate format, using a 100 μL per well reaction volume. The Zen™ Myeloperoxidase (MPO) ELISA Kit can be used to detect from 0.2 to 100 ng/mL MPO at room temperature (Figure 18.2.28).

Assaying Oxidative Activity in Live Cells

The generation of reactive oxygen species (ROS) is inevitable for aerobic organisms and, in healthy cells, occurs at a controlled rate. Under conditions of oxidative stress, however, ROS production is dramatically increased, resulting in subsequent alteration of membrane lipids, proteins and nucleic acids. Oxidative damage of these biomolecules is associated with aging and with a variety of pathological events, including atherosclerosis, carcinogenesis, ischemic reperfusion injury and neurodegenerative disorders.^{40,162,163}

Assaying oxidative activity in live cells with fluorogenic, chemiluminescent or chromogenic probes is complicated by the frequent presence of multiple reactive oxygen species in the same cell. Scavengers and enzymes such as superoxide dismutase and catalase are useful knockdown reagents for triaging the optical response of ROS probes (Table 18.2). Quantitative analysis can be further hindered due to: 1) the high intracellular concentration of glutathione, which can form thyl or sulfanyl radicals or otherwise trap or reduce oxygen species;¹⁶⁴ 2) the variable concentration of metals, which can either catalyze or inhibit radical reactions; and 3) the presence of other free radical-quenching agents such as spermine.¹⁶⁵

Fluorescein, rhodamine and various other dyes can be chemically reduced to colorless, nonfluorescent leuco dyes. These "dihydro" derivatives are readily oxidized back to the parent dye by reactive oxygen species and thus can serve as fluorogenic probes for detecting oxidative activity in cells and tissues.^{166–168} Oxidation also occurs spontaneously, albeit slowly, in air and via photosensitization when illuminated for fluorescence excitation.^{169,170} Careful storage and handling, as well as minimizing the duration and intensity of light exposure, are particularly recommended when using these dyes. In general, dihydrofluorescein and dihydrorhodamine do not discriminate between the various reactive oxygen species. It has been reported that dichlorodihydrofluorescein (H_2DCF) and dihydrorhodamine 123 react with intracellular hydrogen peroxide in a reaction mediated by peroxidase, cytochrome c or Fe^{2+} ,^{23,171} and these leuco dyes also serve as fluorogenic substrates for peroxidase enzymes (Section 10.5).

Dichlorodihydrofluorescein Diacetate

The cell-permeant 2',7'-dichlorodihydrofluorescein diacetate (H_2DCFDA , D399; Figure 18.2.29), also known as dichlorofluorescein diacetate, is commonly used to detect the generation of reactive oxygen intermediates in neutrophils and macrophages.^{172–176} Upon cleavage of the acetate groups by intracellular esterases and subsequent oxidation, the nonfluorescent H_2DCFDA is converted to the highly fluorescent 2',7'-dichlorofluorescein (DCF).

Oxidation of H_2DCFDA is reportedly not sensitive to singlet oxygen directly, but singlet oxygen can indirectly contribute to the formation of DCF through its reaction with cellular substrates that yield peroxy products and peroxy radicals.¹⁷⁰ In a cell-free system, H_2DCF has been shown to be oxidized to DCF by peroxy nitrite anion (ONOO^-), by horseradish peroxidase (in the absence of H_2O_2) and by Fe^{2+} (in the absence of H_2O_2).¹⁷⁷ Furthermore, the oxidation of H_2DCF by Fe^{2+} in the presence of H_2O_2 was reduced by the $\text{HO}\cdot$ radical scavenger formate and the iron chelator deferoxamine.¹⁷⁷ In addition, DCF itself can act as a photosensitizer for H_2DCFDA oxidation, both priming and accelerating the formation of DCF.¹⁷⁰ Because the oxidation of DCF and H_2DCFDA appears to also generate free radicals, their use for measuring free radical production must be carefully controlled.¹⁷⁸

A review by Tsuchiya and colleagues outlined methods for visualizing the generation of oxidative species in whole animals. For example, they suggest using propidium iodide (P1304MP, P3566, P21493; Section 8.1) with H_2DCFDA to simultaneously monitor oxidant production and cell injury.¹⁷⁹ H_2DCFDA has been used to visualize oxidative changes in carbon tetrachloride-perfused rat liver¹⁸⁰ and in venular endothelium during neutrophil activation,¹⁸¹ as well as to examine the effect of ischemia and reperfusion in lung and heart tissue.^{182,183} Using H_2DCFDA , researchers characterized hypoxia-dependent peroxide production in *Saccharomyces cerevisiae* as a possible model for ischemic tissue destruction.¹⁸⁴ In neutrophils, H_2DCFDA has proven

Figure 18.2.28 Typical standard curve for detection of MPO using the Zen™ Myeloperoxidase (MPO) ELISA Kit (Z33857). The sandwich ELISA was carried out as described in the protocol using a mouse anti-MPO primary capture antibody, MPO standards ranging from 0.2 ng/mL to 100 ng/mL, and a rabbit anti-MPO detection antibody.

Figure 18.2.29 2',7'-dichlorodihydrofluorescein diacetate (2',7'-dichlorofluorescein diacetate; H_2DCFDA , D399).

Figure 18.2.30 6-carboxy-2',7'-dichlorodihydrofluorescein diacetate, di(acetoxymethyl ester), C2938.

Figure 18.2.31 Bovine pulmonary artery endothelial (BPAEC) cells were initially stained with the reactive oxygen species (ROS) indicator, 6-carboxy-2',7'-dichlorodihydrofluorescein diacetate, di(acetoxymethyl ester) (C2938). After a 30-minute incubation, the cells were washed and then incubated simultaneously with FM[®] 5-95 (T23360) and Hoechst 33342 (H1399, H3570, H21492) in phosphate-buffered saline (PBS) for an additional 5 minutes before washing and mounting in PBS. The red-fluorescent FM[®] 5-95 appears to stain both the plasma membrane and early endosomes; the green-fluorescent, oxidized carboxydichlorofluorescein localizes to the cytoplasm; and the blue-fluorescent Hoechst 33342 dye stains the nucleus.

Figure 18.2.32 5-(and 6-)chloromethyl-2',7'-dichlorodihydrofluorescein diacetate, acetyl ester (CM-H₂DCFDA, C6827).

useful for flow cytometric analysis of nitric oxide, forming a product that has spectral properties identical to those produced when it reacts with hydrogen peroxide.¹⁸⁵ In this study, H₂DCFDA's reaction with nitric oxide was blocked by adding the nitric oxide synthase inhibitor N^G-methyl-L-arginine (L-NMMA) to the cell suspension.¹⁸⁵ 2',7'-Dichlorofluorescein—the oxidation product of H₂DCF—can reportedly be further oxidized to a phenoxyl radical in a horseradish peroxidase-catalyzed reaction, and this reaction may complicate the interpretation of results obtained with this probe in cells undergoing oxidative stress.¹⁸⁶ Although other more specialized ROS probes have been—and continue to be—developed, H₂DCFDA and its chloromethyl derivative CM-H₂DCFDA remain the most versatile indicators of cellular oxidative stress.¹⁸⁷

Improved Versions of H₂DCFDA

Intracellular oxidation of H₂DCF tends to be accompanied by leakage of the product, 2',7'-dichlorofluorescein,¹⁸⁸ which may make quantitation or detection of slow oxidation difficult. To enhance retention of the fluorescent product, we offer the carboxylated H₂DCFDA analog¹⁸⁹ (carboxy-H₂DCFDA, C400), which has two negative charges at physiological pH, and its di(acetoxymethyl ester) analog, 6-carboxy-2',7'-dichlorodihydrofluorescein diacetate, di(acetoxymethyl ester)¹⁹⁰ (C2938, Figure 18.2.30, Figure 18.2.31). Upon cleavage of the acetate and ester groups by intracellular esterases and oxidation, both analogs form carboxydichlorofluorescein (C368, Section 14.3), with additional negative charges that impede its leakage out of the cell.

The fluorinated analog 5-(and 6-)carboxy-2',7'-difluorodihydrofluorescein diacetate (carboxy-H₂DFFDA, C13293) is also useful for visualizing oxidative bursts and inflammatory and infectious processes.¹⁹¹ As the oxidation potential of deacetylated carboxy-H₂DFFDA is more positive than that of the corresponding chloro compound carboxy-H₂DCFDA, its oxidant sensitivity profile is presumably shifted; however, it is not known if this difference is large enough to have practical utility. The diacetate derivatives of the dichloro- and difluorodihydrofluoresceins are quite stable. When used for intracellular applications, the acetates are cleaved by endogenous esterases, releasing the corresponding dichloro- or difluorodihydrofluorescein derivative. If, however, these nonfluorescent diacetate derivatives are used for *in vitro* assays, they must first be hydrolyzed with mild base to form the colorless probe.¹⁵⁰

In addition, we have developed 5-(and 6-)chloromethyl-2',7'-dichlorodihydrofluorescein diacetate, acetyl ester (CM-H₂DCFDA, C6827; Figure 18.2.32; Figure 18.2.33), which is a chloromethyl derivative of H₂DCFDA that exhibits much better retention in live cells.^{192,193} As with our other chloromethyl derivatives (see the description of our CellTracker™ probes in Section 14.2), CM-H₂DCFDA passively diffuses into cells, where its acetate groups are cleaved by intracellular esterases and its thiol-reactive chloromethyl group reacts with intracellular glutathione and other thiols. Subsequent oxidation yields a fluorescent adduct that is trapped inside the cell, thus facilitating long-term studies.^{192,193} Among its many applications, CM-H₂DCFDA has been used to:

- Analyze FOXO3 transcriptional control of oxidative stress^{194,195}
- Assess ROS-mediated cytotoxicity and apoptosis^{196–199}
- Detect hydroxyl radicals associated with estrogen-induced DNA damage²⁰⁰
- Monitor time courses of ROS generation in neurons and brain slices^{192,201}
- Analyze ROS production in chromosomally unstable human–hamster hybrid cells using flow cytometry²⁰²

Figure 18.2.33 An oxidative burst was detected by flow cytometry of cells labeled with 5-(and 6-)chloromethyl-2',7'-dichlorodihydrofluorescein diacetate, acetyl ester (CM-H₂DCFDA, C6827). Jurkat cells were incubated with 100 nM CM-H₂DCFDA. The cells were washed and resuspended in either phosphate-buffered saline (PBS, red) or PBS with 0.03% H₂O₂ (blue). The samples were analyzed on a flow cytometer equipped with a 488 nm argon-ion laser and a 525 ± 10 nm bandpass emission filter.

Image-iT® LIVE Green Reactive Oxygen Species Detection Kit

The Image-iT® LIVE Green Reactive Oxygen Species Detection Kit (I36007) provides the key reagents for detecting reactive oxygen species (ROS) in live cells (Figure 18.2.34), including:

- Carboxy-H₂DCFDA (5-(and 6-)carboxy-2',7'-dichlorodihydrofluorescein diacetate)
- Hoechst 33342
- *tert*-butyl hydroperoxide (TBHP)
- Dimethylsulfoxide (DMSO)
- Detailed protocols for fluorescence microscopy assays

This assay is based on carboxy-H₂DCFDA (5-(and 6-)carboxy-2',7'-dichlorodihydrofluorescein diacetate), a reliable fluorogenic marker for reactive oxygen species in live cells.^{203,204} In addition to carboxy-H₂DCFDA, this kit provides the common inducer of ROS production, *tert*-butyl hydroperoxide (TBHP), as a positive control^{205–208} and the blue-fluorescent, cell-permeant nucleic acid stain Hoechst 33342. Oxidatively stressed and nonstressed cells can be effectively distinguished by fluorescence microscopy using this combination of dyes and the protocol provided.^{209–211}

Aminophenyl Fluorescein and Hydroxyphenyl Fluorescein

Developed by Nagano, 3'-(*p*-aminophenyl) fluorescein (APF, A36003) and 3'-(*p*-hydroxyphenyl) fluorescein (HPF, H36004) provide greater selectivity and stability than dichlorodihydrofluorescein diacetate (H₂DCFDA, D399) for ROS detection.²¹² H₂DCFDA is probably the most commonly used reagent for detecting intracellular reactive oxygen species despite its lack of specificity and tendency to spontaneously photooxidize. The nonfluorescent H₂DCFDA becomes fluorescent in the presence of a wide variety of reactive oxygen species including, but not limited to, peroxy (ROO•) and hydroxyl (HO•) radicals and the peroxynitrite anion (ONOO⁻). In contrast, APF and HPF show much more limited reactivity and greater resistance to light-induced oxidation (Table 18.4). Both of these fluorescein derivatives are essentially nonfluorescent until they react with the hydroxyl radical,⁶⁰ peroxynitrite anion or singlet oxygen¹⁶ (Figure 18.2.35). APF will also react with the hypochlorite anion (OCl⁻), making it possible to use APF

Figure 18.2.34 Detection of oxidative stress in live cells using the Image-iT® LIVE Green Reactive Oxygen Species (ROS) Detection Kit (I36007). Live bovine pulmonary artery endothelial cells were treated with *tert*-butyl hydroperoxide to induce oxidative stress (bottom) or were left untreated (top). Cells were then labeled with carboxy-H₂DCFDA, which fluoresces when oxidized by ROS, and nuclei were stained with blue-fluorescent Hoechst 33342. The stressed cells exhibited green fluorescence, signaling an increase in ROS, whereas the untreated cells showed minimal fluorescence.

Figure 18.2.35 Detection of reactive oxygen species (ROS) with 3'-(*p*-hydroxyphenyl) fluorescein (HPF, H36004) and 3'-(*p*-aminophenyl) fluorescein (APF, A36003).

Table 18.4 Fluorescence response of APF, HPF and H₂DCFDA to various reactive oxygen species (ROS).

Reactive Oxygen Species (ROS)	ROS Generation Method	APF *	HPF *	H ₂ DCFDA *
Hydrogen peroxide (H ₂ O ₂)	100 μM H ₂ O ₂	<1	2	190
Hydroxyl radical (HO•)	100 μM ferrous perchlorate (II) and 1 mM of H ₂ O ₂	1200	730	7400
Hypochlorite anion (OCl ⁻)	3 μM (final) OCl ⁻	3600	6	86
Nitric oxide (NO)	100 μM 1-hydroxy-2-oxo-3-(3-aminopropyl)-3-methyl-1-triazene (NOC-7)	<1	6	150
Peroxy radical (ROO•)	100 μM 2,2'-azobis(2-amidinopropane), dihydrochloride (AAPH)	2	17	710
Peroxynitrite anion (ONOO ⁻)	3 μM (final) ONOO	560	120	6600
Singlet oxygen (¹ O ₂)	100 μM 3-(1,4-dihydro-1,4-epidioxy-1-naphthyl)propionic acid	9	5	26
Superoxide anion (•O ₂ ⁻)	100 μM KO ₂	6	8	67
Autooxidation	2.5 hours exposure to fluorescent light source	<1	<1	2000

* 10 μM of APF, HPF or DCF (2',7'-dichlorofluorescein) were added to sodium phosphate buffer (0.1 M, pH 7.4); ROS were generated as indicated; and fluorescence was measured using excitation/emission wavelengths of 490/515 nm (for APF and HPF) or 500/520 nm (for DCF). DCF was obtained by hydrolysis of H₂DCFDA with base as described in J Biol Chem (2003) 278:3170; dichlorodihydrofluorescein diacetates are colorless and nonfluorescent until both of the acetate groups are hydrolyzed and the products are subsequently oxidized to fluorescein derivatives.

Figure 18.2.36 Dihydrocalcein, AM (D23805).

Figure 18.2.37 2',7'-dichlorodihydrofluorescein diacetate, succinimidyl ester (OxyBURST® Green H₂DCFDA, SE, D2935).

Figure 18.2.38 Dihydrorhodamine 123 (D632).

Figure 18.2.39 Live bovine pulmonary artery endothelial cells (BPAEC) were first stained with LysoTracker® Red DND-99 (L7528). Then, a solution of dihydrorhodamine 123 (D632, D23806) and Hoechst 33258 (H1398, H3569, H21491) was added and allowed to incubate with the cells for an additional 10 minutes before the cells were subsequently washed and visualized. The green-fluorescent oxidation product (rhodamine 123, R302) localized primarily to the mitochondria. The red-fluorescent LysoTracker® Red DND-99 stain accumulated in the lysosomes, and the blue-fluorescent Hoechst 33258 dye stained the nuclei. The image was acquired with filters appropriate for DAPI, fluorescein and the Texas Red® dye. The image was deconvolved using Huygens software (Scientific Volume Imaging, www.svi.nl). 3D reconstruction was performed using Imaris software (Bitplane AG, www.bitplane.com).

and HPF together to selectively detect the hypochlorite anion (Section 21.2). In the presence of these specific reactive oxygen species, both APF and HPF yield a bright green-fluorescent product (excitation/emission maxima ~490/515 nm) and are compatible with all fluorescence instrumentation capable of visualizing fluorescein. Using APF, researchers have been able to detect the hypochlorite anion generated by activated neutrophils, a feat that has not been possible with traditional ROS indicators.²¹²

Dihydrocalcein AM

We have combined the superior retention of calcein (the intracellular product of calcein AM hydrolysis in viable cells) and the oxidation sensitivity of the dihydrofluoresceins to yield the probe dihydrocalcein AM (D23805, Figure 18.2.36), provided specially packaged as a set of 20 vials, each containing 50 µg. The oxidant sensitivity profile of dihydrocalcein AM has been characterized relative to that of H₂DCFDA²¹³ and of alkaline elution assays of oxidative DNA modification.²¹⁴

OxyBURST® Green Reagents

Fc OxyBURST® Green assay reagent (F2902) was developed in collaboration with Elizabeth Simons of Boston University to monitor the oxidative burst in phagocytic cells using fluorescence instrumentation. The Fc OxyBURST® Green assay reagent comprises bovine serum albumin (BSA) that has been covalently linked to dichlorodihydrofluorescein (H₂DCF) and then complexed with purified rabbit polyclonal anti-BSA antibodies. When these immune complexes bind to Fc receptors, the nonfluorescent H₂DCF molecules are internalized within the phagosome and subsequently oxidized to green-fluorescent dichlorofluorescein (DCF); see Section 16.1 for a more complete description.

OxyBURST® Green H₂HFF BSA (O13291) is a sensitive fluorogenic reagent for detecting extracellular release of oxidative products in a spectrofluorometer or a fluorescence microscope. This reagent comprises BSA that has been covalently linked to dihydro-2',4,5,6,7,7'-hexafluorofluorescein (H₂HFF), a reduced dye with improved stability. Unlike Fc OxyBURST® Green assay reagent, OxyBURST® Green H₂HFF BSA is not complexed with IgG. OxyBURST® Green H₂HFF BSA provides up to 1000-fold greater sensitivity than conventional methods based on spectrophotometric detection of superoxide dismutase-inhibitable reduction of cytochrome *c*.^{215,216}

Amine-Reactive OxyBURST® Green Reagent

As an alternative to Fc OxyBURST® Green assay reagent and OxyBURST® Green H₂HFF BSA, we offer the amine-reactive OxyBURST® Green H₂DCFDA succinimidyl ester (2',7'-dichlorodihydrofluorescein diacetate, SE; D2935; Figure 18.2.37), which can be used to prepare oxidation-sensitive conjugates of a wide variety of biomolecules and particles, including antibodies, antigens, peptides, proteins, dextrans, bacteria, yeast and polystyrene microspheres.^{217,218} Following conjugation to amines, the two acetates of OxyBURST® Green H₂DCFDA can be removed by treatment with hydroxylamine at neutral pH to yield the dihydrofluorescein conjugate. OxyBURST® Green H₂DCFDA conjugates are nonfluorescent until they are oxidized to the corresponding fluorescein derivatives.

Dihydrorhodamine 123

Dihydrorhodamine 123 (D632, D23806; Figure 18.2.38, Figure 18.2.39) is the uncharged and nonfluorescent reduction product of the mitochondrion-selective dye rhodamine 123 (R302, R22420; Section 12.2). This leuco dye passively diffuses across most cell membranes where it is oxidized to cationic rhodamine 123 (Figure 18.2.40), which localizes in the mitochondria. Like H₂DCF, dihydrorhodamine 123 does not directly detect superoxide,²¹⁹ but rather reacts with hydrogen peroxide in the presence of peroxidase, cytochrome *c* or Fe²⁺.²³ However, dihydrorhodamine 123 also reacts with peroxynitrite, the anion formed when nitric oxide reacts with superoxide.¹⁷¹ Peroxynitrite, which may play a role in many pathological conditions, has been shown to react with sulfhydryl groups, DNA and membrane phospholipids, as well as with tyrosine and other phenolic compounds.^{220–223}

Dihydrorhodamine 123 has been used to investigate reactive oxygen intermediates produced by human and murine phagocytes,⁴⁵ activated rat mast cells²²⁴ and vascular endothelial

tissues.^{225,226} It has also been employed to study the role of the CD14 cell-surface marker in H₂O₂ production by human monocytes.²²⁷

Dihydrorhodamine 123 is available as a 10 mg vial (D632) or as a stabilized 5 mM solution in DMSO (D23806). Because of the susceptibility of dihydrorhodamine 123 to air oxidation, the DMSO solution is recommended when only small quantities are to be used at a time.

A Longer-Wavelength Reduced Rhodamine

Intracellular oxidation of dihydrorhodamine 6G (D633) yields rhodamine 6G (R634), which localizes in the mitochondria of live cells (Section 12.2). As compared with rhodamine 123, this cationic oxidation product has longer-wavelength spectra, making it especially useful in multi-color applications and in autofluorescent cells and tissues. Dihydrorhodamine 6G has been used for fluorescence microplate assays of granulocyte activation²²⁸ and for analysis of ROS levels in human umbilical vein endothelial (HUVEC) cells by flow cytometry.¹⁹⁴

Reduced MitoTracker® Probes

Two of our MitoTracker® probes—MitoTracker® Orange CM-H₂TMRos (M7511, Figure 18.2.41) and MitoTracker® Red CM-H₂XRos (M7513, Figure 18.2.42)—are chemically reactive reduced rosamines. Unlike MitoTracker® Orange CM-TMRos and MitoTracker® Red CMXRos (M7510, M7512; Section 12.2), the reduced versions of these probes do not fluoresce until they enter an actively respiring cell, where they are oxidized by reactive oxygen species to the fluorescent mitochondrion-selective probe and then sequestered in the mitochondria. Although CM-H₂TMRos and CM-H₂XRos are widely used as indicators of mitochondrial reactive oxygen species,^{229–231} their fluorescence cannot be unambiguously associated with the site of oxidant generation, as the cationic charge that drives their electrophoretic sequestration in active mitochondria is only present after the probe has been oxidized. This same caveat also applies to dihydrorhodamine 123 and dihydrorhodamine 6G. Probes such as MitoSOX™ Red mitochondrial superoxide indicator resolve this ambiguity by having their oxidant response and mitochondrial localization functions associated with different structural elements (Figure 18.2.8).

RedoxSensor™ Red CC-1 Stain

RedoxSensor™ Red CC-1 stain (2,3,4,5,6-pentafluorotetramethyldihydrorosamine, R14060; Figure 18.2.43) passively enters live cells and is subsequently oxidized in the cytosol to a red-fluorescent product (excitation/emission maxima ~540/600 nm), which then accumulates in the mitochondria. Alternatively, this nonfluorescent probe may be transported to the lysosomes where it is oxidized. The differential distribution of the oxidized product between mitochondria and lysosomes appears to depend on the redox potential of the cytosol.^{232–234} In proliferating cells, mitochondrial staining predominates; whereas in contact-inhibited cells, the staining is primarily lysosomal (Figure 18.2.44).

Glutathiolation Detection with BioGEE

Biotinylated glutathione ethyl ester (BioGEE, G36000; Figure 18.2.45) is a cell-permeant, biotinylated glutathione analog for the detection of glutathiolation. Under conditions of oxidative stress, cells may transiently incorporate glutathione into proteins. Stressed cells incubated with BioGEE will also incorporate this biotinylated glutathione derivative into proteins, facilitating the identification of oxidation-sensitive proteins.^{235,236} Once these cells are fixed and

Figure 18.2.42 MitoTracker® Red CM-H₂XRos (M7513).

Figure 18.2.43 RedoxSensor™ Red CC-1 (R14060).

Figure 18.2.44 Cellular proliferation state determines the distribution of the oxidized product of RedoxSensor™ Red CC-1 (R14060). Normal rat kidney (NRK) cells in different growth states were stained with RedoxSensor™ Red CC-1. In proliferating cells (left panel), the oxidized dye accumulates in mitochondria. In quiescent cells (right panel), the oxidized product localizes in the lysosomes.

Figure 18.2.46 MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide), M6494.

permeabilized, glutathiolation levels can be detected with a fluorescent streptavidin conjugate (Section 7.6, Table 7.9) using either flow cytometry or fluorescence microscopy. Proteins glutathiolated with BioGEE can be captured using streptavidin agarose (S951, Section 7.6) and analyzed by mass spectrometry or by western blotting methods.^{198,237}

Tetrazolium Salts: Chromogenic Redox Indicators

Tetrazolium salts—especially MTT (M6494, Figure 18.2.46)—are widely used for detecting the redox potential of cells for viability, proliferation and cytotoxicity assays. Upon reduction, these water-soluble colorless compounds form uncharged, brightly colored formazans. Several of the formazans precipitate out of solution and are useful for histochemical localization of the site of reduction or, after solubilization in organic solvent, for quantitation by standard spectrophotometric techniques. The extremely water-soluble formazan product of XTT (X6493) does not require solubilization prior to quantitation.

Selected applications of the tetrazolium salts are listed in Table 18.3. Our Vybrant® MTT Cell Proliferation Assay Kit (V13154, Section 15.4) provides a means of counting metabolically active cells; this Vybrant® MTT assay can detect from 2000 to 250,000 cells, depending on the cell type and conditions. See also Section 15.2 for additional cell applications of tetrazolium salts.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. Fluorescence of A7923 and C7924 is weak. Reaction of the nitroxide moiety with superoxide or hydroxyl radicals results in increased fluorescence without a spectral shift. (*Anal Biochem* (1993) 212:85)
2. Peroxidase-catalyzed reaction of the Amplex® Red reagent (A12222, A22177) with H₂O₂ produces fluorescent resorufin (R363). Resorufin is unstable in the presence of thiols such as dithiothreitol (DTT) and 2-mercaptoethanol. (*Bioorg Chem* (1998) 26:63)
3. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
4. Fluorescence of A36003 and H36004 is extremely weak. Highly fluorescent fluorescein F1300 is generated upon oxidation. (*J Biol Chem* (2003) 278:3170)
5. Peroxidase-catalyzed reaction of the Amplex® UltraRed reagent (A36006) with H₂O₂ yields a fluorescent product with Abs = 568 nm (EC = 57,000 cm⁻¹M⁻¹), Em = 581 nm in pH 7.5 buffer.
6. Dihydrofluorescein diacetates are colorless and nonfluorescent until both of the acetate groups are hydrolyzed and the products are subsequently oxidized to fluorescein derivatives. The materials contain less than 0.1% of oxidized derivative when initially prepared. The oxidation products of C400, C2938, C6827, D399 and D2935 are 2',7'-dichlorofluorescein derivatives with spectra similar to C368 (Section 14.3).
7. C2944 emits chemiluminescence (Em = 466 nm) on oxidation by superoxide. (*Anal Biochem* (1992) 206:273)
8. Do NOT dissolve in DMSO.
9. Aqueous solutions of coelenterazine (>1 mM) can be prepared in pH 7 buffer containing 50 mM 2-hydroxypropyl-β-cyclodextrin. (*Biosci Biotechnol Biochem* (1997) 61:1219)
10. Difluorodihydrofluorescein diacetates are colorless and nonfluorescent. Acetate hydrolysis and subsequent oxidation generate a fluorescent 2',7'-difluorofluorescein derivative with spectra similar to O6146 (Section 14.3).
11. This compound is susceptible to oxidation, especially in solution. Store solutions under argon or nitrogen. Oxidation may be induced by illumination.
12. These compounds are essentially colorless and nonfluorescent until oxidized. Oxidation products (in parentheses) are as follows: D632 and D23806 (R302); D633 (R634); M7511 (M7510); M7513 (M7512).
13. Dihydroethidium has blue fluorescence (Em ~420 nm) until oxidized to ethidium (Em ~605 nm). The reduced dye does not bind to nucleic acids. (*FEBS Lett* (1972) 26:169)
14. Oxidation of the polyunsaturated butadienyl portion of the BODIPY® 581/591 dye results in a shift of the fluorescence emission peak from ~590 nm to ~510 nm. (*Methods Enzymol* (2000) 319:603, *FEBS Lett* (1999) 453:278)
15. Oxidation of D7894 occurs rapidly in solution when illuminated. The oxidation product is strongly fluorescent. Em = 379 nm.
16. This product is supplied as a ready-made solution in DMSO with sodium borohydride added to inhibit oxidation.
17. D23805 is colorless and nonfluorescent until the AM ester groups are hydrolyzed and the resulting leuco dye is subsequently oxidized. The final product is calcein (C481).
18. F2902 is essentially colorless and nonfluorescent until oxidized. A small amount (~5%) of oxidized material is normal and acceptable for the product as supplied. The oxidation product is fluorescent (Abs = 495 nm, Em = 524 nm). (*J Immunol Methods* (1990) 130:223)
19. This product consists of a dye-bovine serum albumin conjugate (MW ~66,000) complexed with IgG in a ratio of approximately 1:4 mol:mol (BSA:IgG)
20. L6868 has much stronger absorption at shorter wavelengths (Abs = 368 nm (EC = 36,000 cm⁻¹M⁻¹)).
21. This compound emits chemiluminescence upon oxidation in basic aqueous solutions. Emission peaks are at 425 nm (L8455) and 470 nm (L6868).
22. Isothiocyanates are unstable in water and should not be stored in aqueous solution.
23. Enzymatic reduction products are water-insoluble formazans with Abs = 505 nm (M6494) and 605 nm (N6495) after solubilization in DMSO or DMF. See literature sources for further information. (*Histochemistry* (1982) 76:381, *Prog Histochem Cytochem* (1976) 9:1)
24. M6494 also has Abs = 242 nm (EC = 21,000 cm⁻¹M⁻¹) in MeOH.
25. Generates chemiluminescence (Em = 465 nm in 0.1 M SDS) upon reaction with ¹O₂. (*J Am Chem Soc* (1986) 108:4498)
26. Generates chemiluminescence (Em = 455 nm) upon reaction with superoxide.
27. Spectroscopic properties of the product generated by reaction of M36008 with superoxide are described in *Nat Protoc* (2008) 3:8.
28. Oxidation of O13291 generates a fluorescent protein conjugate (Abs ~508 nm, Em ~528 nm).
29. Phycobiliproteins are packaged as suspensions in 60% ammonium sulfate, pH 7.0. Store refrigerated at 4°C but DO NOT FREEZE.
30. Iodoacetamides in solution undergo rapid photodecomposition to unreactive products. Minimize exposure to light prior to reaction.
31. *Cis*-parinaric acid is readily oxidized to nonfluorescent products. Use under N₂ or Ar except when oxidation is intended. Stock solutions should be prepared in deoxygenated solvents. *Cis*-parinaric acid is appreciably fluorescent in lipid environments and organic solvents but is nonfluorescent in water.
32. Acetate hydrolysis of R14000 yields rose bengal (Abs = 556 nm (EC = 104,000 cm⁻¹M⁻¹), Em = 572 nm in MeOH). (*Photochem Photobiol* (1997) 66:374)
33. R14060 is colorless and nonfluorescent until oxidized. The spectral characteristics of the oxidation product (2,3,4,5,6-pentafluorotetramethylrosamine) are similar to those of T639 (Section 12.2).
34. MW: The preceding ~ symbol indicates an approximate value, not including counterions.
35. The fluorescence of S36002 is relatively weak. Reaction of the dye with singlet oxygen (¹O₂) results in fluorescence enhancement with essentially no change in absorption or emission wavelengths.
36. Enzymatic reduction product is a water-soluble formazan, Abs = 475 nm.

PRODUCT LIST 18.2 GENERATING AND DETECTING REACTIVE OXYGEN SPECIES

Cat. No.	Product	Quantity
A7923	4-((9-acridinecarbonyl)amino)-2,2,6,6-tetramethylpiperidin-1-oxyl, free radical (TEMPO-9-AC)	5 mg
A36003	3'-(<i>p</i> -aminophenyl) fluorescein (APF) *5 mM solution in DMF*	470 µL
A22188	Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit *500 assays*	1 kit
A12222	Amplex® Red reagent	5 mg
A22177	Amplex® Red reagent *packaged for high-throughput screening*	10 x 10 mg
A22182	Amplex® Red Xanthine/Xanthine Oxidase Assay Kit *400 assays*	1 kit
A36006	Amplex® UltraRed reagent	5 x 1 mg
B3932	(<i>E,E</i>)-3,5-bis-(4-phenyl-1,3-butadienyl)-4,4-difluoro-4-bora-3a,4a-diaza- <i>s</i> -indacene (BODIPY® 665/676)	5 mg
C400	5-(and-6)-carboxy-2',7'-dichlorodihydrofluorescein diacetate (carboxy-H ₂ DCFDA) *mixed isomers*	25 mg
C2938	6-carboxy-2',7'-dichlorodihydrofluorescein diacetate, di(acetoxymethyl ester)	5 mg
C13293	5-(and-6)-carboxy-2',7'-difluorodihydrofluorescein diacetate (carboxy-H ₂ DFFDA) *mixed isomers*	5 mg
C7924	5-(2-carboxyphenyl)-5-hydroxy-1-((2,2,5,5-tetramethyl-1-oxypyrrolidin-3-yl)methyl)-3-phenyl-2-pyrrolin-4-one, potassium salt (proxyl fluorescamine)	5 mg
C6827	5-(and-6)-chloromethyl-2',7'-dichlorodihydrofluorescein diacetate, acetyl ester (CM-H ₂ DCFDA) *mixed isomers* *special packaging*	20 x 50 µg
C2944	coelenterazine	250 µg
D399	2',7'-dichlorodihydrofluorescein diacetate (2',7'-dichlorofluorescein diacetate; H ₂ DCFDA)	100 mg
D2935	2',7'-dichlorodihydrofluorescein diacetate, succinimidyl ester (OxyBURST® Green H ₂ DCFDA, SE)	5 mg
D3861	4,4-difluoro-5-(4-phenyl-1,3-butadienyl)-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-undecanoic acid (BODIPY® 581/591 C ₁₁)	1 mg
D23805	dihydrocalcein, AM *special packaging*	20 x 50 µg
D1168	dihydroethidium (hydroethidine)	25 mg
D23107	dihydroethidium (hydroethidine) *5 mM stabilized solution in DMSO*	1 mL
D11347	dihydroethidium (hydroethidine) *special packaging*	10 x 1 mg
D632	dihydrorhodamine 123	10 mg
D23806	dihydrorhodamine 123 *5 mM stabilized solution in DMSO*	1 mL
D633	dihydrorhodamine 6G	25 mg
D7894	diphenyl-1-pyrenylphosphine (DPPP)	5 mg
E33856	EnzChek® Myeloperoxidase (MPO) Activity Assay Kit *400 assays* *for myeloperoxidase chlorination and peroxidation activity*	1 kit
F2902	Fc OxyBURST® Green assay reagent *25 assays* *3 mg/mL*	500 µL
G36000	glutathione ethyl ester, biotin amide (BioGEE) *glutathiolation detection reagent* *special packaging*	10 x 100 µg
H36004	3'-(<i>p</i> -hydroxyphenyl) fluorescein (HPF) *5 mM solution in DMF*	470 µL
H7476	hypericin	1 mg
I36007	Image-iT® LIVE Green Reactive Oxygen Species Detection Kit *for microscopy*	1 kit
L6868	lucigenin (bis- <i>N</i> -methylacridinium nitrate) *high purity*	10 mg
L8455	luminol (3-aminophthalhydrazide)	25 g
M689	malachite green isothiocyanate	10 mg
M7913	<i>trans</i> -1-(2'-methoxyvinyl)pyrene	1 mg
M23800	2-methyl-6-(4-methoxyphenyl)-3,7-dihydroimidazo[1,2- <i>a</i>]pyrazin-3-one, hydrochloride (MCLA)	5 mg
M24571	merocyanine 540	25 mg
M36008	MitoSOX™ Red mitochondrial superoxide indicator *for live-cell imaging*	10 x 50 µg
M7511	MitoTracker® Orange CM-H ₂ TMRos *special packaging*	20 x 50 µg
M7513	MitoTracker® Red CM-H ₂ XRos *special packaging*	20 x 50 µg
M6494	MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide)	1 g
N6495	nitro blue tetrazolium chloride (NBT)	1 g
O13291	OxyBURST® Green H ₂ HFF BSA *special packaging*	5 x 1 mg
P36005	<i>cis</i> -parinaric acid *3 mM in ethanol*	10 mL
P6879	<i>N</i> -(1,10-phenanthrolin-5-yl)iodoacetamide	5 mg
P800	B-phycoerythrin *4 mg/mL*	0.5 mL
P801	R-phycoerythrin *4 mg/mL*	0.5 mL
R14060	RedoxSensor™ Red CC-1 *special packaging*	10 x 50 µg
R14000	rose bengal diacetate	5 mg
S36002	Singlet Oxygen Sensor Green *special packaging*	10 x 100 µg
X6493	XTT (2,3-bis-(2-methoxy-4-nitro-5-sulfophenyl)-2 <i>H</i> -tetrazolium-5-carboxanilide)	100 mg
Z33857	Zen™ Myeloperoxidase (MPO) ELISA Kit *200 assays*	1 kit

18.3 Probes for Nitric Oxide Research

Nitric oxide (NO) plays a critical role as a molecular mediator of a variety of physiological processes, including blood-pressure regulation and neurotransmission.^{1–8} In endothelial cells, as well as in neurons and astrocytes, NO is synthesized from L-arginine in a reaction catalyzed by nitric oxide synthase (NOS)^{9–12} (Figure 18.3.1). NO that diffuses into smooth muscle cells binds to the heme group of guanylate cyclase.

Because free NO is a transient species with a half-life of about 5 seconds, many investigations of this gaseous molecule have relied largely on studies of NOS. Preparing NO solutions and detecting NO in experimental systems require special precautions to achieve reproducibility.^{13,14} NO also reacts at diffusion-controlled rates with superoxide to form a strong oxidant, peroxyxynitrite anion¹⁵ (ONOO[–], Table 18.1). Peroxyxynitrite is a well-known inflammatory mediator in various cardiovascular pathologies but has more recently been recognized as a modulator of signal transduction pathways due to its ability to nitrate tyrosine residues and thereby influence cellular processes dependent on tyrosine phosphorylation.^{15,16} Activated macrophages and neutrophils produce nitric oxide and superoxide, and thus peroxyxynitrite anion, at similar rates.¹⁷ NO generators are also reported to produce an accumulation of chelatable Zn²⁺ in hippocampal neuronal perikarya, as determined with some of our Zn²⁺ indicators¹⁸ (Section 19.7, Table 19.6).

Spontaneous Nitric Oxide Donors and Antagonist

Spermine NONOate

Spermine NONOate (S7916) solids provide a means of preparing aqueous NO solutions.¹⁹ When dissolved in buffer, cell culture medium or blood, spermine NONOate dissociates to form two molecules of NO and one molecule of the corresponding amine²⁰ (Figure 18.3.2). The delivery of NO can be easily controlled by preparing moderately basic solutions of this NONOate and then lowering the pH to initiate NO generation. Spermine NONOate releases NO slowly (half-life of 39 minutes at 37°C in pH 7.4 buffer), making it suitable for whole animal infusions and experiments with long incubations,²¹ as well as for *in situ* calibration of DAF-FM²².

SNAP and SIN-1

NO donors SNAP (S-nitroso-N-acetylpenicillamine; N7892, N7927) and SIN-1 (3-morpholinopyridone, hydrochloride; M7891, M7926) spontaneously release NO (and superoxide in the case of SIN-1) under physiological conditions (Figure 18.3.2), thereby stimulating cyclic GMP production.^{23–27} SNAP and SIN-1 have been shown to be potent vasodilators *in vivo* and *in vitro* and to inhibit smooth muscle cell mitogenesis and proliferation.^{28–31} The relationship between NO generated from SNAP and SIN-1 and intracellular Ca²⁺ has been studied using fluorescent Ca²⁺ indicators^{32–34} (Chapter 19). It has also been reported that NO released from SNAP stimulates Ca²⁺-independent synaptic vesicle release,³⁴ which can be detected with FM[®] 1–43 (T3163, T35356; Section 16.1). We offer SNAP and SIN-1 in 25 mg vials (N7892, M7891) and, because of their potential instability in solution, as specially packaged sets of 20 vials, each containing 1 mg (N7927, M7926).

Carboxy-PTIO: A Nitric Oxide Antagonist

Carboxy-PTIO (C7912) is a water-soluble and stable free radical molecule that reacts stoichiometrically with NO.^{35–37} Carboxy-PTIO can be used *in vivo* to inhibit the physiological effects mediated by NO^{35,37,38} or to quantitate NO levels *in vitro* by ESR spectrometry.^{39,40}

SNAP: A Photoactivatable Nitric Oxide Donor

SNAP (S-nitroso-N-acetylpenicillamine; N7892, N7927) has been shown to release nitric oxide (NO) in response to light stimulation in both aqueous and isopropyl alcohol solutions.⁴¹ The potential spatial and temporal control of NO release made possible by photolysis of NO precursors makes this an attractive approach for generating NO in experimental systems.

Detecting Nitric Oxide, Nitrite and Nitrate

The nitric oxide (NO) radical is short-lived and physiological concentrations are very low,⁴² making *in situ* detection a challenging proposition. NO is readily oxidized to the nitrosonium cation (NO⁺), which is moderately stable in aqueous solutions but highly reactive with nucleophiles or other nitrogen oxides. Under aerobic conditions, these reactive nitrogen oxides (Table 18.1) can be trapped by various amines, in particular by aromatic amines to form diazonium salts or by aromatic 1,2-diamines to form benzotriazoles (Figure 18.3.3).

DAF-FM Nitric Oxide Indicator

First described in 1998,⁴³ vicinal diamine derivatives of fluorescein generate stronger fluorescence signals at longer wavelengths than prototypes such as 2,3-diaminonaphthalene. These characteristics result in much enhanced performance for *in situ* nitric oxide detection. DAF-FM (4-amino-5-methylamino-2',7'-difluorofluorescein) is the foremost example of this class of compounds.⁴⁴ We offer DAF-FM (D23841) and its cell-permeant diacetate derivative (D23842, D23844). Like dihydrofluorescein, dihydrorhodamine and dihydroethidium probes (Section 18.2), and in contrast to BAPTA-based Ca²⁺ indicators (Section 19.2, Section 19.3), DAF-FM is an endpoint dosimeter. DAF-FM is not a reversible equilibrium sensor, limiting its ability to track rapid fluctuations of the target analyte (NO) in real time. Extracellularly applied DAF-FM diacetate spontaneously crosses the plasma membrane and is cleaved by esterases to generate intracellular DAF-FM, which is then oxidized by NO to a triazole product accompanied by increased fluorescence (Figure 18.3.3, Figure 18.3.4). The fluorescence quantum yield of DAF-FM is reported to be 0.005 but increases about 160-fold to 0.81 after reacting with NO.⁴⁴ The second step of the process as depicted in Figure 18.3.3 is an oversimplification. In fact, DAF-FM must first be nonspecifically oxidized to an aniliny radical, which then reacts with NO to form the fluorescent triazole product.⁴⁵ This mechanistic complication must be borne in mind when interpreting experimental data. Specifically, the question of whether nonspecific pre-oxidation or reaction with NO is the dominant factor controlling observed DAF-FM

Figure 18.3.7 Fixed and permeabilized bovine pulmonary artery endothelial cells were treated with either degraded peroxyntirite (top panel) or 100 μM peroxyntirite (bottom panel) for 5 minutes at room temperature to induce protein nitration. Nitrated tyrosine residues were detected with our rabbit anti-nitrotyrosine antibody (A21285) and visualized with the green-fluorescent Alexa Fluor[®] 488 goat anti-rabbit IgG antibody (A11008). Nuclei were counterstained with blue-fluorescent DAPI (D1306, D3571, D21490).

Figure 18.3.8 Specificity of our rabbit anti-nitrotyrosine antibody (A21285) to nitrated proteins. Equal amounts of avidin (A887, lane 1) and CaptAvidin[™] biotin-binding protein (C21385, lane 2) were run on an SDS-polyacrylamide gel (4–20%) and blotted onto a PVDF membrane. CaptAvidin[™] biotin-binding protein, a derivative of avidin, has nitrated tyrosine residues in the biotin-binding site. On a western blot, nitrated proteins were identified with the anti-nitrotyrosine antibody in combination with an alkaline phosphatase conjugate of goat anti-rabbit IgG antibody (G21079) and the red-fluorescent substrate DDAO phosphate (D6487).

1,2-Diaminoanthraquinone

For directly detecting NO levels *in vivo*, we offer 1,2-diaminoanthraquinone (DAA, D23840). This nitric oxide probe is reported to be nonfluorescent until it reacts with NO to produce a red-fluorescent precipitate. 1,2-Diaminoanthraquinone has been used to detect changes in NO levels in rat retinas after injury to the optic nerve.⁵⁵ This methodology may make it possible to test the actions of NO in neurodegeneration, inflammation and other biological processes. The role of NO production in hippocampal long-term potentiation has also been investigated using 1,2-diaminoanthraquinone for spatial imaging of NO in rat brain slices.^{56,57}

NBD Methylhydrazine

NBD methylhydrazine (*N*-methyl-4-hydrazino-7-nitrobenzofurazan, M20490) is a unique reagent for the detection of nitrite. Reaction of NBD methylhydrazine with NO_2^- in the presence of mineral acids leads to formation of fluorescent products with excitation/emission maxima of $\sim 468/537$ nm. This reaction serves as the principle behind a selective fluorogenic method for the determination of NO_2^- (Figure 18.3.6). Although NBD methylhydrazine has been used to quantitate nitrite in water using a fluorescence microplate reader,⁵⁸ it does not seem to have been used yet to detect nitrite formed by spontaneous oxidation of NO.

Dichlorodihydrofluorescein Diacetate and Dihydrorhodamine 123

In addition to their extensive use for detecting other reactive oxygen species such as superoxide, dichlorodihydrofluorescein diacetate (H_2DCFDA) and dihydrorhodamine 123 (D399, D632; Section 18.2) have been reported to be useful for detecting peroxyntirite formation both in solution and in live cells.⁵⁹

Anti-Nitrotyrosine Antibody

High levels of nitrotyrosine are associated with a large number of diseases, including multiple sclerosis, Alzheimer disease and Parkinson disease.^{60–62} Increased levels of nitrotyrosine are also indicative of vascular and tissue injury from ischemia–reperfusion and inflammation.⁶¹ Several pathways for the nitration of tyrosine have been suggested. Peroxyntirite (OONO^-), formed by spontaneous reaction of nitric oxide (NO) with superoxide ($\bullet\text{O}_2^-$), elicits downstream tyrosine nitration.^{61,63} Heme peroxidases, such as myeloperoxidase and eosinophil peroxidase, have been shown to utilize hydrogen peroxide (H_2O_2) to oxidize nitrite (NO_2^-) and catalyze tyrosine nitration.⁶⁴ In addition, other heme proteins such as hemoglobin and catalase may contribute to tyrosine nitration using NO as a substrate.⁶⁵ Tryptophan residues can also be oxidized by peroxyntirite.⁶⁶

We offer a high-activity rabbit polyclonal anti-nitrotyrosine antibody (A21285) for detecting nitrotyrosine-containing proteins and peptides. This antibody is suitable for both immunohistochemical (Figure 18.3.7) and western blotting (Figure 18.3.8) applications and is useful for identifying nitrated proteins and determining the level of protein nitrosylation in tissues.^{67,68} Fluorescence of Green Fluorescent Protein (GFP) is extremely sensitive to tyrosine nitration, as confirmed by correlated anti-nitrotyrosine immunoreactivity.⁶⁹

S-Nitrosothiol Detection

S-nitrosylation of thiols, principally in the form of cysteine sidechains or glutathione, is a primary mechanism for downstream propagation of nitric oxide release events. This reversible posttranslational modification regulates enzymatic activity, subcellular localization, chromatin remodeling and protein degradation.^{49,70} The primary reactive nitrogen species responsible for

Figure 18.3.6 Reaction scheme illustrating the principle of nitrite detection by NBD methylhydrazine (M20490).

S-nitrosylation of protein thiols is dinitrogen dioxide (N_2O_3) formed from O_2 and NO. Techniques for detecting S-nitrosothiol modifications exploit, but are also compromised by, their reversible nature and their susceptibility to photolytic cleavage. The technique with most widespread adoption, often referred to as the biotin switch method,^{71–73} consists of three steps: (1) blocking of free thiols with *N*-ethylmaleimide or another alkylating reagent, (2) selective reduction of S-nitrosothiols to thiols using ascorbate or TCEP (T2556, Section 2.1) and (3) labeling of thiols created in step 2 with a fluorescent or biotinylated maleimide or iodoacetamide reagent^{74,75} (Section 2.2 or Section 4.2, respectively). Streptavidin agarose (S951, Section 7.6) can be used to subsequently pull down biotinylated proteins for further analysis if required. The overall technique is vulnerable to false positives through incomplete blocking of unmodified thiols in step 1 and inadvertent reduction of disulfides in step 2. Other methods take advantage of the fact that S-nitrosothiols can be cleaved by heavy metal ions such as Hg^{2+} or by exposure to ultraviolet light, releasing NO and subsequently nitrite (NO_2^-).⁷⁶ The NO product of this process can be detected using DAF-FM⁷⁷ or the nascent thiol product can be detected using a fluorescent maleimide reagent.⁷⁸

Griess Reagent Kit

Under physiological conditions, NO is readily oxidized to nitrite and nitrate or it is trapped by thiols as an S-nitroso adduct. The Griess reagent provides a simple and well characterized colorimetric assay for nitrites, and nitrates that have been reduced to nitrites, with a detection limit of about 100 nM.^{52,79,80} Nitrites react with sulfanilic acid in acidic solution to form an intermediate diazonium salt that couples to *N*-(1-naphthyl)ethylenediamine to yield a purple azo derivative that can be monitored by absorbance at 548 nm (Figure 18.3.9).

Our Griess Reagent Kit (G7921) contains all of the reagents required for nitrite quantitation, including:

- *N*-(1-Naphthyl)ethylenediamine dihydrochloride
- Sulfanilic acid in 5% H_3PO_4
- Concentrated nitrite quantitation standard for generating calibration curves
- Detailed protocols for spectrophotometer and microplate reader assays

Both the *N*-(1-naphthyl)ethylenediamine dihydrochloride and the sulfanilic acid in 5% H_3PO_4 are provided in convenient dropper bottles for easy preparation of the Griess reagent. Sample pretreatment with nitrate reductase and glucose 6-phosphate dehydrogenase is reported to reduce nitrate without producing excess NADPH, which can interfere with the Griess reaction.⁸¹ A review of the use of the Griess reagent for nitrite and nitrate quantitation in human plasma describes optimal reaction conditions for minimizing interference from plasma constituents (particularly NADPH).⁸² The Griess Reagent Kit can also

Figure 18.3.9 Principle of nitrite quantitation using the Griess Reagent Kit (G7921). Formation of the azo dye is detected via its absorbance at 548 nm.

be used to analyze NO that has been trapped as an S-nitroso derivative by a modification that uses mercuric chloride or copper (II) acetate to release the NO from its complex.^{83,84}

Measure-iT™ High-Sensitivity Nitrite Assay Kit

The Measure-iT™ High-Sensitivity Nitrite Assay Kit (M36051) provides an easy and accurate method for quantitating nitrite. This kit has an optimal range of 20–500 picomoles nitrite (Figure 18.3.10), making it up to 50 times more sensitive than colorimetric methods utilizing the Griess reagent. Nitrates may be analyzed after quantitative conversion to nitrites through enzymatic reduction,⁸⁰ used in this manner, the Measure-iT™ nitrite assay also provides an effective method for quantitating nitric oxide.

Each Measure-iT™ High-Sensitivity Nitrite Assay Kit contains:

- Measure-iT™ nitrite quantitation reagent (100X concentrate in 0.62 M HCl)
- Measure-iT™ nitrite quantitation developer (2.8 M NaOH)
- Measure-iT™ nitrite quantitation standard (11 mM sodium nitrite)
- Detailed protocols

Simply dilute the reagent 1:100, load 100 μ L into the wells of a microplate, add 1–10 μ L sample volumes and mix. After a 10-minute incubation at room temperature, add 5 μ L of developer and read the fluorescence. The assay signal is stable for at least 3 hours, and common contaminants are well tolerated in the assay. The Measure-iT™ High-Sensitivity Nitrite Assay Kit provides sufficient material for 2000 assays, based on a 100 μ L assay volume in a 96-well microplate format; this nitrite assay can also be adapted for use in cuvettes or 384-well microplates.

Figure 18.3.10 Linearity and sensitivity of the Measure-iT™ high-sensitivity nitrite assay. Triplicate 10 μ L samples of nitrite were assayed using the Measure-iT™ High-Sensitivity Nitrite Assay Kit (M36051). Fluorescence was measured using excitation/emission of 365/450 nm and plotted versus picomoles of nitrite. Background fluorescence was not subtracted. The variation (CV) of replicate samples was <2%.

Notes

1. Releases nitric oxide upon acid-catalyzed dissociation in solution. Stable in alkaline solutions. (Methods Enzymol (1996) 268:281)
2. Fluorescence of D7918 is weak. Reaction with nitrite yields highly fluorescent 1*H*-naphthothiazole (Abs = 365 nm, Em = 415 nm in H₂O (pH 12)). (Methods Enzymol (1996) 268:105)
3. 1,2-Diaminoanthraquinone reacts with nitrite or nitric oxide to produce 1*H*-anthratiazole-6,11-dione which forms a red-fluorescent (Em >580 nm) precipitate in water. (Neuroreport (1998) 9:4051)
4. DAF-FM fluorescence is very weak. Reaction with nitrite or nitric oxide generates a highly fluorescent benzotriazole derivative with Abs = 495 nm (EC = 73,000 cm⁻¹M⁻¹), Em = 515 nm in pH 7.4 buffer. (Angew Chem Int Ed Engl (1999) 38:3209)
5. Acetate hydrolysis and subsequent reaction with nitrite or nitric oxide generate a highly fluorescent benzotriazole derivative with Abs = 495 nm (EC = 73,000 cm⁻¹M⁻¹), Em = 515 nm in pH 7.4 buffer. (Angew Chem Int Ed Engl (1999) 38:3209)
6. Spontaneously decomposes in solution.
7. NBD methylhydrazine reacts with nitrite in the presence of strong acid to form fluorescent *N*-methyl-4-amino-7-nitrobenzofurazan (Abs = 459 nm, Em = 537 nm in MeCN). (Anal Chem (1999) 71:3003)

PRODUCT LIST 18.3 PROBES FOR NITRIC OXIDE RESEARCH

Cat. No.	Product	Quantity
A21285	anti-nitrotyrosine, rabbit IgG fraction *1 mg/mL*	0.5 mL
C7912	2-(4-carboxyphenyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide, potassium salt (carboxy-PTIO)	25 mg
D23841	DAF-FM (4-amino-5-methylamino-2',7'-difluorofluorescein)	1 mg
D23842	DAF-FM diacetate (4-amino-5-methylamino-2',7'-difluorofluorescein diacetate)	1 mg
D23844	DAF-FM diacetate (4-amino-5-methylamino-2',7'-difluorofluorescein diacetate) *special packaging*	10 x 50 µg
D23840	1,2-diaminoanthraquinone sulfate (DAA) *high purity*	5 mg

19.1 Introduction to Ca²⁺ Measurements with Fluorescent Indicators

Fluorescent probes that show a spectral response upon binding Ca²⁺ have enabled researchers to investigate changes in intracellular free Ca²⁺ concentrations using fluorescence microscopy, flow cytometry and fluorescence spectroscopy. The properties and applications of these fluorescent indicators—most of which are derivatives of the Ca²⁺ chelators EGTA, APTRA and BAPTA¹—have been extensively reviewed.^{2–4} Several earlier reviews of these ion indicators also contain useful technical information.^{5–8}

We discuss chemical Ca²⁺ indicators according to their excitation requirements in Section 19.2 and Section 19.3, and their high-molecular weight conjugates are described in Section 19.4. Protein-based Ca²⁺ sensors are discussed in Section 19.5.

Selection Criteria for Fluorescent Ca²⁺ Indicators

We offer a wide selection of fluorescent indicators available for detecting changes in intracellular Ca²⁺ over the range of <50 nM to >50 μM (Table 19.1). As the primary suppliers of fura-2, indo-1, fluo-3 (Figure 19.1.1), fluo-4 and rhod-2, we also offer many specialized indicators for intracellular Ca²⁺. Our fura-4F, fura-6F and fura-FF indicators are designed to provide increased response sensitivity to intracellular Ca²⁺ concentration in the 0.5–5 μM range, as compared with fura-2. The fluo-3, fluo-4, Oregon Green® 488 BAPTA, Calcium Green™, X-rhod-1 and Fura Red™ indicators and their variants enable Ca²⁺ detection in confocal microscopy and high-throughput G protein-coupled receptor (GPCR) screening applications. In addition, we offer indicators that are conjugated to high- or low-molecular weight dextrans for improved cellular retention and less compartmentalization (Section 19.4). We strive to provide the highest-purity indicators available anywhere. The AM ester forms of most of our indicators are typically at least 95% pure by HPLC analysis, although purity often

Figure 19.1.1 A pyramidal neuron from rat hippocampus was first exposed to Alzheimer's β-amyloid peptide and then to the excitatory amino acid glutamate. Confocal laser-scanning microscopy imaging using the intracellular Ca²⁺ indicator fluo-3 (F1241, F1242, F14218, F14242, F23915) shows that β-amyloid peptide destabilizes the neuron's calcium homeostasis and increases its vulnerability to excitotoxicity. The image was contributed by Mark P. Mattson, Sanders-Brown Center on Aging, University of Kentucky.

exceeds 98%. Furthermore, the AM esters of many of the Ca²⁺ and Mg²⁺ indicators are available in sets of 50 μg for more convenient handling and reduced risk of deterioration during storage. For high-throughput screening applications, fluo-3 AM and fluo-4 AM are offered in special multi-unit packages (F14242, F14202), as well as in application-specific Fluo-4 NW and Fluo-4 Direct™ Calcium Assay Kits (Section 19.3).

A number of factors should be considered when selecting a fluorescent Ca²⁺ indicator, some of which are summarized in Table 19.1 and include the following:

- Indicator form (salt, AM ester or dextran conjugate), which influences the cell-loading method and affects the indicator's intracellular distribution and retention (Loading and Calibration of Intracellular Ion Indicators—Note 19.1). The salt and dextran forms are typically loaded by microinjection, microprojectile bombardment or electroporation or by using the Influx™ pinocytotic cell-loading reagent (I14402, Section 19.8) (Table 14.1). In contrast, the cell-permeant acetoxymethyl (AM) esters can be passively loaded into cells, where they are cleaved to cell-impermeant products by intracellular esterases.
- Measurement mode, which is dictated by whether qualitative or quantitative ion concentration data are required. Ion indicators that exhibit spectral shifts upon ion binding can be used for ratiometric measurements of Ca²⁺ concentration, which are essentially independent of uneven dye loading, cell thickness, photobleaching effects and dye leakage (Loading and Calibration of Intracellular Ion Indicators—Note 19.1). Excitation and emission wavelength preferences depend on the type of instrumentation being used, as well as on sample autofluorescence and on the presence of other fluorescent or photoactivatable probes in the experiment.
- Dissociation constant (K_d), which must be compatible with the Ca²⁺ concentration range of interest. Indicators have a detectable response in the concentration range from approximately 0.1 × K_d to 10 × K_d. For ratiometric indicators, the Ca²⁺ response range is also somewhat dependent on the measurement wavelengths used.^{9–11} The K_d of Ca²⁺ indicators is dependent on many factors, including pH, temperature,^{12–15} ionic strength, viscosity, protein binding and the presence of Mg²⁺ and other ions. Consequently, K_d values for intracellular indicators are usually significantly higher than corresponding values measured in cell-free solutions (Table 19.2).

Intracellular calibration of Ca²⁺ indicators may be achieved either by manipulating Ca²⁺ levels inside cells using an ionophore or by releasing the indicator into the surrounding medium of known Ca²⁺ concentration via detergent lysis of the cells. We also offer several compounds and buffers for measuring and manipulating intracellular and extracellular Ca²⁺. These products, which are discussed in Section 19.8, include caged Ca²⁺ reagents and caged chelators (NP-EGTA, DMNP-EDTA and diazo-2), as well as Calcium Calibration Buffer Kits, BAPTA-derived buffers, ion-selective chelating polymers (Calcium Sponge™) and the important Ca²⁺ ionophores ionomycin, A-23187 and its nonfluorescent analog, 4-bromo A-23187. Reagents for probing Ca²⁺ regulation and second-messenger activity are described in more detail in Chapter 17. Our reagents for the study of Ca²⁺ channels are described in Section 16.3.

Table 19.1 Summary of Molecular Probes® fluorescent Ca²⁺ indicators.

* Catalog number(s) for the cell-impermeant salt. † Catalog number(s) for the cell-permeant AM ester. ‡ Catalog number(s) for the dextran conjugates. § Measurement wavelengths, in nm, where Ex = fluorescence excitation and Em = fluorescence emission. Indicators for which a pair of wavelengths are listed have dual-wavelength, ratio-measurement capability. ** Ca²⁺ dissociation constant, measured *in vitro* at 22°C in 100 mM KCl, 10 mM MOPS, pH 7.2, unless otherwise noted. K_d values depend on temperature, ionic strength, pH and other factors, and are usually higher *in situ*. Because indicator dextrans are intrinsically polydisperse and have variable degrees of substitution, these values may vary; lot-specific K_d values are printed on the vial in most cases. †† Low-affinity dextran conjugate. ††† High-affinity dextran conjugate.

Notes: 1. Ca²⁺-dependent fluorescence response similar to fura-2 but ~75% greater molar absorptivity. 2. The AM ester form is fluorescent (a major potential source of error in Ca²⁺ measurements). 3. The AM ester form is nonfluorescent. 4. Calcium Green™-1 is more fluorescent than fluo-3 in both Ca²⁺-bound and Ca²⁺-free forms. The magnitude of the Ca²⁺-dependent fluorescence increase is greater for fluo-3; see Section 19.3. 5. Larger Ca²⁺-dependent fluorescence increase than Calcium Green™-1. 6. The K_d value for the low-affinity fluo-4 dextran (F14240) is ~3 μM, which is much higher than that of the free dye. The K_d value for the high-affinity fluo-4 dextran (F36250) is ~600 nM. 7. Can also be used in combination with fluo-3 for dual-wavelength ratio measurements, Ex = 488 nm, Em = 530/670 nm (Cell Calcium (1995) 18:377; Cytometry (1994) 17:135; Cell Calcium (1993) 14:359). 8. K_d determined in 100 mM KCl, 40 mM HEPES, pH 7.0 at 22°C (Biochem Biophys Res Commun (1991) 177:184). 9. Larger Ca²⁺-dependent fluorescence increase than Oregon Green® 488 BAPTA-1. 10. K_d determined in 120 mM KCl, 20 mM NaCl, pH 7.05 at 37°C (Methods Enzymol (1989) 172:230). 11. The K_d value for the high-affinity rhod dextran (R34676) is ~780 nM.

Table 19.2 Comparison of *in vitro* and *in situ* K_d values for various Ca²⁺ indicators.

Indicator	K _d <i>in vitro</i> (nM) *	K _d <i>in situ</i> (nM) †	Cell/Tissue Type
Calcium Green™-1	190	930	HeLa cells ¹
Fluo-3	390	2570	Frog skeletal muscle ²
Fluo-4	345	1000	HeLa cells ¹
Fura-2	145	371	U373-MG astrocytoma cell ³
Fura-2	145	350	Rabbit gastric gland ⁴
Indo-1	230	844	Rabbit cardiac myocyte ⁵
Oregon Green® 488 BAPTA-1	170	430	HeLa cells ¹
Rhod-2	570	720	Mouse heart ⁶

* Values determined at 22°C in 100 mM KCl, 10 mM MOPS, pH 7.2, 0–10 mM CaEGTA. † Values determined in the cellular environments listed in the adjacent column. 1. Cell Calcium (2000) 28:213; 2. NOTE 19.1

Loading and Calibration of Intracellular Ion Indicators

There are two major prerequisites for measuring intracellular ion concentrations using fluorescent indicators:

- **Loading:** The indicator must be localized in the region (most commonly the cytosol but sometimes the mitochondria) where the ion concentration is to be measured.
- **Calibration:** The fluorescence of the indicator must be quantitatively related to the concentration of the free ion.

Loading

Cell loading methods can be divided into two groups. Bulk loading procedures are applicable to large populations of cells and include:

- Acetoxymethyl (AM) ester loading^{4–7}
- ATP-induced permeabilization⁸
- Electroporation^{9–11}
- Hypoosmotic shock¹²
- Influx™ pinocytic cell-loading reagent¹³ (I14402, Section 19.8)
- Coupling to cell-penetrating peptides (CPP)^{14–16}
- Ballistic microprojectile delivery^{17–20}

Procedures such as microinjection²¹ and infusion from whole-cell patch pipettes²² must be carried out one cell at a time. Reviews of some of these techniques have been published,²³ see also Table 14.1.

The AM Ester Loading Technique

The noninvasive and technically straightforward AM ester technique is by far the most popular method for loading fluorescent ion indicators (Figure 1). The carboxylate groups of indicators for Ca^{2+} and other cations and the phenolic hydroxyl groups of pH indicators are derivatized

Figure 1 Schematic diagram of the processes involved in loading cells using membrane-permeant acetoxymethyl (AM) ester derivatives of fluorescent indicators, in this case fura-2. Note the generation of potentially toxic by-products (formaldehyde and acetic acid).

as acetoxymethyl or acetate esters, respectively, rendering the indicator permeant to membranes and insensitive to ions. Once inside the cell, these derivatized indicators are hydrolyzed by ubiquitous intracellular esterases, releasing the ion-sensitive polyanionic indicator.

In practice, a 1–10 mM stock solution of the ester probe in *anhydrous* dimethylsulfoxide (DMSO) is prepared and divided into appropriately sized aliquots that can be stored desiccated at -20°C . This procedure will curtail the spontaneous ester hydrolysis that can occur in moist environments. Before loading, the DMSO stock solution should be diluted at least 1:200 in *serum-free* culture medium to a final concentration of about 1–10 μM . The nonionic and nondenaturing detergent Pluronic® F-127 or the related PowerLoad™ reagent (P3000MP, P6866, P6867, P10020; Section 19.8) are frequently added to help disperse the indicator in the loading medium.²⁴ After incubation at $20\text{--}37^{\circ}\text{C}$ for 15–60 minutes, the cells should be washed two to three times with fresh *serum-free* culture medium (serum may contain esterase activity). The loading medium should also be free of amino acids or buffers containing primary or secondary amines because aliphatic amines may cleave the AM esters and prevent loading. The overall loading efficiency is typically 10–40%, depending on the molecular structure of the indicator, the type of cells and the incubation conditions.

Problems with AM Ester Loading

Compartmentalization: For calibration purposes, it is usually assumed that fluorescent indicators are homogeneously distributed in the cytosol and equally responsive to variations of intracellular ion concentration. However, AM esters and their hydrolysis products are capable of accumulating in any membrane-enclosed structure within the cell. In addition, indicators in polyanionic form may be sequestered within organelles via active transport processes.²⁵ Compartmentalization is usually more pronounced at higher loading temperatures and is particularly acute in plant and fungal cells.^{26,27} The extent of compartmentalization can be assessed by image analysis, as well as fluorometrically using membrane permeabilization reagents, such as Triton X-100.²⁴

Incomplete AM ester hydrolysis: Residual unhydrolyzed AM esters may be present extracellularly due to incomplete removal by washing. Inside the cell, low levels of intracellular esterase activity, which can vary considerably from one cell type to another, may produce only partial AM ester hydrolysis.^{28–30} Because even partially hydrolyzed AM esters are Ca^{2+} -insensitive, detection of their fluorescence as part of the total signal leads to an underestimation of the Ca^{2+} concentration.^{31,32} Fluorescence quenching by Mn^{2+} , which only binds with high affinity to completely de-esterified indicators, can be used to quantitate these effects. Note that although some indicators are fluorescent in the AM ester form, others are not (Table 19.1).

Extracellular AM ester hydrolysis: High levels of extracellular esterase activity can make AM ester loading ineffective, particularly for *in vivo* applications.³³

Leakage: Extrusion of anionic indicators from cells by organic ion transporters can be reduced by cooling the sample or by applying inhibitors such as probenecid (P36400, Section 19.8), sulfapyrazone and MK571.^{25,34} AM esters have been shown to be extruded by the P-glycoprotein multidrug transporter³⁵ (Section 15.6). Ratiometric measurements help to minimize the impact of indicator leakage on experimental data.³⁶

Calibration

Ion Dissociation Constants

The dissociation constant (K_d) is the key conversion parameter linking fluorescence signals to ion concentrations, assuming that the indicator is operating as an equilibrium sensor. This conventional assumption requires that the concentration of the indicator is close to the K_d value. Because intracellular indicator concentrations can easily reach 10–100 μM , even if the externally applied concentration is only 1–10 μM , this assumption is not always valid.³⁷ For pH indicators, K_d is conventionally expressed as its negative log ($\text{p}K_a$). The concentration range over which an indicator produces an observable response is approximately $0.1 \times K_d$ to $10 \times K_d$. For ratiometric measurements, the response range also depends on wavelength-dependent parameters.^{38,39} For BAPTA-based Ca²⁺ indicators in particular, the K_d is very sensitive to a number of environmental factors, including temperature, pH, ionic strength and interactions of the indicator with proteins.^{40–43} Examination of published data shows that values of K_d determined *in situ* within cells can be up to 5-fold higher than values determined *in vitro*.^{3,40,44–46} (Table 19.2), underscoring the importance of performing calibrations to determine the K_d directly in the system under study.

Calibration Methodology

Calibration procedures basically consist of recording fluorescence signals corresponding to a series of precisely manipulated ion concentrations. The resulting sigmoidal titration curve is either linearized by means of a Hill plot or analyzed directly by nonlinear regression to yield K_d . For *in vitro* calibrations of Ca²⁺ indicators, EGTA buffering is widely used to produce defined Ca²⁺ concentrations that can be calculated from the K_d of the Ca²⁺-EGTA complex.^{24,47,48} This technique is used in the Calcium Calibration Buffer Kits (Section 19.8). *In situ* calibrations of intracellular indicators generally utilize an ionophore to equilibrate the controlled external ion concentration with the ion concentration within the cell.^{4,49} Commonly used ionophores include:

- A-23187 (A1493), 4-bromo A-23187 (B1494) or ionomycin (I24222) for Ca²⁺ and Mg²⁺ (Section 19.8)
- Nigericin (N1495; Section 20.2, Section 21.2) for H⁺ and Cl⁻
- Gramicidin (G6888, Section 21.1) for Na⁺
- Valinomycin (V1644, Section 21.1) for K⁺

Ratiometric Calibration

Indicators that show an excitation or emission spectral shift upon ion binding can be calibrated using a ratio of the fluorescence intensities measured at two different wavelengths, resulting in the cancellation of artifactual variations in the fluorescence signal that might otherwise be misinterpreted as changes in ion concentration (Figure 2). Note that background levels must be subtracted from the component fluorescence intensities *before* calculation of the ratio. Examples of indicators exhibiting ion-dependent spectral shifts include the Ca²⁺ indicators fura-2 (Figure 3) and indo-1 (Section 19.2), and the pH indicators BCECF and SNARF-1 (Section 20.2). The ratio of two intensities with opposite ion-sensitive responses (for example, 340 nm/380 nm in Figure 3) gives the largest possible dynamic range of ratio signals for a particular indicator. Alternatively, the ratio of an ion-sensitive intensity to an ion-insensitive intensity (measured at a spectral isosbestic point, e.g., 360 nm in Figure 3) can be used (Figure 2). Ratiometric measurements reduce or eliminate variations of several determining factors in the measured fluorescence intensity, including indicator concentration, excitation path length, excitation intensity and detection efficiency.^{50,51} Artifacts that are eliminated include photobleaching and leakage of the indicator, variable cell thickness, and nonuniform indicator distribution within cells (due to compartmentalization) or among populations of cells (due to loading efficacy variations).

Figure 2 Simulated data demonstrating the practical importance of ratiometric fluorescence techniques. This figure represents an ion indicator that exhibits a fluorescence intensity increase in response to ion binding at wavelength λ_1 , and a corresponding decrease at λ_3 . Fluorescence measured at an isosbestic point (λ_2) is independent of ion concentration. The intracellular indicator concentration diminishes rapidly due to photobleaching, leakage (assuming the extracellular indicator is not detectable) or some other process. The change of intracellular ion concentration due to a stimulus applied at the time indicated by the arrow is unambiguously identified by recording the fluorescence intensity ratios λ_1/λ_3 or λ_1/λ_2 .

19.2 Fluorescent Ca²⁺ Indicators Excited with UV Light

Fura-2, Indo-1 and Related Derivatives

Fura-2 and Indo-1

Fura-2 and indo-1 are UV light-excitable, ratiometric Ca²⁺ indicators. Fura-2 has become the dye of choice for ratio-imaging microscopy (Figure 19.2.1), in which it is more practical to change excitation wavelengths than emission wavelengths.^{1,2} Upon binding Ca²⁺, fura-2 exhibits an absorption shift that can be observed by scanning the excitation spectrum between 300 and 400 nm, while monitoring the emission at ~510 nm (Figure 19.2.2). In contrast, indo-1 is a preferred dye for flow cytometry, where it is more practical to use a single laser for excitation—usually the 351–364 nm spectral lines of the argon-ion laser—and monitor two emissions.^{3,4} The emission maximum of indo-1 shifts from ~475 nm in Ca²⁺-free medium to ~400 nm when the dye is saturated with Ca²⁺ (Figure 19.2.3).

Modern two-photon excitation imaging techniques used with fura-2 and indo-1^{5–9} avoid the deleterious effects of conventional ultraviolet illumination on live specimens. Indo-1 may be less subject to compartmentalization than fura-2,¹⁰ whereas fura-2 is more resistant to photobleaching than indo-1.^{11,12} Both fura-2 and indo-1 exhibit K_d values that are close to typical basal Ca²⁺ levels in mammalian cells (~100 nM) and display high selectivity for Ca²⁺ binding relative to Mg²⁺.¹³ Nevertheless, Ca²⁺ binding is discernibly perturbed by physiological levels of Mg²⁺; the K_d for Ca²⁺ of fura-2 is ~135 nM in Mg²⁺-free Ca²⁺ buffers and ~224 nM in the presence of 1 mM Mg²⁺ (measured at 37°C in 100 mM KCl, 10 mM MOPS, pH 7.0).¹³ Fura-2 and indo-1 also exhibit high affinities for other divalent cations such as Zn²⁺ and Mn²⁺, a property that is discussed further in Section 19.7.

The sodium and potassium salts of fura-2 (F6799, F1200; Figure 19.2.4; Figure 19.2.5) and potassium salt of indo-1 (I1202, Figure 19.2.6) are cell-impermeant probes that can be delivered into cells by microinjection or using our Influx™ pinocytotic cell-loading reagent (I14402, Section 19.8). Free acids of fura-2 and indo-1 can also be loaded into some plant cells at pH 4–5.^{14–18} In addition, these salts are useful as standards for calibrating Ca²⁺ measurements.

Figure 19.2.1 False-color image of free Ca²⁺ concentration in a Purkinje neuron from embryonic mouse cerebellum. Neurons were grown in dispersed tissue culture for 12 days, loaded with the pentapotassium salt of fura-2 (F1200) using a microelectrode and then challenged with trans-ACPD, an agonist of metabotropic glutamate receptors, in the absence of extracellular Ca²⁺. The composite image, which represents the ratio of images obtained with excitation at 340 nm and 380 nm, reveals the mobilization of internal Ca²⁺ stores without contribution from Ca²⁺ influx. The image was contributed by D.J. Linden, Johns Hopkins University, and M. Smeysne and J.A. Connor, Roche Institute of Molecular Biology.

Unlike the salt forms, the acetoxymethyl (AM) esters of fura-2 (Figure 19.2.7) and indo-1 (Figure 19.2.8) can passively diffuse across cell membranes, enabling researchers to avoid the use of invasive loading techniques. Once inside the cell, these esters are cleaved by intracellular esterases to yield cell-impermeant fluorescent indicators (Loading and Calibration of Intracellular Ion Indicators—Note 19.1). We offer fura-2 AM and indo-1 AM in 1 mg vials (F1201, I1203) or specially packaged in 20 vials of 50 μg each (F1221, I1223); the special packaging is recommended when small quantities of the dyes are to be used over a long period of time. We also provide stock solutions of fura-2 AM and indo-1 AM in anhydrous DMSO at 1 mg/mL (~1 mM; F1225, I1226). Our standard analytical specifications for fura-2 AM require ≥95% purity by HPLC. We also offer a special packaged high-purity grade of fura-2 AM that is specified to have ≥98% purity by HPLC (as a set of 20 vials, each containing 50 μg; F14185). The 10,000 MW dextran conjugate of fura is described in Section 19.4.

Fura-2 Calcium Imaging Calibration Kit

The Fura-2 Calcium Imaging Calibration Kit (F6774) is designed to facilitate rapid calibration and standardization of digital imaging microscopes.^{2,19} This kit provides 11 CaEGTA:EGTA buffer solutions with free Ca²⁺ concentrations from zero (10 mM EGTA) to 39 μM. Each solution also includes 50 μM fura-2, as well as 15 μm unstained polystyrene microspheres to act both as spacers that ensure uniform separation between the slide and the coverslip and as focusing aids. We also provide a twelfth buffer—identical to the 10 mM CaEGTA standard but lacking fura-2—that serves as a control for background fluorescence. Our Calcium Calibration Kits are described further in Section 19.8.

Bis-Fura-2: Brighter Signal with Lower Affinity for Ca²⁺

By linking two fura fluorophores with one BAPTA chelator (Figure 19.2.9), we have produced bis-fura-2, a Ca²⁺ indicator that exhibits approximately twice the absorptivity of fura-2. Bis-fura-2 has a K_d for Ca²⁺ of ~370 nM and ~525 nM in the absence and presence of 1 mM Mg²⁺, respectively (measured at ~22°C using our Calcium Calibration Buffer Kits). In other aspects, the quantum yield of bis-fura-2 and its spectral response to Ca²⁺ (Figure 19.2.10) are virtually identical to those of fura-2. Although the difference between the K_d of fura-2 and bis-fura-2 for Ca²⁺ is small, the change in excitation ratio for bis-fura-2 in response to Ca²⁺ concentrations >500 nM is larger than that of fura-2 (Figure 19.2.2); this difference can improve the dynamic range for Ca²⁺ measurements in cells.^{20,21} Other potential advantages of bis-fura-2 include:

- Higher fluorescence output per indicator, which may allow the use of lower dye concentrations²¹
- Lower affinity for Ca²⁺, which decreases the buffering of intracellular Ca²⁺ and produces a faster response to Ca²⁺ spikes²⁰
- An additional negative charge, which may facilitate dye retention

The hexapotassium salt of bis-fura-2 (B6810) is available for loading by microinjection^{22,23} or by infusion from a patch pipette.²⁴ We do not currently offer a membrane-permeant AM ester of bis-fura-2.

Quin-2

Quin-2 belongs to the first generation of Ca²⁺ indicators developed by Tsien²⁵ (Figure 19.2.11). Quin-2 has lower absorptivity and quantum yield values than the fura-2, indo-1, fluo-3, fluo-4 and Calcium Green™ indicators and thus requires higher loading concentrations. The resulting high intracellular concentration of the indicator may buffer intracellular Ca²⁺ transients.²⁶ Quin-2 AM has been used to intentionally deplete cytosolic free Ca²⁺^{27,28} and to ensure unidirectional Ca²⁺ influx.²⁹ Measurement of cytosolic free Ca²⁺ with quin-2 has been thoroughly reviewed by Tsien and Pozzan.³⁰ We offer quin-2 as a high-purity, cell-impermeant free acid (Q23918).

Indicators with Intermediate Calcium-Binding Affinity

Fura-4F and Fura-6F

Calcium concentrations above 1 μM produce almost complete binding saturation of fura-2 but very low fractional saturation of the low-affinity fura analog mag-fura-2 (M1290). To bridge this gap in the Ca²⁺ measurement range of fura-type indicators, we currently offer two additional ratiometric Ca²⁺ indicators—fura-4F (F14174) and fura-6F (F14178)—as well as the membrane-permeant fura-4F AM³¹ (F14175); fura-5F may be available upon request at www.invitrogen.com/handbook/customorganics. Attachment of a single electron-withdrawing fluorine substituent at different positions on the BAPTA chelator moiety of fura-2 (Figure 19.2.4) results in an increase of the K_d value to ~770 nM, ~400 nM and 5.3 μM for fura-4F, fura-5F and fura-6F, respectively (measured at 22°C at 100 mM KCl, 10 mM MOPS, pH 7.2). Except for the change in the Ca²⁺ concentration response range (Figure 19.2.12), the Ca²⁺-dependent spectral shifts produced by fura-4F, fura-5F and fura-6F are essentially identical to those of fura-2 (Figure 19.2.13) and the probes use the same optical filter sets.

Fura-FF

Fura-FF is a difluorinated derivative of fura-2 (Figure 19.2.4) with a K_d value of ~5.5 μM ^{32–34} (measured at 22°C in 100 mM KCl, 10 mM MOPS, pH 7.2) and similar spectroscopic properties (Figure 19.2.14). Fura-FF has negligible Mg²⁺ sensitivity, making Ca²⁺ detection less susceptible to interference than with mag-fura-2.^{32–34} These

properties have made fura-FF particularly useful for spatial and functional characterization of intracellular Ca²⁺ stores³⁵ and for tracking Ca²⁺ oscillations driven by the inositol 1,4,5-triphosphate receptor.^{36,37} The low-affinity indicator fura-FF detected NMDA- and kainate-induced neuronal Ca²⁺ fluxes that were not detectable with the higher-affinity indicator fura-2.³⁸ Fura-FF has also been used in combination with FluoZin™-3 (Section 19.7) for simultaneous detection of Ca²⁺ and Zn²⁺.³⁹ Fura-FF is available in water-soluble potassium salt form (F14180) and as a membrane-permeant AM ester derivative (F14181).

Low-Affinity Calcium Indicators

BTC

The coumarin benzothiazole-based Ca²⁺ indicator BTC (B6790, Figure 19.2.15) and its cell-permeant derivative BTC AM (B6791) were developed in collaboration with Haralambos Katerinopoulos of the University of Crete.⁴⁰ This Ca²⁺ indicator exhibits a shift in excitation maximum from about 480 nm to 400 nm upon binding Ca²⁺ (Figure 19.2.16), permitting ratiometric measurements that are essentially independent of uneven dye loading, cell thickness, photobleaching and dye leakage.^{41,42} Its high selectivity and moderate affinity for Ca²⁺ (K_d ~7 μM)⁴² allows accurate quantitation of high intracellular Ca²⁺ levels that are underestimated by fura-2 measurements.^{43,44} When loaded into neurons as its AM ester, BTC exhibits little compartmentalization; however, prolonged excitation appears to cause conversion of the indicator to a calcium-insensitive form.⁴⁴

Figure 19.2.12 Fluorescence excitation ratio versus Ca²⁺ concentration curves for fura-2 (red), fura-5F (orange), fura-4F (green) and fura-6F (blue).

Figure 19.2.16 Fluorescence excitation spectra of BTC (B6790) in solutions containing 0–100 μM free Ca²⁺.

Figure 19.2.17 Mag-fura-2, tetrapotassium salt (M1290).

Figure 19.2.18 Ca²⁺ transients evoked by trains of 1–4 action potentials in rat cerebellar granule cells detected by fura-2 (upper panel, F1200) and mag-fura-2 (lower panel, M1290). The stimulus pulses are 50 milliseconds apart (20 Hz); timing is indicated by the double-headed arrows. The amplitude of the transients detected by fura-2 decreases with each successive stimulus due to Ca²⁺ saturation. Mag-fura-2 avoids saturation due to its lower Ca²⁺ binding affinity (K_d for Ca²⁺ = 25 μM), recording transients of approximately equal amplitude from successive action potentials. Adapted with permission from *Biophys J* (1995) 68:2165.

BTC has been employed in investigations of Ca²⁺-dependent exocytosis in pancreatic β-cells,⁴⁵ CHO fibroblasts⁴⁶ and pheochromocytoma cells.^{47,48} Neuronal Ca²⁺ transients detected by the low-affinity Ca²⁺ indicators BTC and mag-fura-2 are significantly more rapid than those reported by the higher-affinity indicators fura-2 and Calcium Green™-2.^{44,49}

Mag-Fura-2 and Mag-Indo-1

Mag-fura-2 (also called furaptra, Figure 19.2.17) and mag-indo-1 were originally designed to report intracellular Mg²⁺ levels (Section 19.6); however, these indicators actually have much higher affinity for Ca²⁺ than for Mg²⁺. Although Ca²⁺ binding by these indicators may complicate analysis when they are employed to measure intracellular Mg²⁺,^{50,51} their increased effective range and improved linearity for Ca²⁺ measurements has been exploited for measuring intracellular Ca²⁺ levels between 1 μM and 100 μM.³⁵

The spectral shifts of mag-fura-2 and mag-indo-1 are very similar to those of fura-2 and indo-1 but occur at higher Ca²⁺ concentrations. Because the off-rates for Ca²⁺ binding of these indicators are much faster than those of fura-2 and indo-1, these dyes have been used to monitor action potentials in skeletal muscle and nerve terminals with little or no kinetic delay^{52–55} (Figure 19.2.18). The spectral properties, kinetics and selectivity of several of our low-affinity Ca²⁺ indicators have been reviewed by Zhao,⁵⁶ Hyrc³² and their co-workers.

The moderate Ca²⁺ affinity of mag-fura-2 and the tendency of its AM ester to accumulate in subcellular compartments have proven useful for *in situ* monitoring of inositol 1,4,5-triphosphate-sensitive Ca²⁺ stores.^{35,57} Mag-fura-2 has also been employed to follow Ca²⁺ transients in presynaptic nerve terminals,^{49,58–60} gastric epithelial cells⁶¹ and cultured myocytes.⁶² Mag-indo-1 has been used to detect gonadotropin-releasing hormone-induced Ca²⁺ oscillations in gonadotrope⁶³ and to investigate the role of Ca²⁺/K⁺ exchange in intracellular Ca²⁺ storage and release processes.⁶⁴ Mag-fura-2 (M1290, M1291, M1292) and mag-indo-1 (M1295) are available as cell-impermeant potassium salts or as cell-permeant AM esters.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Dissociation constants are known to vary considerably depending on the temperature, pH, ionic strength, viscosity, protein binding, presence of other ions (especially polyvalent ions), instrument setup and other factors. It is strongly recommended that these values be verified under user-specific experimental conditions.
- Spectra measured in aqueous buffers containing 10 mM EGTA (H₂O) or a >10-fold excess of free Ca²⁺ relative to the K_d (H₂O/Ca²⁺).
- Dissociation constant determined by fluorescence measurements in 100 mM KCl, 10 mM MOPS, pH 7.2, 0 to 1 mM free Ca²⁺ at 22°C.
- Dissociation constant determined by fluorescence measurements in 100 mM KCl, 10 mM MOPS, pH 7.2, 0 to 39 μM free Ca²⁺ at 22°C.
- K_d(Ca²⁺) for fura-2 and indo-1 from the original reference by Grynkiewicz, Poenie and Tsien (J Biol Chem (1985) 260:3440) are 224 nM and 250 nM, respectively, measured in 1 mM EGTA, 100 mM KCl, 1 mM free Mg²⁺, 10 mM MOPS, pH 7.0 at 37°C. For bis-fura-2, K_d(Ca²⁺) in presence of Mg²⁺ is 525 nM (determined in our laboratories using 100 mM KCl, 10 mM MOPS, pH 7.2, 1 mM Mg²⁺ at 22°C).
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- The emission spectrum of Ca²⁺-bound mag-indo-1 excited at 340 nm has approximately equal peak intensities at ~390 nm and ~480 nm. (Biochemistry (1991) 30:702)
- Dissociation constant determined in 100 mM KCl, 40 mM HEPES, pH 7.0 at 22°C. (Biochem Biophys Res Commun (1991) 177:184)
- K_d(Ca²⁺) for quin-2 was measured in 120 mM KCl, 20 mM NaCl, pH 7.05 at 37°C. Under the same conditions with addition of 1 mM Mg²⁺, K_d = 115 nM. (Methods Enzymol (1989) 172:230)

PRODUCT LIST 19.2 FLUORESCENT Ca²⁺ INDICATORS EXCITED WITH UV LIGHT

Cat. No.	Product	Quantity
B6810	bis-fura-2, hexapotassium salt *cell impermeant*	1 mg
B6791	BTC, AM *cell permeant*	100 μg
B6790	BTC, tetrapotassium salt *cell impermeant*	1 mg
F6774	Fura-2 Calcium Imaging Calibration Kit *zero to 10 mM CaEGTA, 50 μM fura-2 (11 x 1 mL)*	1 kit
F1225	fura-2, AM *1 mM solution in anhydrous DMSO* *cell permeant*	1 mL
F1201	fura-2, AM *cell permeant*	1 mg
F1221	fura-2, AM *cell permeant* *special packaging*	20 x 50 μg
F14185	fura-2, AM *FluoroPure™ grade* *special packaging*	20 x 50 μg
F1200	fura-2, pentapotassium salt *cell impermeant*	1 mg
F6799	fura-2, pentasodium salt *cell impermeant*	1 mg
F14175	fura-4F, AM *cell permeant* *special packaging*	10 x 50 μg
F14174	fura-4F, pentapotassium salt *cell impermeant*	500 μg
F14178	fura-6F, pentapotassium salt *cell impermeant*	500 μg
F14181	fura-FF, AM *cell permeant* *special packaging*	10 x 50 μg
F14180	fura-FF, pentapotassium salt *cell impermeant*	500 μg
I1226	indo-1, AM *1 mM solution in anhydrous DMSO* *cell permeant*	1 mL
I1203	indo-1, AM *cell permeant*	1 mg
I1223	indo-1, AM *cell permeant* *special packaging*	20 x 50 μg
I1202	indo-1, pentapotassium salt *cell impermeant*	1 mg
M1291	mag-fura-2, AM *cell permeant*	1 mg
M1292	mag-fura-2, AM *cell permeant* *special packaging*	20 x 50 μg
M1290	mag-fura-2, tetrapotassium salt *cell impermeant*	1 mg
M1295	mag-indo-1, AM *cell permeant* *special packaging*	20 x 50 μg
Q23918	quin-2, free acid *cell impermeant*	5 mg

19.3 Fluorescent Ca²⁺ Indicators Excited with Visible Light

Fluo-3, Fluo-4, Rhod-2 and Related Derivatives

Fluo-3

The Ca²⁺ indicator fluo-3 (Figure 19.3.1) was developed by Tsien and colleagues for use with visible-light excitation sources in flow cytometry and confocal laser-scanning microscopy.¹ More recently, imaging with fluo-3 and its derivatives has been extended to include two-photon excitation techniques^{2–5} (Figure 19.3.2) and total internal reflection fluorescence (TIRF) microscopy.⁶ Fluo-3 imaging has revealed the spatial dynamics of many elementary processes in Ca²⁺ signaling^{7–11} (Figure 19.3.3, Figure 19.3.4). Since about 1996, fluo-3 has also been extensively used in cell-based high-throughput screening assays for drug discovery.^{12,13} Fluo-3 is essentially nonfluorescent unless bound to Ca²⁺ and exhibits a quantum yield at saturating Ca²⁺ of ~0.14 (Figure 19.3.5) and a K_d for Ca²⁺ of 390 nM (measured at 22°C using our Calcium Calibration Buffer Kits). The intact acetoxy-methyl (AM) ester derivative of fluo-3 is almost nonfluorescent, unlike the AM esters of fura-2 and indo-1. The green-fluorescent emission (~525 nm) of Ca²⁺-bound fluo-3 is conventionally detected using optical filter sets designed for fluorescein (FITC).

In a careful study of the spectral properties of highly purified fluo-3, Harkins, Kurebayashi and Baylor characterized the effects of pH and viscosity on Ca²⁺ measurements with fluo-3 and demonstrated that binding of the indicator to proteins has a significant effect on its K_d for Ca²⁺¹⁴ (Table 19.2). The temperature dependence of the K_d for fluo-3 has also been reported.¹⁵ In addition, the fluorescence output of fluo-3—the product of the molar absorptivity and the fluorescence quantum yield—may also vary significantly in different cellular environments.^{16,17}

Fluo-3 exhibits an at least 100-fold Ca²⁺-dependent fluorescence enhancement.^{4,14} However, fluo-3 lacks a significant shift in emission or excitation wavelength upon binding to Ca²⁺, which precludes the use of ratiometric measurements (Figure 19.3.6). Simultaneous loading of cells with fluo-3 and our Fura Red™ indicator, which exhibit reciprocal shifts in fluorescence intensity upon binding Ca²⁺, has enabled researchers to make ratiometric measurements of intracellular Ca²⁺ (Figure 19.3.7) using confocal laser-scanning microscopy^{18,19} (Figure 19.3.8) or flow cytometry.^{20–22} For ratiometric measurements, fluo-3 (or fluo-4) can also be co-loaded into cells with a spectrally distinct Ca²⁺-insensitive dye, such as CellTracker™ Orange CMRA²³ (C34551, Section 14.2) or CellTrace™ calcein red-orange AM²⁴ (C34851, Section 15.2). It is common practice when loading neurons in brain slices via patch pipette infusion with green-fluorescent calcium indicators, such as fluo-3, fluo-4, fluo-5F and Oregon Green® 488 BAPTA-1, to add in a Ca²⁺-insensitive structural marker such as Alexa Fluor® 594 hydrazide (A10438, A10442; Section 14.3).^{25–27}

Fluo-3 is available as a cell-impermeant potassium salt (F3715) or ammonium salt (F1240). The cell-permeant fluo-3 AM is available as a 1 mg vial (F1241), as a set of 20 vials each containing 50 µg (F1242), as a set of 10 vials each containing 50 µg of our high-purity grade fluo-3 AM (F23915) and as a 1 mM solution in DMSO (F14218). A set of 40 vials, each containing 1 mg of fluo-3 AM (F14242), is available at a discounted price to provide a larger quantity for high-throughput screening applications.

Indicator	K _d (Ca ²⁺)	R ^{2'}	R ^{7'}	R ⁵	R ⁶
Fluo-3	0.39 M	Cl	Cl	CH ₃	H
Fluo-4	0.35 M	F	F	CH ₃	H
Fluo-5F	2.3 M	F	F	F	H
Fluo-5N	90 M	F	F	NO ₂	H
Fluo-4FF	9.7 M	F	F	F	F

Figure 19.3.1 Fluo indicators.

Figure 19.3.3 Fluo-3 (F1240) confocal image of a spiral Ca²⁺ wave initiated by injection of a nonhydrolyzable analog of inositol 1,4,5-triphosphate in a *Xenopus laevis* oocyte. The image was contributed by David Clapham, Harvard University, and reproduced with permission from Cell (1992) 69:283.

Figure 19.3.4 Spontaneous intracellular Ca²⁺ fluctuations of neurons developing *in vivo*. The spinal cord was dissected from a neurula-stage *Xenopus* embryo and loaded with fluo-3 AM (F1241, F1242, F14218, F14242, F23915). Regions of fluo-3 fluorescence on the ventral side of the spinal cord are pseudocolored in gold and indicate areas of highest intracellular Ca²⁺ (Nature (1995) 375:784). The image was obtained with a Bio-Rad® MRC600 confocal laser-scanning microscope. The image was contributed by Nicholas C. Spitzer, University of California, San Diego.

Figure 19.3.2 Two-photon excitation imaging of Ca²⁺ influx in a CA1 pyramidal cell spine. The images are overlays of anatomical images generated by Alexa Fluor® 594 hydrazide (A10438, A10442) and Ca²⁺ signals generated by fluo-5F (F14221). The imaging system uses two-photon excitation at 810 nm and two-channel emission detection (fluo-5F in the green channel, Alexa Fluor® 594 hydrazide in the red channel). The observed Ca²⁺ influx is through NMDA receptors that are activated by glutamate released from the presynaptic terminal following electrode stimulation of a collateral CA3 pyramidal cell axon. The brief (0.2 ms) depolarizing stimulus was applied after the first frame in the image sequence. The frame rate is four frames/second, and each frame represents an area of 5 µm × 5 µm. The image was contributed by Thomas Oertner and Karel Svoboda, Cold Spring Harbor Laboratory.

Fluo-4

Fluo-4 (Figure 19.3.9), an analog of fluo-3 with the two chlorine substituents replaced by fluorine atoms (Figure 19.3.1), exhibits a K_d for Ca²⁺ of 345 nM^{28–30} (measured at 22°C using our Calcium Calibration Buffer Kits); the temperature dependence of the K_d for fluo-4 has been reported.¹⁵ The fluorescence quantum yields of Ca²⁺-bound fluo-3 and fluo-4 are essentially identical. Significantly, however, the absorption maximum of fluo-4 is blue-shifted about 12 nm as compared with fluo-3, resulting in increased fluorescence excitation at 488 nm and consequently higher signal levels for confocal laser-scanning microscopy (Figure 19.3.10), flow cytometry and microplate screening applications (Figure 19.3.11, Figure 19.3.12).

Figure 19.3.5 Comparison of fluorescence intensity responses to Ca²⁺ for the fluo-3 (F1240, F3715) and Calcium Green™-1 (C3010MP) indicators. Responses were calculated from the Ca²⁺ dissociation constants for the two indicators and the extinction coefficients and fluorescence quantum yields of their ion-free and ion-bound forms. They, therefore, represent the relative fluorescence intensities that would be obtained from equal concentrations of the two indicators excited and detected at their peak wavelengths.

Figure 19.3.7 Fluorescence emission spectra of a 1:10 mole:mole mixture of the fluo-3 (F1240, F3715) and Fura Red™ (F14219) indicators, simultaneously excited at 488 nm, in solutions containing 0–39.8 μM free Ca²⁺.

Figure 19.3.9 Pseudocolored images of changes in intracellular free Ca²⁺ in AtT-20/D16v-F2 cells, monitored at 9-second intervals with fluo-4, AM (F14201, F14202, F14217, F23917). In order to induce an influx of Ca²⁺, the cells were depolarized with 50 mM KCl in frame 2 and exposed to 5 μM ionomycin (I24222, a Ca²⁺ ionophore) in frame 8. The images are pseudocolored according to fluorescence intensity, with red representing high Ca²⁺ concentrations and blue representing low Ca²⁺ concentrations. The images were acquired using a fluorescence microscope equipped with a longpass filter set appropriate for fluorescein and a Photometrics® Quantix cooled CCD camera.

Figure 19.3.6 Ca²⁺-dependent fluorescence emission spectra of fluo-3 (F1240, F3715). The spectrum for the Ca²⁺-free solution is indistinguishable from the baseline.

Figure 19.3.8 Frog olfactory bulb neurons labeled with fluo-3 (F1240, F3715) and Fura Red™ (F14219) Ca²⁺ indicators, demonstrating a Ca²⁺ response to treatment with KCl and nifedipine. (*J Physiol* (1995) 487:305). The image is a ratio of fluo-3 and Fura Red™ fluorescence images acquired with a Leica confocal laser-scanning microscope. The image was contributed by J. Bischofberger and D. Schild, Physiology Institute, University of Göttingen.

Figure 19.3.10 Fast confocal recording of spontaneous Ca²⁺ sparks in a rat ventricular myocyte. Single myocytes were isolated from rat hearts and loaded with fluo-4 AM (F14201, F14202, F14217, F23917). Images of loaded cells were obtained with a PerkinElmer® UltraVIEW™ LCI confocal imaging system at a constant frame rate of 66 frames/second. A illustrates the outline of a single cell and the position of the four regions of interest that were averaged to produce the kinetic traces shown in B. The traces are color coded in accordance with the regions marked in A and show numerous spontaneous Ca²⁺ sparks. C illustrates a sequence of confocal images taken around the black region in A, indicating the spatiotemporal properties of an individual Ca²⁺ spark. The image was contributed by Peter Lipp, The Babraham Institute, Cambridge, UK, and reproduced with permission from Biomedical Products (2001) 9:52.

Figure 19.3.11 Fluorescence emission spectra at equal concentrations of fluo-4 (blue, F14200) and fluo-3 (red; F1240, F3715) in solutions containing 0–39.8 μM free Ca²⁺.

Figure 19.3.12 High-throughput Ca²⁺ influx assays for G-protein-coupled receptor activation. CHO (DHFR-) cells, co-transfected with the orphanin FQ receptor and G_{αq3} chimeric G-protein, were loaded with 4 μM fluo-3 AM (F1241, F1242, F14218, F14242, F23915) or fluo-4 AM (F14201, F14202, F14217, F23917) for 60 minutes at 37°C. Ca²⁺-dependent fluorescence traces (1 data point/second, excitation at 488 nm) from loaded cell samples in a 96-well microplate were measured simultaneously by a Fluorometric Imaging Plate Reader (FLIPR®). Ca²⁺ transients were initiated by addition of 25 nM orphanin FQ (nociceptin), as indicated by the baseline discontinuities at approximately 10 seconds. Each trace represents the average of five transient recordings from separate microplate wells. The data were supplied by Sven Merten, Hans-Peter Nothacker and Olivier Civelli, University of California, Irvine.

Figure 19.3.13 Rhod indicators with varying Ca²⁺ affinities.

Intracellular Ca²⁺ measurements using fluo-3 and fluo-4 have become essential for certain types of high-throughput pharmacological screening.^{12,13} Applications of this technology include screening for compounds that activate or deactivate G-protein-coupled receptors and identifying receptors for ligands known to be pharmacologically active. Molecular Devices FLIPR® (Fluorometric Imaging Plate Reader) systems have been the leading instrument platforms for these measurements (Figure 19.3.12). Parallel comparisons of fluo-4 with fluo-3, carried out in collaboration with researchers at Molecular Devices, show that the advantages of fluo-4 in microscopy and solution fluorometry measurements are replicated in the FLIPR® system. For example, fluo-4 generates the same fluorescence response as fluo-3 to carbachol-stimulated Ca²⁺ activation in Chinese hamster ovary (CHO) cells using half the AM ester-loading concentration and half the incubation time (Table 19.3). When fluo-4 is substituted for fluo-3 (i.e., using identical loading protocols), fluorescence signals are at least doubled. The stronger fluorescence signals provided by fluo-4 are particularly advantageous in cell types such as human embryonic kidney (HEK 293) cells, which are seeded at low densities for pharmacological screening assays.

Fluo-4 is available as a cell-impermeant potassium salt (F14200) or as its cell-permeant AM ester. The AM ester is available specially packaged as a 1 mM solution in DMSO (F14217), as a set of 10 vials, each containing 50 μg (F14201, F23917) or—for high-throughput screening applications—as a set of five vials, each containing 1 mg (F14202). We also offer both low-affinity and high-affinity 10,000 MW dextran conjugates of the fluo-4 indicator.³¹ (F14240, F36250; Section 19.4).

We also offer the Fluo-4 Direct™ Calcium Assay Kits (F10471, F10472, F10473) which offer a proprietary assay formulation that allows direct addition to wells containing cells growing in culture media without the requirement of media removal or a wash step. Eliminating the media removal step from the workflow can result in lower variability and higher Z' values³² compared with the standard fluo-4 assay, while also providing an easier and faster assay. Contributions to baseline fluorescence by the growth medium are eliminated by the addition of a suppression dye, which reduces background fluorescence. Another source of background fluorescence is extrusion of the indicator out of the cell by organic anion transporters. To address this background issue, the Fluo-4 Direct™ Calcium Assay Kits provide a proprietary, water-soluble probenecid, which inhibits this transport and reduces the baseline signal.^{33,34} The water-soluble form of probenecid

Table 19.3 Parallel performance comparison of fluo-3 and fluo-4 on the Molecular Devices FLIPR® system.

Indicator	μM *	Time (min) *	Fluorescence †		
			Basal	Stimulated ‡	Increase §
Fluo-3	4	60	1700	5700	3.4-fold
Fluo-4	4	60	4900	21300	4.3-fold
Fluo-4	2	30	1200	5400	4.5-fold

* CHO cells stably transfected with rat muscarinic M₁ receptors were loaded with fluo-3 AM or fluo-4 AM according to standard protocols, with variations in indicator concentration (μM) and incubation time, as shown. † Relative fluorescence intensities after subtraction of background fluorescence. ‡ Cells were stimulated by addition of the muscarinic agonist carbachol (50 μM). § Ratio of stimulated to basal fluorescence intensities.

Figure 19.3.14 Pseudocolored micrograph of a single living smooth muscle cell labeled with a reduced form of rhod-2 AM (R1244, R1245MP), dihydrorhod-2. Images were acquired at focal planes spaced at 0.25 μm intervals and then processed using a constrained iterative deconvolution algorithm. This image shows that the rhod-2 fluorescence primarily arises from the mitochondria. The image was contributed by Fredric S. Fay, Program in Molecular Medicine, University of Massachusetts Medical Center.

is easy to dissolve in physiological buffers, unlike the conventionally used free acid form, which must be initially dissolved in strong base.

Each Fluo-4 Direct™ Calcium Assay Kit provides:

- Fluo-4 calcium assay reagent
- Water-soluble probenecid
- Fluo-4 Direct™ calcium assay buffer (only provided with the Starter pack F10471 and the Surveyor pack F10472)
- Detailed protocols

Sufficient material is supplied for 20 × 96- or 384-well plates (F10471, F10472) or 200 × 96- or 384-well plates (F10473). The Fluo-4 Direct™ Calcium Assay Kits are designed for microplates and high-throughput screening (HTS), and the assay can be performed on adherent as well as nonadherent cells. Water-soluble probenecid is also available separately (P36400, Section 19.8).

The Fluo-4 NW Calcium Assay Kits (F36205, F36206) offer a proprietary assay formulation that requires neither a wash step nor a quencher dye. The fluo-4 NW indicator is nonfluorescent and stable in pH 7–7.5 buffer for several hours, so spontaneous conversion to the Ca²⁺-sensitive form is not a significant source of background fluorescence. Contributions to baseline fluorescence by the growth medium (e.g., esterase activity, proteins interacting with receptors of interest, or phenol red) are eliminated by removing the medium prior to adding the indicator dye to the wells. A water-soluble form of probenecid is provided to inhibit extrusion of the indicator out of the cell by organic anion transporters.^{33,34}

Each Fluo-4 NW Calcium Assay Kit provides:

- Fluo-4 NW dye mix
- Water-soluble probenecid
- Assay buffer (only provided in the Fluo-4 NW Calcium Assay Kit starter pack with buffer, F36206)
- Detailed protocols

The Fluo-4 NW Calcium Assay Kit starter pack with buffer (F36206) contains enough materials for 10 microplates and includes assay buffer; the Fluo-4 NW Calcium Assay Kit for high-throughput assays (F36205) contains enough materials for 100 microplates and does not include the assay buffer. These kits are designed for microplates and HTS, and the assay can be performed on adherent as well as nonadherent cells.

Rhod-2 and X-Rhod-1

The long-wavelength Ca²⁺ indicators rhod-2 (Figure 19.3.13, Figure 19.3.14) and X-rhod-1 are valuable for measuring Ca²⁺ in cells and tissues that have high levels of autofluorescence^{35,36} and also for detecting Ca²⁺ release generated by photoreceptors and photoactivatable chelators.^{37,38} Our chemists have optimized the purification of rhod-2, yielding a highly purified preparation that shows greater than 100-fold enhancement in fluorescence upon binding Ca²⁺ (Figure 19.3.15). The K_d for Ca²⁺ of rhod-2 in the absence of Mg²⁺ has been determined to be 570 nM (measured at 22°C using our Calcium Calibration Buffer Kits), which is considerably lower than that cited in the original paper on rhod-2.¹ Rhod-2 is available as a cell-impermeant potassium salt (R14220) or as a cell-permeant AM ester in either a 1 mg vial (R1244) or specially packaged as a set of 20 vials, each containing 50 µg (R1245MP).

X-rhod-1 is a Ca²⁺ indicator with excitation/emission maxima of ~580/602 nm and a K_d for Ca²⁺ of 700 nM (measured at 22°C using our Calcium Calibration Buffer Kits). It has spectral characteristics that are similar to our Calcium Crimson™ indicator, but the fluorescence response of X-rhod-1 is much more sensitive to Ca²⁺ binding (Figure 19.3.16). The long-wavelength emission characteristics of X-rhod-1 allow simultaneous detection Ca²⁺ transients and Green Fluorescent Protein (GFP) with minimal crosstalk³⁹ (Using Organic Fluorescent Probes in Combination with GFP—Note 12.1). X-rhod-1 is available as a cell-permeant AM ester (X14210), specially packaged as a set of 10 vials, each containing 50 µg.

Figure 19.3.15 Fluorescence emission spectra of rhod-2 (R14220) in solutions containing 0–39.8 µM free Ca²⁺. The spectrum for the Ca²⁺-free solution is indistinguishable from the baseline.

Figure 19.3.16 Fluorescence emission spectra of the tripotassium salt of X-rhod-1 in solutions containing 0–39.8 µM free Ca²⁺.

Figure 19.3.17 Colocalization of fluorescent staining by rhod-2 AM (R1244, R1245MP; upper panel) and mitochondrion-selective MitoFluor™ Green stain (lower panel) in an adult rat cortical astrocyte. Cells were simultaneously loaded with rhod-2 AM (4.5 μM) and the MitoFluor™ Green stain (20 nM) for 30 minutes at 22°C. Confocal laser-scanning microscopy using 488 nm excitation and spectrally resolved detection, at 505–530 nm for MitoFluor™ Green stain and ≥585 nm for rhod-2, shows almost identical staining distribution. The images were contributed by Michael Duchen, University College, London. Reproduced with permission from *J Cell Biol* (1999) 145:795.

Figure 19.3.18 Ca²⁺-dependent fluorescence emission spectra of fluo-5N (F14203).

Rhod-3 Imaging Kit

As compared with other red-fluorescent calcium dyes such as rhod-2 AM, rhod-3 AM is an improved red-shifted calcium indicator that displays a more uniform cytosolic distribution and improved signal. The cationic nature of rhod-2 AM results in potential-driven, subcellular localization (Figure 19.3.17). Imaging studies with the rhod-3 AM, however, show minimal subcellular localization. In the presence of PowerLoad™ concentrate and probenecid, the cell-permeant, nonfluorescent rhod-3 AM can be passively loaded into the cells, where intracellular esterases cleave the dye to the cell-impermeant, active form that fluoresces upon Ca²⁺ binding. Rhod-3 exhibits a large increase (>2.5 fold) in fluorescence upon binding Ca²⁺ and very low fluorescence in the absence of Ca²⁺ binding. Rhod-3 has a K_d of 570 nM for Ca²⁺ (determined at 22°C in 30 mM MOPS, pH 7.2 with 100 mM KCl).

We offer the Rhod-3 Imaging Kit (R10145), which provides:

- Rhod-3 AM
- Dimethylsulfoxide (DMSO)
- PowerLoad™ concentrate
- Water-soluble probenecid
- Detailed protocols

Sufficient reagents are supplied for 10 assays using the protocol provided. PowerLoad™ concentrate, an optimized formulation of nonionic, Pluronic® surfactant polyols, aids the solubilization of rhod-3 AM dye in physiological media and is available separately (P10200, Section 19.8). Probenecid, also available separately (P36400, Section 19.8), inhibits organic anion pumps that actively extrude the de-esterified dye.^{33,34}

Lower-Affinity Calcium Indicators Based on Fluo-3 and Rhod-2

With Ca²⁺ dissociation constants well above 1 μM, our relatively low-affinity Ca²⁺ indicators can be used to detect intracellular Ca²⁺ levels in the micromolar range—levels that would saturate the response of fluo-3 and rhod-2. Such elevated Ca²⁺ levels are generated by mobilization of intracellular Ca²⁺ stores⁴⁰ and by excitatory stimulation of smooth muscle^{41,42} and neurons.^{43,44} Moreover, low-affinity indicators have faster ion dissociation rates, making them more suitable for tracking the kinetics of rapid Ca²⁺ fluxes than indicators with K_d values <1 μM.^{41,42}

Fluo-5F, Fluo-4FF, Fluo-5N and Mag-Fluo-4

Fluo-5F, fluo-4FF, fluo-5N and mag-fluo-4⁴⁵ are analogs of fluo-4 with much lower Ca²⁺-binding affinity, making them suitable for detecting intracellular Ca²⁺ levels in the 1 μM to 1 mM range. Fluo-5F, fluo-4FF, fluo-5N and mag-fluo-4 have K_d values for Ca²⁺ of ~2.3 μM, ~9.7 μM, ~90 μM and ~22 μM, respectively, as compared with fluo-4, which has a K_d for Ca²⁺ of ~345 nM (measured at 22°C using our Calcium Calibration Buffer Kits) (Figure 19.3.1). The temperature dependence of the K_d for fluo-5F has been reported.¹⁵ These low Ca²⁺-binding affinities are ideal for detecting high concentrations of Ca²⁺ in the endoplasmic reticulum^{46,47} and neurons (Figure 19.3.2), as well as for tracking Ca²⁺ flux kinetics.⁴⁵ Fluo-5N has been found to be particularly useful for monitoring calcium oscillations in the sarcoplasmic reticulum.^{46,48,49} Like fluo-4, these indicators are essentially nonfluorescent in the absence of divalent cations and exhibit strong fluorescence enhancement with no spectral shift upon binding Ca²⁺ (Figure 19.3.18). Because mag-fluo-4 is less Ca²⁺/Mg²⁺ selective than fluo-5N, it is also useful as an indicator for intracellular Mg²⁺ levels (Section 19.6). Fluo-5F (F14221, F14222), fluo-4FF (F23980, F23981), fluo-5N (F14203, F14204) and mag-fluo-4 (M14205, M14206) are available as cell-impermeant potassium salts or as cell-permeant AM esters. The AM esters are specially packaged as a set of 10 vials, each containing 50 μg.

Rhod-5N

Rhod-5N (Figure 19.3.13) has a lower binding affinity for Ca²⁺ than any other BAPTA-based indicator ($K_d = \sim 320 \mu\text{M}$, measured at 22°C using our Calcium Calibration Buffer Kits). These properties confer suitability for Ca²⁺ detection in environmental⁵⁰ and food⁵¹ testing applications. Like the parent rhod-2 indicator, rhod-5N is essentially nonfluorescent in the absence of divalent cations and exhibits strong fluorescence enhancement with no spectral shift upon binding Ca²⁺. Furthermore, rhod-5N has very little detectable response to Mg²⁺ concentrations up to at least 100 mM. Rhod-5N is available as a cell-impermeant potassium salt (R14207).

Rhod-FF and X-Rhod-5F

The fluorinated analogs of rhod-2—rhod-FF (Figure 19.3.13) and X-rhod-5F^{52,53}—have intermediate Ca²⁺ sensitivity relative to rhod-2 and rhod-5N. Their Ca²⁺ dissociation constants (K_d) are 19 μM and 1.6 μM , respectively (measured at 22°C using our Calcium Calibration Buffer Kits). X-rhod-5F is available as a water-soluble potassium salt (X23984), and rhod-FF and X-rhod-5F are available as cell-permeant AM esters (R23983, X23985). The AM esters are specially packaged as a set of 10 vials, each containing 50 μg .

Indicators of Mitochondrial Ca²⁺ Transients

Our AM esters of rhodamine-based indicators include:

- Rhod-2 (R1244, R1245MP)
- Rhod-FF (R23983)
- X-rhod-1 (X14210)
- X-rhod-5F (X23985)

These rhodamine derivatives form a set of cell-permeant Ca²⁺ indicators with a net positive charge. This property promotes their sequestration into mitochondria in some cells, most likely via membrane potential-driven uptake, and results in a staining pattern that is characteristic of mitochondria (Figure 19.3.14, Figure 19.3.17, Figure 19.3.19). Mitochondria have a high capacity for Ca²⁺ uptake and therefore require low-affinity Ca²⁺ indicators to accurately measure internal Ca²⁺ concentrations. Because the range of Ca²⁺ concentrations that can be detected using rhod-2 AM is limited to within about one order-of-magnitude above and below its Ca²⁺ dissociation constant ($K_d = 570 \text{ nM}$), we offer a selection of rhod-2 analogs with Ca²⁺ dissociation constants up to 320 μM (Table 19.1, Figure 19.3.13).

The extent of mitochondrial versus cytosolic localization is influenced by the temperature and incubation time used for AM ester loading.^{54–57} By reducing rhod-2 AM to the colorless, nonfluorescent dihydrorhod-2 AM, the discrimination between cytosolic and mitochondrially localized dye can be further improved.^{58–61} The AM ester of dihydrorhod-2 exhibits Ca²⁺-dependent fluorescence only after it is oxidized and its AM esters are cleaved to yield the rhod-2 indicator, processes that occur rapidly in the mitochondrial environment.⁶² A detailed protocol for reducing rhod-2 AM to generate dihydrorhod-2 AM is available. The procedure should also be suitable for reduction of the AM esters of the other rhod indicators. Co-loading of cells with rhod-2 AM or X-rhod-1 AM in combination with green-fluorescent Ca²⁺ indicators such as fura-2, fluo-3, fluo-4, Calcium Green™-1 and Oregon Green® 488 BAPTA-1 enables simultaneous two-color imaging of mitochondrial and cytoplasmic Ca²⁺ (Figure 19.3.20). Mitochondrial Ca²⁺ and mitochondrial NADH can be simultaneously measured using rhod-2 and intrinsic NADH fluorescence, respectively.⁶⁷

Figure 19.3.19 A live bovine pulmonary artery endothelial cell stained with 500 nM X-rhod-1 AM (X14210) for 30 minutes at 30°C. The image was deconvolved using Huygens software (Scientific Volume Imaging, www.svi.nl).

Figure 19.3.20 Simultaneous measurement of intracellular and mitochondrial Ca²⁺ in pulmonary artery smooth muscle cells. Cells were loaded with 2 μM rhod-2 AM (R1244, R1245MP) for 60 minutes at 22°C and were subsequently patch-clamped for electrophysiological measurements. Fura-2 (50 μM ; F1200, F6799) was loaded by infusion from the patch pipette; at the same time, residual cytosolic rhod-2 was dialyzed out. Fluorescence excitation was rapidly alternated between 340 nm and 380 nm (for fura-2) and 500 nm (for rhod-2). The Ca²⁺ transient was detected following application of 100 μM ATP for 10 seconds. The observed increases in mitochondrial Ca²⁺ may provide a feedback mechanism for matching ATP supply and demand by activating Ca²⁺-dependent dehydrogenases in the ATP synthesis pathway. This figure was reproduced with permission from J Physiol (1999) 516:139.

Calcium Green™, Calcium Orange™ and Calcium Crimson™ Indicators

Calcium Green™-1 and Calcium Green™-2 Indicators

Molecular Probes® Calcium Green™-1 (Figure 19.3.21, Figure 19.3.22) and Calcium Green™-2 (Figure 19.3.23) indicators, as well as Calcium Orange™ and Calcium Crimson™ indicators (described below), are visible light-excitable indicators developed in our laboratories. Like fluo-3 and fluo-4, the Calcium Green™ indicators exhibit an increase in fluorescence emission intensity upon binding Ca²⁺ with little shift in wavelength^{68,69} (Figure 19.3.24, Figure 19.3.25); the fluorescence spectra of the Calcium Green™ indicators are almost identical to those of fluo-3. Further comparison of the Calcium Green™ indicators and fluo-3 reveals that, at high Ca²⁺ levels, Calcium Green™-1 and Calcium Green™-2 are several times brighter than fluo-3 (Figure 19.3.5). Calcium Green™-1 has a quantum yield of 0.75 at saturating Ca²⁺ concentrations,⁷⁰ as compared with about 0.14 for fluo-3.¹

The Calcium Green™ indicators have several other important features:

- Calcium Green™-1 is more fluorescent in resting cells than is fluo-3 (Figure 19.3.5), which increases the visibility of unstimulated cells, facilitates the determination of baseline fluorescence and makes calculations of intracellular Ca²⁺ concentrations more reliable.
- Calcium Green™-1 has been a preferred indicator for multiphoton excitation imaging of Ca²⁺ in living tissues.^{4,71-73}
- Calcium Green™-1 is useful for measuring intracellular Ca²⁺ by fluorescence lifetime imaging (FLIM).⁷⁴
- The Ca²⁺ affinity of Calcium Green™-1 in the absence of Mg²⁺ (K_d for Ca²⁺ = 190 nM) is higher than that of fluo-3 (K_d for Ca²⁺ = 390 nM) or Calcium Green™-2 (K_d for Ca²⁺ = 550 nM, measured at 22°C using our Calcium Calibration Buffer Kits).
- Like fluo-3 and fluo-4, Calcium Green™-2 is essentially nonfluorescent in the absence of Ca²⁺ and exhibits an approximately 100-fold increase in emission intensity upon Ca²⁺ binding, which leads to a very large dynamic range.
- Like fluo-3 AM and fluo-4 AM, the AM esters of the Calcium Green™ indicators are nonfluorescent.

Furthermore, the Calcium Green™ indicators are less phototoxic to cells than fluo-3.^{75,76} This observation stems at least in part from the fact that the Calcium Green™ indicators are intrinsically more fluorescent than fluo-3, thus requiring lower illumination intensities and lower dye concentrations to achieve the same signal⁷⁷ (Figure 19.3.5).

Simultaneous loading of Calcium Green™-2 and carboxy SNARE®-1 AM, acetate (C1271, C1272; Section 20.2) enabled researchers to make ratiometric

Figure 19.3.24 Ca²⁺-dependent fluorescence emission spectra of the Calcium Green™-1 indicator (C3010MP).

measurements of intracellular Ca²⁺ in cardiac myocytes.⁷⁷ A variation on this approach has been reported by Oheim and co-workers in which Calcium Green™-1 and a Ca²⁺-insensitive reference dye similar to lucifer yellow CH (L453, L12926; Section 14.3) were loaded into bovine adrenal chromaffin cells by whole-cell patch clamping.⁷⁸ Ratio images were obtained using 420/488 nm dual excitation (emission >515 nm) and exhibited superior signal-to-noise characteristics, as compared with conventional UV-excited fura-2 images. This technique should be equally applicable to other 488 nm-excited Ca²⁺ indicators such as fluo-3, fluo-4, fluo-5N and the Oregon Green® 488 BAPTA series. Calcium Green™-1 and Calcium Green™-2 are available as cell-impermeant potassium salts (C3010MP, C3730) or as cell-permeant AM esters (C3011MP, C3012, C3732).

Calcium Orange™ and Calcium Crimson™ Indicators

Like the Calcium Green™ indicators, Calcium Orange™ (C3013, Figure 19.3.26) and Calcium Crimson™ exhibit an increase in fluorescence emission intensity upon binding to Ca²⁺ with little shift in wavelength (Figure 19.3.27, Figure 19.3.28) and can be loaded into cells as their AM esters (C3015, C3018). Both the Calcium Orange™ and Calcium Crimson™ indicators are more photostable than either fluo-3 or the Calcium Green™ indicators.¹⁶

Calcium Orange™ has an excitation maximum near 550 nm and is compatible with standard tetramethylrhodamine optical filters. Calcium Orange™ has been used to monitor Ca²⁺ in intact photoreceptors containing a genetically altered rhodopsin pigment,³⁸ as well as to follow Ca²⁺ influx and release in hippocampal astrocytes.⁷⁹

The excitation maximum (~590 nm) of Calcium Crimson™ makes it useful in situations where interference by cellular autofluorescence is problematic.⁸⁰ Selective uptake of Calcium Crimson™ AM (C3018) at *Drosophila* motor nerve terminals has been used to obtain images of stimulus-dependent Ca²⁺ influx.^{81,82}

Calcium Green™-5N and Magnesium Green™: Low-Affinity Ca²⁺ Indicators

The Ca²⁺ indicators Calcium Green™-5N (Figure 19.3.21) and Magnesium Green™ (Figure 19.3.29) have dissociation constants for Ca²⁺ in the absence of Mg²⁺ of ~14 μM and ~6 μM, respectively (measured at 22°C using our Calcium Calibration Buffer Kits) (Figure 19.3.30). These low-affinity Ca²⁺ indicators exhibit relatively little fluorescence, except in cells in which high-amplitude Ca²⁺ influx or release is occurring.^{83,84} Calcium Green™-5N and Magnesium Green™ buffer intracellular Ca²⁺ to a lesser extent than do the higher-affinity Ca²⁺ indicators. Furthermore, the high Ca²⁺ dissociation rates of these indicators are advantageous for tracking rapid Ca²⁺-release kinetics.^{85,86} Use of the low-affinity Ca²⁺ indicator Calcium Green™-5N in combination with the higher-affinity indicator Calcium Green™-2 in the same experimental protocol can give an indication of the absolute magnitude of Ca²⁺ spikes.⁸⁷ Furthermore, coinjection of Ca²⁺-sensitive Calcium Green™-5N and Ca²⁺-insensitive 8-aminonaphthalene-1,3,6-trisulfonic acid (ANTS, A350; Section 14.3) into *Limulus* ventral nerve photoreceptors permitted ratiometric measurement of Ca²⁺ flux.⁸⁸

Calcium Green™-5N is available as a cell-impermeant potassium salt (C3737) or as a cell-permeant AM ester (C3739). Magnesium Green™, which is also discussed in Section 19.6 with the other Mg²⁺ indicators, is available as a cell-impermeant potassium salt (M3733) or as a cell-permeant AM ester (M3735).

Oregon Green® 488 BAPTA Indicators

Oregon Green® 488 BAPTA indicators are based on our exceptionally bright Oregon Green® 488 dyes (Section 1.5). The absorptivity of Oregon Green® 488 BAPTA-1 (Figure 19.3.21) at 488 nm is ~93% of its peak value, whereas the absorptivity of fluo-3 and the Calcium Green™ indicators at 488 nm is only ~45% of their maxima. Consequently, the Oregon Green® 488 BAPTA indicators are more efficiently excited by the 488 nm spectral line of the argon-ion laser than are the fluo-3 and Calcium Green™ indicators.

Oregon Green® 488 BAPTA-1 and Oregon Green® 488 BAPTA-2

The spectral properties of the Oregon Green® 488 BAPTA indicators permit the use of lower dye concentrations when using argon-ion laser excitation sources, making the Oregon Green® 488 BAPTA indicators well suited for intracellular Ca²⁺ measurements by confocal laser-scanning microscopy.^{89,90} Oregon Green® 488 BAPTA-1 is also recommended for fluorescence lifetime imaging⁹¹ (FLIM) and applications involving photoactivatable ("caged") probes^{92,93} (Figure 19.3.31).

Furthermore, the quantum yields of the Ca²⁺ complexes of Oregon Green® 488 BAPTA-1 and Calcium Green™-1 are ~0.7, as compared with only ~0.14 for fluo-3. As with Calcium Green™-1 (Figure 19.3.5), Oregon Green® 488 BAPTA-1 is moderately fluorescent in Ca²⁺-free solution, and its fluorescence is enhanced about 14-fold at saturating Ca²⁺ (Figure 19.3.32). In some cases, it may be advantageous to mix Oregon Green® 488 BAPTA-1 and fluo-4 indicators to obtain a calcium response that combines a finite basal signal level with a large stimulus-dependent increase.⁹⁴ Oregon Green® 488 BAPTA-1 has a K_d for Ca²⁺ in the absence of Mg²⁺ of about 170 nM. Oregon Green® 488 BAPTA-2 is similar to Calcium Green™-2 in that it contains two dye molecules per BAPTA chelator (Figure 19.3.23) and exhibits very low fluorescence in the absence of Ca²⁺. The fluorescence of Oregon Green® 488 BAPTA-2 is enhanced at least 37-fold at saturating Ca²⁺, and it has a K_d for Ca²⁺ in the absence of Mg²⁺ of ~580 nM (Figure 19.3.33) (K_d values for Ca²⁺ are determined at ~22°C using our Calcium Calibration Buffer Kits).

Several research groups are exploiting the power of two-photon laser-scanning microscopy and fluorescent Ca²⁺ indicators for functional imaging of neurons in brain slice preparations^{95,96} and intact live brains.^{8,97-99} Oregon Green® 488 BAPTA-1 and Calcium Green™-1, excited in the wavelength range 800–850 nm are the indicators of choice in many of these investigations.¹⁰⁰⁻¹⁰⁶ The Oregon Green® 488 BAPTA-2 Ca²⁺ indicator and red-fluorescent, Ca²⁺-insensitive sulforhodamine 101 reference dye (S359, Section 14.3) have been loaded together into optic nerves to image Ca²⁺ distribution in axons.⁹⁰

Oregon Green® 488 BAPTA-1 and Oregon Green® 488 BAPTA-2 are available as cell-impermeant potassium salts (O6806, O6808) or as cell-permeant AM esters (O6807, O6809), which are specially packaged as a set of 10 vials, each containing 50 µg. A 10,000 MW dextran conjugate of the Oregon Green® BAPTA-1 indicator (O6798) is described in Section 19.4.

Figure 19.3.32 Ca²⁺-dependent fluorescence emission spectra of the Oregon Green® 488 BAPTA-1 indicator (O6806).

Figure 19.3.33 Ca²⁺-dependent fluorescence emission spectra of the Oregon Green® 488 BAPTA-2 indicator (O6808).

Figure 19.3.31 Confocal linescan image of calcium "puffs" in a *Xenopus* oocyte. Oregon Green® 488 BAPTA-1 (O6806) was used as the calcium indicator and Ca²⁺ liberation was evoked by flash photolysis of NPE-caged Ins 1,4,5-P₃ (I23580). Image contributed by Ian Parker and Nick Callamaras, University of California at Irvine.

Oregon Green® 488 BAPTA-6F and Oregon Green® 488 BAPTA-5N

Oregon Green® 488 BAPTA-6F (Figure 19.3.21) and Oregon Green® 488 BAPTA-5N (Figure 19.3.21) are low-affinity Ca²⁺ indicators (K_d for Ca²⁺ ~3 μ M and ~20 μ M, respectively, measured at ~22°C using our Calcium Calibration Buffer Kits) designed for measuring intracellular Ca²⁺ levels above 1 μ M.^{107–110} By simultaneously imaging Oregon Green® 488 BAPTA-5N and rhod-2, researchers have been able to compare cytosolic and mitochondrial Ca²⁺ responses to action potentials in amphibian motor nerve terminals.^{61,111} Oregon Green® 488 BAPTA-6F and Oregon Green® BAPTA-5N are available as cell-impermeant potassium salts (O23990, O6812).

Figure 19.3.34 Fura Red™, tetrapotassium salt (F14219).

Fura Red™ Indicator

Fura Red™ indicator (Figure 19.3.34), a visible light–excitable fura-2 analog, offers unique possibilities for ratiometric measurement of Ca²⁺ in single cells by microphotometry, imaging or flow cytometry. The visible-wavelength excitation (450–500 nm) and very long-wavelength emission maximum (~660 nm) of the Fura Red™ indicator (Figure 19.3.35) minimize interference from autofluorescence and pigmentation in tissues and biological fluids.¹¹² Fluorescence of the Fura Red™ indicator excited at 488 nm *decreases* once the indicator binds Ca²⁺ (Figure 19.3.35). Even in the absence of Ca²⁺, fluorescence of the Fura Red™ indicator is much weaker than that of the other visible light–excitable Ca²⁺ indicators, necessitating use of higher concentrations of the indicator in cells to produce equivalent fluorescence. Fura Red™ indicator is available as either a cell-impermeant tetrapotassium salt (F14219) or as a cell-permeant AM ester (F3020, F3021).

Ratiometric measurements of intracellular Ca²⁺ levels with Fura Red™ indicator have been made using excitation wavelengths of 420 nm and 480 nm¹¹³ or 457 nm and 488 nm.¹¹⁴ A simultaneous assay for Ca²⁺ uptake and ATP hydrolysis by sarcoplasmic reticulum has been developed that uses the large *absorbance* change of Fura Red™ indicator upon Ca²⁺ binding.¹¹⁵ This assay can measure Ca²⁺ uptake—and probably uptake of heavy metal ions through channels—from the medium in real time without the use of radioactive Ca²⁺, making it generally useful for measuring Ca²⁺ uptake by cells. In several cell types, simultaneous labeling with Fura Red™ indicator and fluo-3 (Figure 19.3.7) has enabled researchers to use ratiometric measurements for estimating intracellular Ca²⁺ levels using confocal laser-scanning microscopy^{19,116–119} or flow cytometry.^{20,21}

Furthermore, the huge Stokes shift of Fura Red™ indicator permits multicolor analysis of Fura Red™ indicator fluorescence in combination with fluorescein or fluorescein-like dyes using only a single excitation wavelength (Figure 19.3.7). For example, researchers have been able to simultaneously measure Ca²⁺ fluxes and oxidative bursts in monocytes and granulocytes by simultaneously measuring the fluorescence of Fura Red™ indicator and rhodamine 123—the oxidation product of the probe dihydorhodamine 123¹²⁰ (D632, D23806; Section 18.2). Fura Red™ indicator has also been used in combination with blue-fluorescent protein in transfected cells.³⁹

Figure 19.3.36 Calcein (C481).

Calcein

Calcein (C481, Section 19.7) is a relatively low-affinity Ca²⁺ chelator. The dissociation constants for both the Ca²⁺ and Mg²⁺ complexes of calcein at physiological pH are about 10⁻³ to 10⁻⁴ M.¹²¹ As a derivative of iminodiacetic acid (Figure 19.3.36), this dye exhibits an ion affinity that increases considerably at higher pH, and thus it is not particularly useful for measuring Ca²⁺ or Mg²⁺ in cells. Instead, it is primarily useful for detecting mineralized Ca²⁺, particularly in the context of bone^{122–124} and bacterial spores. Calcein is also widely used for fluorescence quenching-based detection of Ni²⁺, Co²⁺, Cu²⁺ and Fe³⁺ (Section 19.7).

Notes

- Dissociation constants are known to vary considerably depending on the temperature, pH, ionic strength, viscosity, protein binding, presence of other ions (especially polyvalent ions), instrument setup and other factors. It is strongly recommended that these values be verified under user-specific experimental conditions.
- Spectra measured in aqueous buffers containing 10 mM EGTA (H₂O) or a >10-fold excess of free Ca²⁺ relative to the K_d (H₂O/Ca²⁺).
- Dissociation constant determined by fluorescence measurements in 100 mM KCl, 10 mM MOPS, pH 7.2, 0 to 39 μM free Ca²⁺ at 22°C.
- This indicator exhibits fluorescence enhancement in response to ion binding, with essentially no change in absorption or emission wavelengths.
- Dissociation constant determined by fluorescence measurements in 100 mM KCl, 10 mM MOPS, pH 7.2, 0 to 1 mM free Ca²⁺ at 22°C.
- Fluorescence of the free indicator is very weak and is enhanced >100-fold on binding Ca²⁺.
- Fluorescence of this AM ester derivative is very weak and is enhanced only after hydrolytic cleavage followed by binding of divalent cations to the anionic indicator.
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- The fluorescence quantum yield of Fura Red™ is low (~0.013 in Ca²⁺-free solution). (Methods Cell Biol (1994) 40:155)
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- Spectra measured in 90:10 (v/v) CHCl₃:MeOH.
- Dissociation constant determined by fluorescence measurements in 100 mM KCl, 10 mM MOPS, pH 7.2, 0 to 10 mM free Ca²⁺ at 22°C.

PRODUCT LIST 19.3 FLUORESCENT Ca²⁺ INDICATORS EXCITED WITH VISIBLE LIGHT

Cat. No.	Product	Quantity
C3018	Calcium Crimson™, AM *cell permeant* *special packaging*	10 x 50 μg
C3011MP	Calcium Green™-1, AM *cell permeant*	500 μg
C3012	Calcium Green™-1, AM *cell permeant* *special packaging*	10 x 50 μg
C3010MP	Calcium Green™-1, hexapotassium salt *cell impermeant*	500 μg
C3732	Calcium Green™-2, AM *cell permeant* *special packaging*	10 x 50 μg
C3730	Calcium Green™-2, octapotassium salt *cell impermeant*	500 μg
C3739	Calcium Green™-5N, AM *cell permeant* *special packaging*	10 x 50 μg
C3737	Calcium Green™-5N, hexapotassium salt *cell impermeant*	500 μg
C3015	Calcium Orange™, AM *cell permeant* *special packaging*	10 x 50 μg
C3013	Calcium Orange™, tetrapotassium salt *cell impermeant*	500 μg
F14218	fluo-3, AM *1 mM solution in DMSO* *cell permeant*	1 mL
F1241	fluo-3, AM *cell permeant*	1 mg
F1242	fluo-3, AM *cell permeant* *special packaging*	20 x 50 μg
F23915	fluo-3, AM *FluoroPure™ grade* *special packaging*	10 x 50 μg
F14242	fluo-3, AM *packaged for high-throughput screening*	40 x 1 mg
F1240	fluo-3, pentaammonium salt *cell impermeant*	1 mg
F3715	fluo-3, pentapotassium salt *cell impermeant*	1 mg
F10473	Fluo-4 Direct™ Calcium Assay Kit, High-Throughput Pack	1 kit
F10471	Fluo-4 Direct™ Calcium Assay Kit, Starter Pack	1 kit
F10472	Fluo-4 Direct™ Calcium Assay Kit, Surveyor Pack	1 kit
F36205	Fluo-4 NW Calcium Assay Kit (high-throughput) *for 100 microplates*	1 kit

X23984	X-rhod-5F, tripotassium salt *cell impermeant*	500 µg

19.4 Fluorescent Ca²⁺ Indicator Conjugates

When ion indicators are loaded into cells as their acetoxymethyl (AM) esters, they may translocate to intracellular compartments, where they are still fluorescent but no longer respond to changes in cytosolic ion levels.^{1,2} This problem frequently limits the experiment's duration because sequestration of the indicator into organelles will cause errors in the estimated cytosolic ion levels. Furthermore, Ca²⁺ indicators such as fura-2 and indo-1 may bind to cellular proteins,¹⁻⁵ which can markedly alter the indicator's response to Ca²⁺ (Table 19.2).

To overcome these limitations, we have prepared dextran conjugates of some Molecular Probes® ion indicators⁶ (Table 19.1). Dextran is a hydrophilic polysaccharide characterized by their moderate to high molecular weight, good water solubility and low toxicity. They are also biologically inert due to their uncommon poly-(α -D-1,6-glucose) linkages, which render them resistant to cleavage by most endogenous cellular glycosidases. Indicator dextrans must be loaded into cells by

microinjection, whole-cell patch clamping, microprojectile bombardment⁷⁻⁹ or electroporation,^{10,11} or by using our Influx™ pinocytic cell-loading reagent (I14402, Section 19.8; Figure 19.4.1). Calcium indicator dextrans are actively transported in adult nerve fibers over a significant distance and are retained in presynaptic terminals in a form that allows monitoring of presynaptic Ca²⁺ levels.^{12,13} Dextran conjugates above ~2000 MW are well retained in viable cells, will not readily pass through gap junctions¹³ and are less likely to become compartmentalized.^{14,15} Also, fluorescence photobleaching measurements have shown that, as compared with low molecular weight dyes, dextran conjugates are much less likely to bind to proteins.¹⁶ Because dextran conjugates are intrinsically polydisperse and their degree of substitution may vary with the production lot, the Ca²⁺ dissociation constant of each lot of these indicators should be calibrated independently using one of our Calcium Calibration Buffer Kits (Section 19.8).

Fura Dextran

Fura dextran (F3029) tends to remain in the cytosol without compartmentalization or leakage and is less likely to bind to cellular proteins, making it useful for long-term Ca²⁺ measurements.¹⁷ Although the spectral response curves of fura dextran are very similar to those of the free dye, its affinity for Ca²⁺ is somewhat weaker. The dissociation constant for Ca²⁺ of fura dextran in the absence of Mg²⁺ varies between 200 nM and 400 nM (measured at ~22°C using our Calcium Calibration Buffer Kits), depending on the molecular weight of the dextran and individual batch characteristics.

Dye compartmentalization has been especially problematic for measurements of ions in plant cells, where the dye is frequently transported out of the cytosol in minutes. Unlike microinjected fura-2 salt, fura dextran is retained for hours in the cytosol of stamen hair cells and *Lilium* pollen tubes¹⁸ (Figure 19.4.2). A comparison of the dextran conjugates of fura and Calcium Green™ with conventional indicators for imaging Ca²⁺ levels in plant and fungal cells has been published.¹⁹

Visible-Excitation Ca²⁺ Indicator Dextrans

We offer 3000 MW; 10,000 MW; and 70,000 MW dextran conjugates of the Calcium Green™-1 indicator (C6765, C3713, C3714), as well as the 10,000 MW dextran conjugate of the Oregon Green® 488 BAPTA-1 indicator (O6798). We have also developed both low-affinity and high-affinity 10,000 MW dextran conjugates of the fluo-4 indicator (F14240, F36250) and low-affinity and high-affinity 10,000 MW dextran conjugates of our rhod indicator⁶ (R34677, R34676). Table 19.1 provides a complete list of our Ca²⁺ indicator dextran conjugates.

A review by Read and co-workers compares the Calcium Green™-1 and fura dextrans with conventional indicators for imaging Ca²⁺ levels in plant and fungal cells.¹⁹ The Calcium Green™ dextran conjugates (and the other green-fluorescent Ca²⁺-indicating dextrans) can be co-injected with red-fluorescent Texas Red® dextrans (Section 14.5, Table 14.4) to permit ratiometric measurements of Ca²⁺ flux in cells that can be microinjected, including oocytes^{20,21} (Figure 19.4.3). Spectra

Figure 19.4.1 Adherent 3T3 fibroblasts labeled with 3000 MW Texas Red® dextran (D3329) and 70,000 MW Calcium Green™-1 dextran (C3714). Both dextrans were loaded into the fibroblasts using the Influx™ pinocytic cell-loading reagent (I14402). The images were acquired using a fluorescence microscope equipped with a cooled CCD camera and band-pass filter sets appropriate for either the Texas Red® dye (left image) or fluorescein (right image). The center image represents a composite of the cells labeled with both dextrans. The 3000 MW Texas Red® dextran is distributed throughout the cell, but the 70,000 MW Calcium Green™-1 dextran is excluded from the nucleus by the nuclear membrane.

Figure 19.4.2 Top panel: Pseudocolored image of a pollen tube of *Lilium longiflorum* injected with fura dextran (F3029). The cell continues elongating and clearly shows a Ca²⁺ gradient. Bottom panel: The same pollen tube after injection with dibromo BAPTA (D1211) remains healthy but is no longer elongating. The images were contributed by Debra Miller, Dale Callahan, David Gross and Peter Hepler, University of Massachusetts.

Figure 19.4.3 Rhizoid cells from the marine alga *Fucus serratus* were pressure-microinjected with Ca²⁺-sensitive 10,000 MW Calcium Green™-1 dextran (C3713) and Ca²⁺-insensitive 10,000 MW Texas Red® dextran (D1828). Patterns of Ca²⁺ elevation following hypoosmotic treatment in dividing cells were visualized by confocal ratio imaging of Calcium Green™-1 (excited at 488 nm) and Texas Red® (excited at 568 nm). Emission ratio values were pseudocolored to represent calcium concentrations according to the scale bar in the lower left-hand corner. **A**) Sequential ratio images during the onset of a hypoosmotically induced (100% seawater to 50% seawater) Ca²⁺ wave shows an initial elevation of Ca²⁺ in the rhizoid apex, which declines before the onset of Ca²⁺ elevation arising in the apical nucleus (n1) region. **B**) A variation in this pattern was evident in a minority of cells where Ca²⁺ elevations were observed to arise in the subapical nucleus (n2) simultaneously with the apical Ca²⁺ elevation. The image was contributed by Colin Brownlee, Marine Biological Association of the United Kingdom, Plymouth, UK, and reproduced with permission from Proc Natl Acad Sci U S A (2000) 97:1932.

Figure 19.4.4 Reticulospinal neurons in the hindbrain of a live zebrafish labeled with 10,000 MW Calcium Green™-1 dextran (C3713) and optically sectioned in a Bio-Rad® MRC 600 confocal laser-scanning microscope. Image contributed by D.M. O'Malley and J.R. Fetcho, SUNY at Stony Brook.

Figure 19.4.5 Confocal images taken at five-second intervals of a fertilization-induced calcium wave in a *Pisaster ochraceus* starfish oocyte that was microinjected with 10,000 MW Calcium Green™-1 dextran (C3713). The image was contributed by Stephen A. Stricker, University of New Mexico.

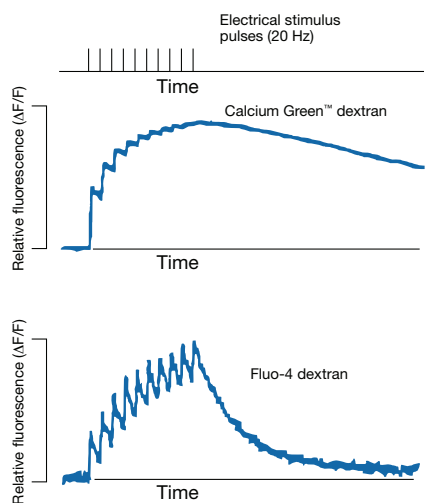

Figure 19.4.6 Ca²⁺ transients in rat climbing fiber pre-synaptic terminals evoked by sequences of 10 applied electrical stimulus pulses (20 Hz) monitored by 10,000 MW Calcium Green™-1 dextran (C3713) (upper panel) and the low-affinity version of fluo-4 dextran (F14240) (lower panel). Each trace represents an average of five recordings. Adapted with permission from Neuron (2000) 27:25.

of the Oregon Green® 488 BAPTA-1 dextrans and fluo-4 dextrans match the 488 nm spectral line of the argon-ion laser and standard fluorescein optical filters better than do dextran conjugates of the Calcium Green™-1 indicator, which should permit the use of lower probe concentrations to achieve the same signal. The red-orange-fluorescent rhod dextran, which exhibits a 50-fold fluorescence enhancement upon Ca²⁺ binding, is valuable for multicolor applications and for experiments in cells and tissues that have high levels of autofluorescence.

The visible light-excitabile Calcium Green™-1 and Oregon Green® 488 BAPTA-1 indicator dextrans have been used to:

- Assay Ca²⁺ influx in taste receptors responding to bitter stimuli²²
- Detect changes in Ca²⁺ levels during cell cleavage in mouse²³ and zebrafish²⁴ embryos
- Follow transmission of changes in cytosolic Ca²⁺ levels to the nucleus in permeabilized cardiomyocytes²⁵ and airway epithelial cells²⁶
- Label neurons via retrograde or anterograde transport, allowing real-time imaging of neuronal activity^{27,28} (Figure 19.4.4)
- Monitor presynaptic Ca²⁺ dynamics^{12,29}
- Perform functional imaging of neurons and myocytes during development^{30–32}
- Visualize cADP ribose-induced Ca²⁺ waves in starfish eggs³³ (Figure 19.4.5)
- Detect depletion of Ca²⁺ stores in organelles of yeast and mammalian cells³⁴
- Examine the regulation of size-specific entry of molecules into the *Xenopus* oocyte nucleus by the nuclear Ca²⁺ store³⁵
- Monitor changes in intracellular free Ca²⁺ accompanying photolysis of diazo-2, caged EGTA, caged EDTA or other caged Ca²⁺ probes³⁶
- Perform multiphoton excitation functional imaging of brain activity^{37,38}

In mammalian presynaptic terminals, the response of Calcium Green™-1 dextran to successive electrical stimuli progressively weakens due to Ca²⁺-binding saturation (Figure 19.4.6). To solve this problem, we have synthesized fluo-4 dextran (F14240) with a lower Ca²⁺ binding affinity (a batch-dependent K_d for Ca²⁺ ~3 μM). Developed in collaboration with Wade Regehr's laboratory at Harvard University, the low-affinity fluo-4 dextran is a valuable tool for recording Ca²⁺ transients in presynaptic terminals of long axonal projections in heterogeneous fiber tracts.^{29,39} We also offer a high-affinity fluo-4 dextran (K_d for Ca²⁺ ~600 nM, F36250) and high-affinity rhod dextran (K_d for Ca²⁺ ~780 nM, R34676). Coinjection of fluo-4 dextran together with a reference marker (e.g., 10,000 MW Texas Red® dextran, D1828; Section 14.5) may be necessary for initial identification of labeled cells due to the intrinsically weak fluorescence of the fluo-4 indicator in the absence of Ca²⁺.^{7,29}

The lack of a ratiometric Ca²⁺ response (Loading and Calibration of Intracellular Ion Indicators—Note 19.1) among the visible light-excitabile indicator dextrans can be partially circumvented by co-loading Ca²⁺-insensitive reference markers. Mixtures of Calcium Green™ dextran and Ca²⁺-insensitive dextrans (such as the tetramethylrhodamine or Texas Red® dextrans in Section 14.5) have been co-loaded into cells for use in ratio-imaging microscopy^{24,40–43} (Figure 19.4.3).

Notes

- Dissociation constants are known to vary considerably depending on the temperature, pH, ionic strength, viscosity, protein binding, presence of other ions (especially polyvalent ions), instrument setup and other factors. It is strongly recommended that these values be verified under user-specific experimental conditions.
- Spectra measured in aqueous buffers containing 10 mM EGTA (H₂O) or a >10-fold excess of free Ca²⁺ relative to the K_d (H₂O/Ca²⁺).
- Because indicator dextran conjugates are polydisperse both in molecular weight and degree of substitution, dissociation constants and spectra may vary between batches.
- Dissociation constant determined by fluorescence measurements in 100 mM KCl, 10 mM MOPS, pH 7.2, 0 to 39 μM free Ca²⁺ at 22°C.
- The molecular weight is nominally as specified in the product name but may have a broad distribution.
- This indicator exhibits fluorescence enhancement in response to ion binding, with essentially no change in absorption or emission wavelengths.
- ND = not determined.
- Dissociation constant determined by fluorescence measurements in 100 mM KCl, 10 mM MOPS, pH 7.2, 0 to 1 mM free Ca²⁺ at 22°C.
- Fluorescence of the free indicator is very weak and is enhanced >100-fold on binding Ca²⁺.

PRODUCT LIST 19.4 FLUORESCENT Ca²⁺ INDICATOR CONJUGATES

Cat. No.	Product	Quantity
C6765	Calcium Green™-1 dextran, potassium salt, 3000 MW, anionic	5 mg
C3713	Calcium Green™-1 dextran, potassium salt, 10,000 MW, anionic	5 mg
C3714	Calcium Green™-1 dextran, potassium salt, 70,000 MW, anionic	5 mg
F36250	fluo-4 dextran, potassium salt, 10,000 MW, anionic (high-affinity version)	5 mg
F14240	fluo-4 dextran, potassium salt, 10,000 MW, anionic (low-affinity version)	5 mg
F3029	fura dextran, potassium salt, 10,000 MW, anionic	5 mg
O6798	Oregon Green® 488 BAPTA-1 dextran, potassium salt, 10,000 MW, anionic	5 mg
R34676	rhod dextran, potassium salt, 10,000 MW, anionic (high-affinity version)	5 mg

19.5 Protein-Based Ca²⁺ Indicators

Premo™ Cameleon Calcium Sensor

Premo™ Cameleon Calcium Sensor (P36207, P36208) is a ratiometric calcium-sensitive fluorescent protein that is delivered by BacMam baculovirus-mediated transduction (BacMam Gene Delivery and Expression Technology—Note 11.1) to a variety of mammalian cell types (Figure 19.5.1). This content and delivery system provides an effective and robust technique for measuring Ca²⁺ mobilization in transduced cells using microplate assays or fluorescence microscopy.^{1–3}

The Premo™ Cameleon Calcium Sensor is based on the YC3.60 version of the fluorescent protein-based sensor (cameleon) family developed by Tsien, Miyawaki and co-workers,⁴ which is reported to have a Ca²⁺ dissociation constant of 250 nM.⁵ The sensor comprises two fluorescent proteins (enhanced cyan-fluorescent protein or ECFP and Venus variant of yellow-fluorescent protein or YFP), linked by the calmodulin-binding peptide M13 and calmodulin. Upon binding four calcium ions, calmodulin undergoes a conformational change by wrapping itself around the M13 peptide, which changes the efficiency of the fluorescence resonance energy transfer (FRET) between the CFP donor and the YFP acceptor fluorophores (Figure 19.5.2). Following this conformational change, there is an increase in YFP emission (525–560 nm) and a simultaneous decrease in CFP emission (460–500 nm) (Figure 19.5.3), making Cameleon an effective reporter of calcium mobilization.⁶ This Ca²⁺-dependent emission ratio response reduces assay variations due to compound or cellular autofluorescence, nonuniform cell plating, differences in expression levels between cells, instability of instrument illumination and changes in illumination pathlength.

The Premo™ Cameleon Calcium Sensor is designed to readily and accurately detect intracellular calcium flux from different receptors. An example of the robustness and reproducibility and accuracy of the system is demonstrated using the endogenous histamine receptor in conjunction with histamine, pyrilamine, and thioperamide in HeLa cells (Figure 19.5.4). The no-wash, no-dye format and ratiometric readout eliminates wash steps that can dislodge cells, reduces data variability and increases data integrity. Expression levels will be maintained for several days, enabling iterative assays to be run; for instance, when examining agonist/antagonist

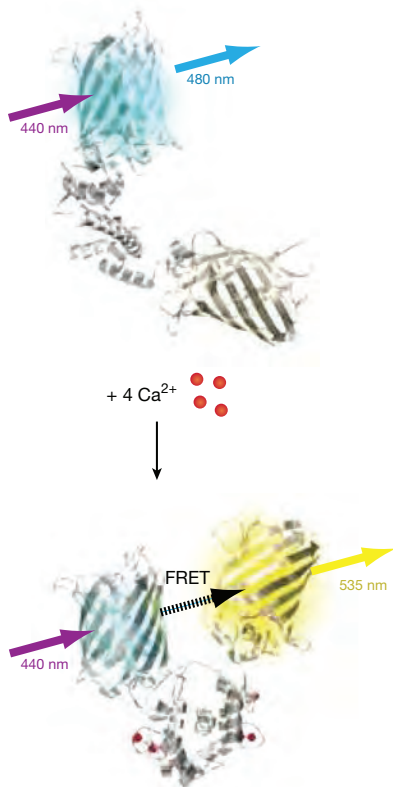

Figure 19.5.2 Schematic of the Premo™ Cameleon Calcium Sensor (P36207, P36208) mechanism.

Figure 19.5.3 Fluorescence emission spectra of Premo™ Cameleon Calcium Sensor (P36207, P36208). The dashed line indicates the spectra in the absence of Ca²⁺; the solid line shows the fluorescence resonance energy transfer (FRET)-based change upon Ca²⁺ binding.

Figure 19.5.1 Schematic representation of BacMam-mediated transduction and expression of the Premo™ Cameleon Calcium Sensor (P36207, P36208). The combination of fluorescent protein biosensors and BacMam delivery technology yields easy-to-use, genetically encoded sensors for cell-based assays. A BacMam virus carrying the Cameleon fusion gene transduces a cell and traffics to the nucleus where only the Cameleon gene is transcribed; baculovirus promoters are not recognized by the mammalian transcriptional machinery, hence no virus replication occurs. Following transcription, the Cameleon mRNA is expressed in the cytosol, or in a specific compartment, depending on the presence of targeting tags.

relationships in the same cells. Premo™ Cameleon Calcium Sensor is provided as a ready-to-use baculovirus stock suspension containing the Cameleon DNA, which is efficiently delivered to target cells, including primary and stem cells, prior to cell plating. If required, immunolocalization of Premo™ Cameleon Calcium Sensor in fixed specimens can be accomplished using our anti-Green Fluorescent Protein (anti-GFP) antibodies⁷ (Section 7.5). Both stable cell lines and human primary cells can be prepared frozen and "assay-ready" and can be subsequently plated as little as four hours prior to screening. Cell-based assays or imaging experiments can be conducted in complete medium without any intervening wash steps. More information is available at www.invitrogen.com/handbook/premocalcium.

Aequorin: A Bioluminescent Calcium Sensor

Bioluminescence is defined as the production of light by biological organisms. Because light is produced by a chemical reaction of specific photoproteins within the organism and does not require illumination, bioluminescence-based assays can be extremely sensitive and free of background.⁸ However, the intensity of light produced by bioluminescent cells is often very low, necessitating the use of image enhancement to obtain sufficient signals.

Properties and Applications of Aequorin

We offer recombinant aequorin as well as a variety of synthetic coelenterazine analogs for quantitative Ca²⁺ measurements with aequorin, a photoprotein originally isolated from luminescent jellyfish and other marine organisms. The aequorin complex comprises a 22,000-dalton apoaequorin protein,⁹ molecular oxygen and the luminophore coelenterazine^{10–14} (Figure 19.5.5). When three Ca²⁺ ions bind to this complex, coelenterazine is oxidized to coelenteramide, with a concomitant release of carbon dioxide and blue light^{15–17} (Figure 19.5.6, Figure 19.5.7). The approximately third-power dependence of aequorin's bioluminescence on Ca²⁺ concentration

Figure 19.5.5 Ribbon representation of the aequorin/coelenterazine complex showing the secondary structural elements in the protein. Coelenterazine and the side chain of Tyr 184 are shown as stick representations. Reproduced with permission from Nature (2000) 405:372.

Figure 19.5.6 The Ca²⁺-induced luminescence emission spectrum of native aequorin incorporating the coelenterazine luminophore (C2944).

Figure 19.5.7 Ca²⁺-dependent generation of luminescence by the aequorin complex, which contains apoaequorin (APO) and coelenterazine (C2944).

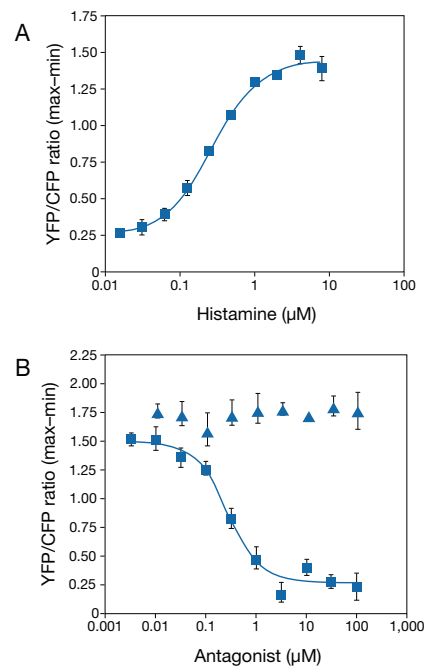

Figure 19.5.4 Agonist and antagonist dose response curves. HeLa cells were plated in a 96-well plate at a density of 15,000 cells/well, transduced with Premo™ Cameleon Calcium Sensor (P36207, P36208), and incubated overnight at 37°C. The following day, a histamine dose response was performed (A). A separate plate was used to evaluate an antagonist dose response with pyrillamine (closed squares) and thioperamide (closed triangles) in the presence of an EC₈₀ concentration of histamine (B). Pyrillamine is a known H1 receptor antagonist that couples through G_q proteins and the second messenger Ca²⁺. Thioperamide is a known H3 receptor antagonist that couples through G_i proteins and the second messenger cAMP.

gives it a broad detection range, allowing the measurement of Ca²⁺ concentrations from ~0.1 μM to >100 μM.^{18,19}

Unlike fluorescent Ca²⁺ indicators, Ca²⁺-bound aequorin²⁰ can be detected without illuminating the sample, thereby eliminating interference from autofluorescence and allowing simultaneous labeling with caged probes²¹ (Section 5.3). Moreover, aequorin that has been microinjected into eggs usually reports higher wave amplitudes (3–30 μM) than do fluorescent ion indicators.^{22–25} Aequorin is not exported or secreted, nor is it compartmentalized or sequestered within cells; thus, aequorin measurements can be used to detect Ca²⁺ changes that occur over relatively long periods. In several experimental systems, aequorin's luminescence was detectable many hours to days after cell loading.^{18,26,27} Aequorin also does not disrupt cell functions or embryo development¹⁸ (Figure 19.5.8).

Recombinant Aequorin

Conventional purification of aequorin from the jellyfish *Aequorea victoria* requires laborious extraction procedures and sometimes yields preparations that are substantially heterogeneous or that are toxic to the organisms under study.^{28,29} Two tons of jellyfish typically yield ~125 mg of the purified photoprotein.³⁰ In contrast, recombinant AquaLite® aequorin (A6785) is produced by purifying apoaequorin from genetically engineered *Escherichia coli*, followed by reconstitution of the aequorin complex *in vitro* with pure coelenterazine.³¹ This method of preparation yields a pure, nontoxic, fully charged aequorin complex that is suitable for measuring intracellular Ca²⁺ by microinjection or other loading techniques, as well as for calibrating aequorin-based assays. Pressure injection is a commonly cited loading method, despite the fact that only large cells can be loaded in this way. Pressure injection has been employed to study the effects of caffeine on mouse diaphragm muscle fibers³² and the role of Ca²⁺ in the fertilization of sea urchin eggs.³³ Alternatively, human platelets have been transiently permeabilized to the aequorin complex with DMSO,³⁴ and monkey kidney cells

have been loaded by hypoosmotic shock.³⁵ A method based on the osmotic lysis of pinocytotic vesicles—a technique that can be conveniently implemented using our Influx™ pinocytotic cell-loading reagent (I14402, Section 19.8)—has been successfully used for cellular loading of aequorin and the related photoprotein obelin.³⁶

Because of its Ca²⁺-dependent luminescence, the aequorin complex has been extensively used as an intracellular Ca²⁺ indicator. *Aequorea victoria* aequorin has been used to:

- Analyze the secretion response of single adrenal chromaffin cells to nicotinic cholinergic agonists³⁷
- Calibrate micropipettes with injection volumes of as little as 3 picoliters³⁸
- Clarify the role of Ca²⁺ release in heart muscle damage³⁹
- Demonstrate the massive release of Ca²⁺ during fertilization⁴⁰
- Study the regulation of the sarcoplasmic reticulum Ca²⁺ pump expression in developing chick myoblasts⁴¹

Coelenterazine and Its Synthetic Analogs

We offer coelenterazine and several synthetic coelenterazine analogs for reconstituting aequorin in cells that have been transfected with apoaequorin cDNA (Table 19.4). Cell permeation of coelenterazine, which has been demonstrated in organisms as diverse as *Escherichia coli*,⁴² yeast,^{43,44} *Dictyostelium* cells,⁴⁵ fish eggs,⁴⁶ mammalian cells^{47–49} and plants,^{21,50,51} is the rate-limiting step in the reconstitution process.⁵² Coelenterazine is also required for generating the bioluminescent aequorin complex when using chimeric aequorin constructs.⁵³ Furthermore, coelenterazine and its analogs are substrates for the bioluminescent *Renilla* luciferase.^{54,55}

In addition to native coelenterazine (C2944), we have synthesized three derivatives of coelenterazine that confer different Ca²⁺ affinities and spectral properties on the aequorin complex^{56–58} (Table 19.4). Like native coelenterazine, these derivatives can be used to reconstitute the

Figure 19.5.8 Images of Ca²⁺ waves in gastrulating zebrafish embryos detected by microinjected *f* aequorin (recombinant aequorin reconstituted with the coelenterazine *f* luminophore, C6779). The images are pseudocolored to represent Ca²⁺-dependent luminescent flux in (photons/pixel/second × 10⁻²) according to the color scales shown at the left of each of the three time-lapse image sequences (a,b,c). Time in seconds is indicated in the lower left-hand corner of each frame. The sequences depict three different spatial wave types that are represented schematically at the end of each sequence. PM indicates the dorsal midline pacemaker; its position in the luminescence images is marked by a red asterisk. The image was contributed by Edwin Gilland, Marine Biological Laboratory, Woods Hole, MA, and reproduced with permission from Proc Natl Acad Sci U S A (1999) 96:157.

aequorin complex both *in vivo* and *in vitro*. However, intracellular reconstitution of aequorin from coelenterazine analogs can be relatively slow.⁵⁷ Aequorins containing the *cp*, *f* or *h* form of coelenterazine (C14260, C6779, C6780) exhibit relative intensities that are reported to be 10–20 times that of apoaequorin reconstituted with native coelenterazine.^{21,58,59} Coelenterazine *cp* has been used in an automated high-throughput screening assay for G-protein-coupled receptors.⁶⁰ Coelenterazine is readily solubilized in aqueous solutions containing 50 mM hydroxypropyl- β -cyclodextrin.⁶¹

Table 19.4 Coelenterazines and their properties.

Cat. No.	Coelenterazine Analog	Em (nm)*	RLC †	Relative Intensity ‡	Half-Rise Time (msec) §
C2944	native	466	1.00	1	6–30

19.6 Fluorescent Mg²⁺ Indicators

Figure 19.6.1 Mag-fura-2, tetrapotassium salt (M1290).

Figure 19.6.2 Mag-indo-1, tetrapotassium salt.

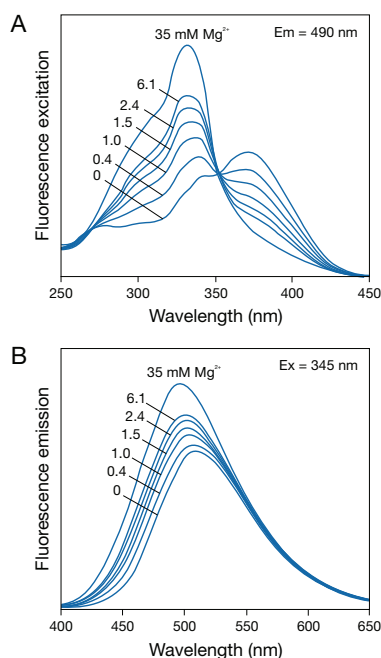

Figure 19.6.3 A) Fluorescence excitation and B) fluorescence emission spectra of mag-fura-2 (M1290) in solutions containing 0–35 mM Mg²⁺.

Intracellular Mg²⁺ is important for mediating enzymatic reactions, DNA synthesis, hormonal secretion and muscular contraction. To facilitate the investigation of magnesium's role in these and other cellular functions, we offer several different fluorescent indicators for measuring intracellular Mg²⁺ concentration. They include furaptra,^{1,2} which we refer to as mag-fura-2 to denote the similarity of its structure (Figure 19.6.1) and spectral response with the Ca²⁺ indicator fura-2; and mag-indo-1, with a structure (Figure 19.6.2) and spectral response similar to that of indo-1. For applications such as confocal laser-scanning microscopy and flow cytometry, we offer the Magnesium Green™ and mag-fluo-4 indicators. The various methods for measuring intracellular Mg²⁺ have been reviewed.³

Mg²⁺ indicators are generally designed to maximally respond to the Mg²⁺ concentrations commonly found in cells, typically ranging from about 0.1 mM to 6 mM. Intracellular free Mg²⁺ levels have been reported to be ~0.3 mM in synaptosomes,⁴ 0.37 mM in hepatocytes⁵ and 0.5–1.2 mM in cardiac cells,⁶ whereas the concentration of Mg²⁺ in normal serum is ~0.44–1.5 mM.⁷ Measurements using fluorescent Mg²⁺ indicators are somewhat more demanding than intracellular Ca²⁺ determinations because physiological changes in Mg²⁺ concentration are relatively small. Compartmentalization and binding to proteins can also be a problem in use of these indicators in cells.⁸ Mg²⁺ indicators also bind Ca²⁺; however, typical physiological Ca²⁺ concentrations (10 nM–1 μM) usually do not interfere with Mg²⁺ measurements because the affinity of these indicators for Ca²⁺ is low. For ultrasensitive Mg²⁺ measurement applications, intracellular Ca²⁺ background can be suppressed using BAPTA AM (B1205, B6769; Section 19.8).⁹ Although Ca²⁺ binding by Mg²⁺ indicators can be a complicating factor in Mg²⁺ measurements,^{10,11} this property can also be exploited for measuring high Ca²⁺ concentrations (1–100 μM);¹² see Section 19.2 and Section 19.3 for further examples.

For intracellular calibration of Mg²⁺ indicators, we offer the ionophores A-23187 and the nonfluorescent 4-bromo A-23187 (A1493, B1494; Section 19.8), which are preferred over ionomycin (I24222) because they transport Mg²⁺ more effectively.^{2,13} Solutions used to calibrate Mg²⁺ indicators should be initially free of heavy metals such as Mn²⁺ that can interact with the indicators. These metals can be removed by treating the solution with the divalent cation chelator TPEN (T1210, Section 19.8).

Magnesium Indicators Excited by UV Light

Mag-Fura-2 and Mag-Indo-1

The dissociation constant for Mg²⁺ of mag-indo-1 is 2.7 mM, slightly higher than that of mag-fura-2, which is 1.9 mM. The lower-affinity mag-indo-1 indicator is sensitive to somewhat higher spikes in intracellular Mg²⁺.^{14,15} The affinities of mag-fura-2 and mag-indo-1 for Mg²⁺ are reported to be essentially invariant at pH values between 5.5 and 7.4 and at temperatures between 22°C and 37°C.¹⁶ A detailed study of the photophysics of mag-fura-2 has been published.¹⁷ Comparisons of intracellular and solution dissociation constants for mag-fura-2 have been published by Günther³ and by Tashiro and Konishi.¹³

As with their Ca²⁺ indicator analogs, mag-fura-2 undergoes an appreciable shift in excitation wavelength upon Mg²⁺ binding (Figure 19.6.3), and mag-indo-1 exhibits a shift in both its excitation and emission wavelengths (Figure 19.6.4). Equipment, optical filters and calibration methods are very similar to those required for the Ca²⁺ indicators. The excitation-ratioable mag-fura-2 indicator is most useful for fluorescence microscopy, whereas the emission-ratioable mag-indo-1 indicator is preferred for flow cytometry.¹⁸ Many applications of mag-fura-2 involve estimation of the affinity and selectivity of Mg²⁺ binding to proteins.^{19,20} Displacement of bound Mg²⁺ by Li⁺ provides a surrogate assay for Li⁺ transport, a process for which few direct detection methods exist.^{21,22} Researchers have used mag-fura-2 to measure intracellular Mg²⁺ in a wide variety of cells, organelles and tissues, including:

- Cortical neurons²³
- Isolated mitochondria^{24,25}
- Platelets^{26,27}
- Rat hepatocytes²⁸
- Rat ventricular myocytes²⁹
- *Xenopus* oocytes³⁰

In addition to the cell-impermeant potassium salt of mag-fura-2 (M1290), we offer the cell-permeant AM esters of mag-fura-2 and mag-indo-1 as a set of 20 vials, each containing 50 µg (M1292, M1295). The special packaging is recommended when small quantities of the dyes are to be used over a long period of time. Mag-fura-2 AM is also available in a single vial containing 1 mg (M1291).

Magnesium Indicators Excited by Visible Light

We also offer visible light-excitable Mg²⁺ indicators, including the Magnesium Green™ and mag-fluo-4 indicators. As with mag-fura-2 and mag-indo-1, these visible light-excitable Mg²⁺ indicators can also be used as low-affinity Ca²⁺ indicators (Section 19.3) and may be useful as indicators for Zn²⁺ and other metals (Section 19.7).

Magnesium Green™ Indicator

The Magnesium Green™ indicator (Figure 19.6.5) exhibits a higher affinity for Mg²⁺ ($K_d \sim 1.0$ mM) than does mag-fura-2 ($K_d \sim 1.9$ mM) or mag-indo-1 ($K_d \sim 2.7$ mM); this indicator also binds Ca²⁺ with moderate affinity (K_d for Ca²⁺ in the absence of Mg²⁺ is ~ 6 µM, measured at 22°C using our Calcium Calibration Buffer Kits). The spectral properties of the Magnesium Green™ indicator are similar to those of the Calcium Green™ indicators. Upon binding Mg²⁺, Magnesium Green™ exhibits an increase in fluorescence emission intensity without a shift in wavelength (Figure 19.6.6). The Magnesium Green™ indicator has been used to investigate the binding of free Mg²⁺ by the bacterial SecA protein³¹ and by protein tyrosine kinases.³² By exploiting the fact that ATP has greater Mg²⁺-binding affinity than ADP, researchers have used Magnesium Green™ to indirectly measure ATP in pancreatic acinar cells,³³ in bullfrog hair cells,³⁴ in cultured *Xenopus* spinal neurons³⁵ and in isolated mitochondria.³⁶ Magnesium Green™ is available as a cell-impermeant potassium salt (M3733) or as a cell-permeant AM ester (M3735).

Mag-Fluo-4

Mag-fluo-4 (Figure 19.6.7) is an analog of fluo-4 with a K_d for Mg²⁺ of 4.7 mM and a K_d for Ca²⁺ of 22 µM (measured at 22°C using our Calcium Calibration Buffer Kits), making it useful as an intracellular Mg²⁺ indicator as well as a low-affinity Ca²⁺ indicator (Section 19.3). Mag-fluo-4 has a much more sensitive fluorescence response to Mg²⁺ binding than does our Magnesium Green™ indicator. Because physiological fluctuations of intracellular Mg²⁺ concentration are typically small, this increased sensitivity is a considerable advantage.⁹ Like fluo-4, mag-fluo-4 is essentially non-fluorescent in the absence of divalent cations and exhibits strong fluorescence enhancement with no spectral shift upon binding Mg²⁺ (Figure 19.6.8). Mag-fluo-4 is available as a cell-impermeant potassium salt (M14205) or as a cell-permeant AM ester (M14206).

Notes

- Dissociation constants are known to vary considerably depending on the temperature, pH, ionic strength, viscosity, protein binding, presence of other ions (especially polyvalent ions), instrument setup and other factors. It is strongly recommended that these values be verified under user-specific experimental conditions.
- This indicator binds Ca²⁺ with higher affinity than Mg²⁺, producing a similar spectral response.
- K_d(Mg²⁺) values have been determined in 115 mM KCl, 20 mM NaCl, 10 mM Tris, pH 7.05, 0 to 35 mM Mg²⁺ at 22°C.
- Spectra measured in aqueous buffers containing zero or 35 mM Mg²⁺, indicated as H₂O and H₂O/Mg²⁺, respectively.
- This indicator exhibits fluorescence enhancement in response to ion binding, with essentially no change in absorption or emission wavelengths.
- Fluorescence of the free indicator is very weak and is enhanced >100-fold on binding Mg²⁺.
- Fluorescence of this AM ester derivative is very weak and is enhanced only after hydrolytic cleavage followed by binding of divalent cations to the anionic indicator.

PRODUCT LIST 19.6 FLUORESCENT Mg²⁺ INDICATORS

Cat No.	Product	Quantity
M14206	mag-fluo-4, AM *cell permeant* *special packaging*	10 x 50 µg
M14205	mag-fluo-4, tetrapotassium salt *cell impermeant*	500 µg
M1291	mag-fura-2, AM *cell permeant*	1 mg
M1292	mag-fura-2, AM *cell permeant* *special packaging*	20 x 50 µg
M1290	mag-fura-2, tetrapotassium salt *cell impermeant*	1 mg
M1295	mag-indo-1, AM *cell permeant* *special packaging*	20 x 50 µg
M3735	Magnesium Green™, AM *cell permeant* *special packaging*	20 x 50 µg
M3733	Magnesium Green™, pentapotassium salt *cell impermeant*	1 mg

19.7 Fluorescent Indicators for Zn²⁺ and Other Metal Ions

Not only do transition metal ions play an important role in biological structure and activity,¹ but they can also serve as surrogates and blockers of ion transport through Ca²⁺ channels^{2,3} (Figure 19.7.1). Measuring heavy metal ion concentrations in cells and environmental samples with indicators originally designed for detection of Ca²⁺ and Mg²⁺ has been hampered by competitive binding of other, more abundant, cations.⁴ Detection methods rely both on novel fluorescent ion sensors specifically designed for metal detection,⁵ as well as on new applications for indicators originally designed for detection of Ca²⁺ and Mg²⁺⁶ (Table 19.5, Figure 19.7.2, Figure 19.7.3).

Several of our fluorescent indicators can be used to selectively determine polyvalent cation concentrations inside cells or to follow metal ion transport through ion channels. Other indicators are primarily useful for measurements in solutions or in extracts of environmental samples.⁷ In most cases, the high affinity of the indicators for metal ions allows interference from other compounds to be minimized by diluting the sample with deionized water. As with Ca²⁺ and Mg²⁺ detection, spectroscopic responses to metal ion binding and dissociation constant (K_d) values are dependent on many factors, including pH, temperature, viscosity, protein binding and the presence of other ions. These responses may vary significantly in complex environments such as seawater and the cytosol.⁸

Figure 19.7.2 Visual screening of fluorescent indicator responses to metal ions. The image shows a 96-well microplate containing various combinations of ions and indicators in 50 mM MOPS pH 7.0. Each row of wells represents a different indicator; each column of wells represents a different ion. The indicators (top to bottom) are: Calcium Green™-5N (0.5 μM), Calcium Green™-2 (0.2 μM), fluo-4 (2 μM), fluo-5N (2 μM), FluoZin™-1 (2 μM), Newport Green™ DCF (2 μM), Phen Green™ FL (2 μM; this indicator salt is no longer routinely available, please inquire) and calcein (0.5 μM). The left-hand column of wells contains 10 mM EGTA + 10 μM TPEN (ion-free reference solution). Subsequent columns (left to right) represent 1 μM concentrations of Ca²⁺, Ba²⁺, Mn²⁺, Fe²⁺, Co²⁺, Ni²⁺, Cu²⁺, Zn²⁺, Cd²⁺, Hg²⁺ and Pb²⁺, respectively. The microplate was scanned using a FLA3000G laser scanner (Fuji® Photo Film Co.) with excitation at 473 nm and fluorescence emission detected at 520 nm. The image is pseudocolored according to fluorescence intensity (high = red > orange > yellow > green > blue = low).

Table 19.5 Response of fura-2 and indo-1 to some divalent cations other than Ca²⁺ and Mg²⁺.

Ion	Indicator	K _d *	Spectroscopic Effect	Reference
Ba ²⁺	fura-2	1.4 × 10 ⁻⁶ M	Spectra similar to Ca ²⁺ complex; no quenching	1
Cd ²⁺	fura-2	1.0 × 10 ⁻¹² M	Spectra similar to Ca ²⁺ complex; higher intensity	2
Co ²⁺	fura-2	8.6 × 10 ⁻⁹ M	>99% Quenched relative to Ca ²⁺ complex	1
Mn ²⁺	fura-2	2.8 × 10 ⁻⁹ M	>99% Quenched relative to Ca ²⁺ complex	1
Pb ²⁺	fura-2	4.2 × 10 ⁻¹² M	Spectra shifted relative to Ca ²⁺ complex; no quenching	3
Pb ²⁺	indo-1	3.5 × 10 ⁻¹¹ M	Fluorescence quenched	4
Sr ²⁺	fura-2	7.6 × 10 ⁻⁶ M	Spectra similar to Ca ²⁺ complex; no quenching	1
Zn ²⁺	fura-2	3.0 × 10 ⁻⁹ M	Spectra similar to Ca ²⁺ complex; no quenching	5
Zn ²⁺	indo-1	1.6 × 10 ⁻¹⁰ M	Spectra similar to Ca ²⁺ complex; no quenching	6

Figure 19.7.1 Discrimination of ATP-induced intracellular Ca²⁺ release from capacitative Ca²⁺ entry in bovine vascular endothelial cells using quenching of fura-2 fluorescence by Mn²⁺. Intracellular Ca²⁺ release was detected by fura-2 fluorescence excited alternately at 360 nm and 380 nm (F₃₆₀/F₃₈₀). Capacitative entry of extracellular Mn²⁺ was detected by its quenching effect on the Ca²⁺-insensitive fura-2 fluorescence signal excited at 360 nm (F₃₆₀). Successive Ca²⁺ spikes induced by sustained applications of low ATP concentrations (A) or transient 5-second applications of 2 μM ATP (B) were followed by accelerated entry of Mn²⁺. Experiments were conducted in Ca²⁺-free extracellular medium containing 100 μM Mn²⁺. Under these conditions, Mn²⁺ functions as an ionic surrogate for Ca²⁺ with respect to transmembrane conductance, and Ca²⁺ signals were unambiguously attributed to release from intracellular stores. Figure reproduced with permission from Sedova M, Kiishin A, Huser J, Blatter LA, J Physiol (2000) 523:549.

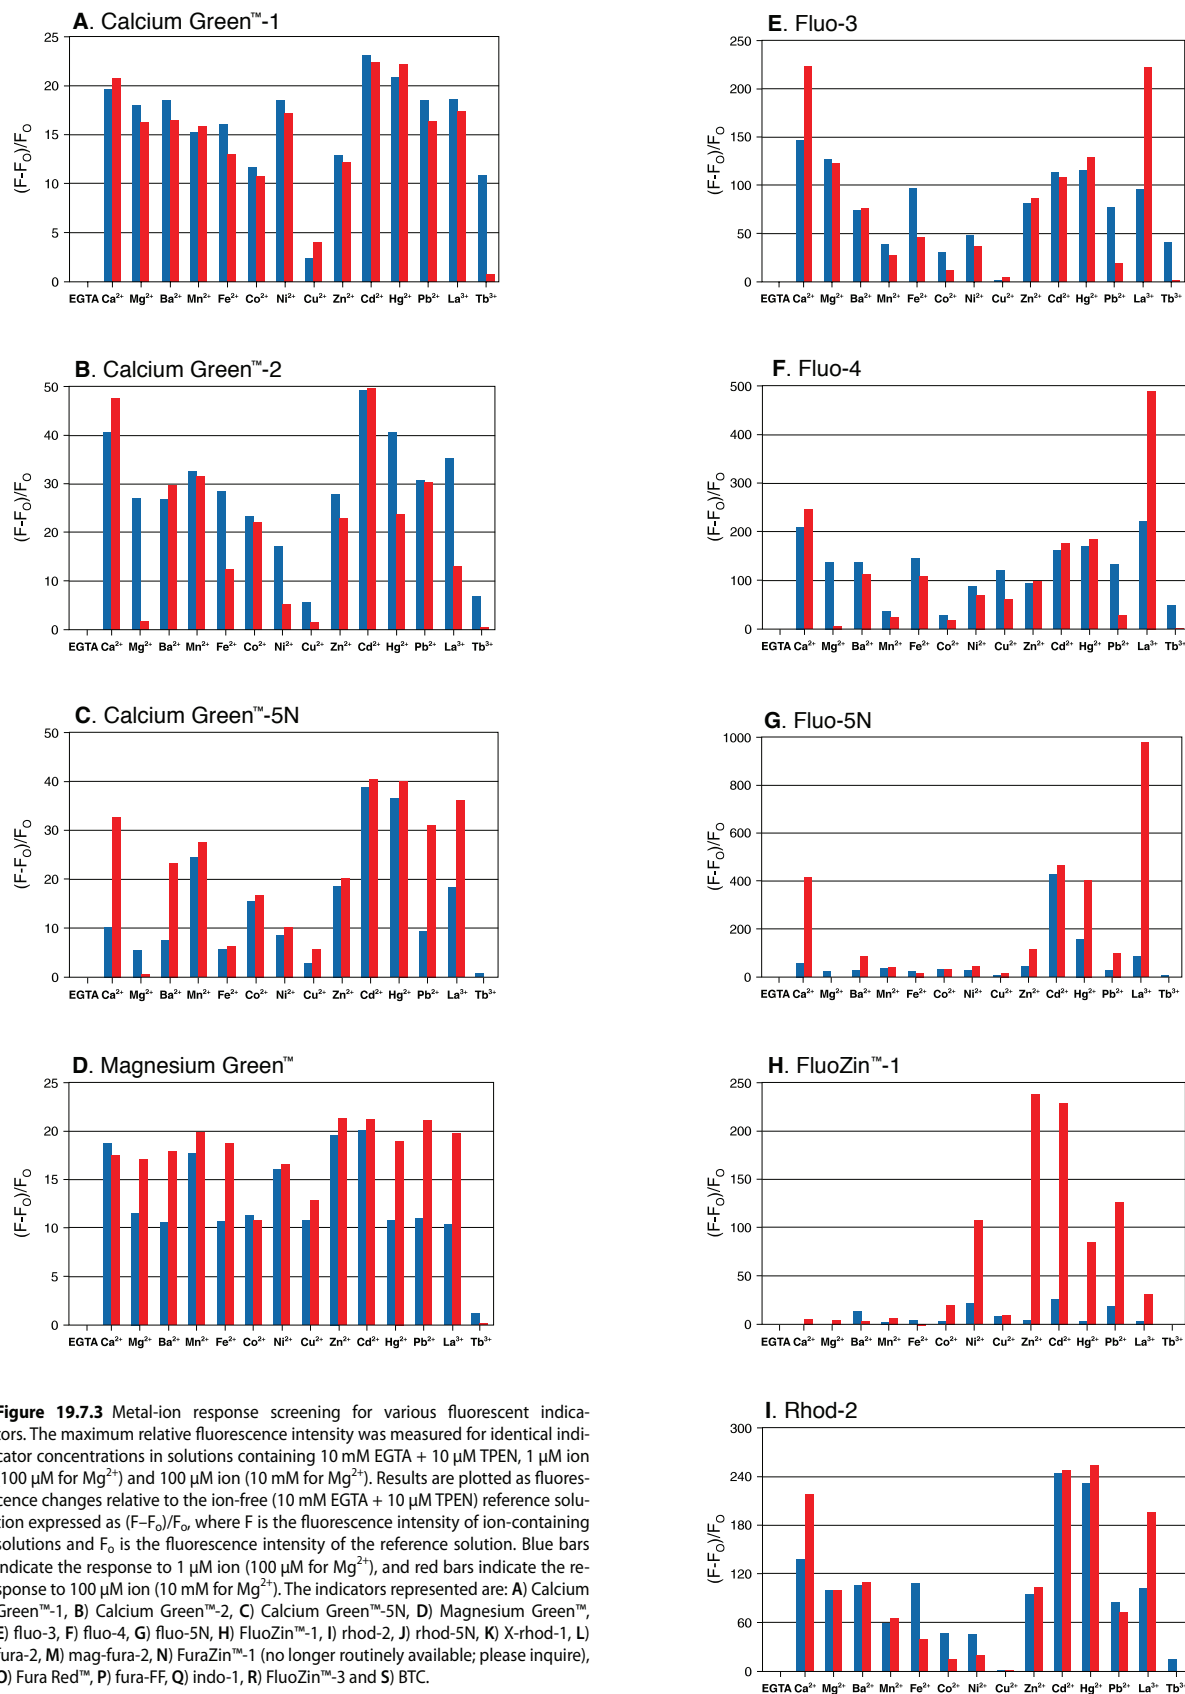

Figure 19.7.3 Metal-ion response screening for various fluorescent indicators. The maximum relative fluorescence intensity was measured for identical indicator concentrations in solutions containing 10 mM EGTA + 10 μM TPEN, 1 μM ion (100 μM for Mg²⁺) and 100 μM ion (10 mM for Mg²⁺). Results are plotted as fluorescence changes relative to the ion-free (10 mM EGTA + 10 μM TPEN) reference solution expressed as $(F-F_0)/F_0$, where F is the fluorescence intensity of ion-containing solutions and F_0 is the fluorescence intensity of the reference solution. Blue bars indicate the response to 1 μM ion (100 μM for Mg²⁺), and red bars indicate the response to 100 μM ion (10 mM for Mg²⁺). The indicators represented are: A) Calcium Green™-1, B) Calcium Green™-2, C) Calcium Green™-5N, D) Magnesium Green™, E) fluo-3, F) fluo-4, G) fluo-5N, H) FluoZin™-1, I) rhod-2, J) rhod-5N, K) X-rhod-1, L) fura-2, M) mag-fura-2, N) FuraZin™-1 (no longer routinely available; please inquire), O) Fura Red™, P) fura-FF, Q) indo-1, R) FluoZin™-3 and S) BTC.

Figure 19.7.4 Metal-ion response screening for calcein, Newport Green™ and Phen Green™ indicators. The maximum relative fluorescence intensity was measured for identical indicator concentrations in solutions containing 10 mM EGTA + 10 μM TPEN, 1 μM ion and 100 μM ion. Results are plotted as fluorescence changes relative to the ion-free (10 mM EGTA + 10 μM TPEN) reference solution expressed as $(F-F_0)/F_0$, where F is the fluorescence intensity of ion-containing solutions and F_0 is the fluorescence intensity of the reference solution. Blue bars indicate the response to 1 μM ion, and red bars indicate the response to 100 μM ion. The indicators represented are: A) calcein, B) Newport Green™ DCF, C) Newport Green™ PDX, D) Phen Green™ FL and E) Phen Green™ SK. The water-soluble salt forms of the Newport Green™ PDX and Phen Green™ FL indicators are no longer routinely available; please inquire.

Applications of Ca²⁺ and Mg²⁺ Indicators for Detection of Zn²⁺ and Other Metals

We have tested the responses of many of the Ca²⁺ and Mg²⁺ indicators (described in Section 19.2 through Section 19.6) to a series of polyvalent metal ions (Figure 19.7.2, Figure 19.7.3). The BAPTA-based indicators, including the Calcium Green™ dyes, fluo-3 and fluo-4, exhibit the highest emission intensities upon binding La³⁺, Hg²⁺ and Cd²⁺. The response of the Calcium Green™-1 and Magnesium Green™ indicators shows relatively little variability amongst the ions tested. Indicators nominally designed for detecting low Ca²⁺ concentrations, such as Calcium Green™-5N, fluo-5N and rhod-5N, show little response to transition metal ions such as Fe²⁺, Co²⁺, Ni²⁺ and Co²⁺ and much stronger responses to heavier ions such as Cd²⁺, Hg²⁺ and Pb²⁺.⁹ Note that the responses shown in Figure 19.7.3 are not necessarily saturated or even uniform in some cases. Some indication of the overall response pattern can be obtained by comparing the effects of the 1 μM and 100 μM ion concentrations sampled in these experiments. Also, note that our selection of excitation and emission wavelengths for the measurements may significantly affect the absolute and relative magnitudes of the changes observed.

Fura-2 and indo-1, like other BAPTA-based Ca²⁺ indicators, are highly selective for Ca²⁺ over Mg²⁺; however, they bind other divalent and trivalent cations with significantly higher affinity. In terms of spectroscopic detection, some of these ions (e.g., Ba²⁺, Cd²⁺ and Sr²⁺) mimic the effects of Ca²⁺,^{10–12} others (e.g., Mn²⁺, Co²⁺ and Ni²⁺) exert strong fluorescence quenching effects (Table 19.5). Although heavy metal cations are a potentially serious source of interference in Ca²⁺ measurements using fluorescent indicators, intracellular concentrations are fortunately very low in most cases. When interference occurs, it can be identified and controlled using the selective heavy metal ion chelator TPEN^{13–16} (T1210, Section 19.8). Quenching of indicator fluorescence by Mn²⁺ has several useful applications:

- Calibrating the intracellular Ca²⁺ response of fluo-3, fluo-4, rhod-2 and related indicators^{17–19}
- Discriminating fluorescence signals from mitochondrial and cytosolic indicator populations^{20,21}
- Estimating the fraction of residual Ca²⁺-insensitive indicators after AM ester loading^{2,22}
- Estimating indicator leakage in measurements on cell suspensions in cuvettes²³

Mn²⁺ is also extensively used as an ionic surrogate for measuring Ca²⁺ influx through ion channels^{3,24–27} (Figure 19.7.1). Because the effect of Mn²⁺ on fura-2 fluorescence is quite different from that of Ca²⁺ (Table 19.5), influx can be clearly distinguished from Ca²⁺ elevation due to mobilization of intracellular stores,^{2,28} although such clarity may be impaired by the existence of alternative Mn²⁺-influx pathways.²⁹ A similar analysis applies when using fura-2 and indo-1 to study the antagonistic effects of ions such as Ni²⁺, La³⁺ and Co²⁺ on voltage-activated and Ca²⁺ release-activated Ca²⁺ channels. In this case, the Ca²⁺-dependent fluorescence signal is of primary interest and permeability of the antagonist ion, resulting in direct interactions with the indicator, will usually invalidate the measurement.^{30–32} For the Calcium Green™, Oregon Green® 488 BAPTA and Magnesium Green™ indicator series, the response to Mn²⁺ is not markedly different from the Ca²⁺ response (Figure 19.7.3), making these indicators generally unsuitable for the applications based on Ca²⁺/Mn²⁺ discrimination described above. A variety of fluorescent

indicators, including fura-2, fura-FF and our Calcium Orange™ and Magnesium Green™ indicators, have been utilized to detect Sr²⁺, an ion that can replace Ca²⁺ in triggering neurotransmitter release^{33,34} and also serves as a blocker of mitochondrial permeability transition pore opening.³⁵

Fluorescence of calcein (C481) is quenched strongly by Co²⁺, Ni²⁺ and Cu²⁺ and appreciably by Fe³⁺ and Mn²⁺ at physiological pH³⁶ (panel A, Figure 19.7.4). This fluorescence quenching response can be exploited for detecting the opening of the mitochondrial permeability transition pore,^{37–39} for assaying membrane fusion (Assays of Volume Change, Membrane Fusion and Membrane Permeability—Note 14.3) and for monitoring cellular iron transport and the cellular labile iron pool.^{36,40–43}

Indicators for Zinc

Zinc is the second most abundant transition metal in living organisms after iron. It is of particular importance in the regulation of gene expression, as Zn²⁺ binding proteins account for nearly 50% of the transcription regulatory proteins in the human genome. Zn²⁺ is also functionally active in pancreatic insulin secretion^{44,45} and is a contributory factor in neurological disorders including epilepsy and Alzheimer disease.^{46–48} Free Zn²⁺ is released from metalloprotein complexes during oxidative stress.^{49,50} The intracellular concentration of free Zn²⁺ is extremely low in most cells (<1 nM), with the remainder being bound to proteins or nucleic acids.⁵¹ One calculation⁵² yields an intracellular free Zn²⁺ concentration of six orders of magnitude less than one atom per cell. We prepare a variety of Zn²⁺ indicators (Table 19.6) to help elucidate the role of Zn²⁺ release and the localization of free or chelatable Zn²⁺ in cells.⁵³

FluoZin™ Indicators

Zinc concentrations in the 1–100 nM range can be measured using fluorescent indicators nominally designed for Ca²⁺ detection such as fura-2, or more recently developed indicators with greater Zn²⁺ selectivity.^{6,54} We have focused our development efforts on probes for detection of higher Zn²⁺ concentrations that are present in synaptic vesicles and released in response to electrical stimulation or excitotoxic agonists.⁴⁸ Peak concentrations of synaptically released Zn²⁺ may exceed 100 μM. We have developed FluoZin™-1 (F24180, F24181) and FluoZin™-2 (F24189), a series of unique indicators designed for detection of Zn²⁺ in the 0.1–100 μM range with minimal interfering Ca²⁺ sensitivity⁵³ (panel H, Figure 19.7.3; Figure 19.7.5). In our laboratories, we determined a K_d(Zn²⁺) of 8.2 μM for FluoZin™-1; however, dissociation constants are known to vary considerably depending on the experimental conditions and a K_d(Zn²⁺) of 0.4 μM for this same indicator has been reported elsewhere,⁵⁵ underscoring the importance of calibrating the indicator directly in the system under study. Published applications of FluoZin™-1 have primarily involved characterization of Zn²⁺-binding proteins.^{55–57}

The FluoZin™-3 indicator^{53,58} (F24194, Figure 19.7.6; F24195) is a Zn²⁺-selective indicator with a structure that resembles fluo-4. FluoZin™-3 exhibits high Zn²⁺-binding affinity (K_d for Zn²⁺ ~15 nM) that is unperturbed by Ca²⁺ concentrations up to at least 1 μM.^{15,54,59} The Zn²⁺-specificity of FluoZin™-3 evident from measurements in calibration solutions is reproduced in cell-based experiments. The responses of FluoZin™-3 to transition metals, including Zn, Mn, Fe, Co, Cu(I), Cu(II), Ni and Cd, have been extensively characterized.⁵ In addition, FluoZin™-3 exhibits a large increase in fluorescence in response to saturating levels of Zn²⁺ (greater than 50 fold, Figure 19.7.7). FluoZin™-3 has been found to be a brighter alternative to Zinquin for measuring

Figure 19.7.5 Zn²⁺ dependence of the fluorescence emission spectra of FluoZin™-2.

Figure 19.7.6 FluoZin™-3, tetrapotassium salt (F24194).

Figure 19.7.7 Zn²⁺ dependence of the fluorescence emission spectra of FluoZin™-3 (F24194). The spectrum for the Zn²⁺-free solution is indistinguishable from the baseline.

Table 19.6 Fluorescent indicators for Zn²⁺.

Indicator	Water-Soluble Salt	Cell-Permeant Ester	Ex/Em *	K _d for Zn ²⁺ †

Newport Green™ PDX	NA	N24191	495/520	30 μM

* Excitation (Ex) and Emission (Em) maxima, in nm. † Dissociation constant of the indicator Zn²⁺ complex measured in 50 mM MOPS, pH 7.0, at 22°C. ‡ Excitation peak shifts upon binding Zn²⁺. § Emission peak shifts upon binding Zn²⁺. ** K_d determined in 135 mM NaCl, 1.1 mM EGTA, 20 mM HEPES, pH 7.4, 0–10 μM free Zn²⁺ at 22°C. NA = not available.

Figure 19.7.8 Newport Green™ DCF, dipotassium salt (N7990).

Figure 19.7.9 A human pancreatic islet stained with Newport Green™ DCF diacetate (N7991) and propidium iodide (P1304MP, P3566, P21493). The image represents a projection of 60 optical sections acquired at 2 μm intervals by confocal laser-scanning microscopy. The green-fluorescent Newport Green™ DCF indicator identifies viable insulin-producing β-cells via binding to intracellular zinc. Dead cells are identified by red-fluorescent propidium iodide staining. Image contributed by Brigitte Vandewalle, University of Lille, and reproduced with permission from J Histochem Cytochem (2001) 49:519.

the exocytotic release of Zn²⁺ from pancreatic β-cells after stimulation with glucose or potassium.^{60,61} Although imaging applications of FluoZin™-3 are predominant, cell-based microplate assays^{47,62} and flow cytometry protocols⁶³ have also been developed.

RhodZin™-3 Indicator

The orange-fluorescent RhodZin™-3 zinc indicator exhibits a dramatic 75-fold increase in fluorescence at saturating levels of Zn²⁺ and also possesses a K_d for Zn²⁺ of ~65 nM.⁶⁴ The cell-permeant AM ester form of RhodZin™-3 (R36351) effectively localizes into mitochondria and is a valuable tool for investigating the physiological consequences of mitochondrial Zn²⁺ sequestration.^{65,66} The cell-impermeant RhodZin™-3 salt (R36350) can be used to measure extracellular Zn²⁺ concentrations.⁶⁷

Newport Green™ DCF and Newport Green™ PDX Indicators

The Newport Green™ DCF indicator (N7990, Figure 19.7.8; N7991) has moderate zinc-binding affinity (K_d for Zn²⁺ ~1 μM) but is essentially insensitive to Ca²⁺ (K_d for Ca²⁺ >100 μM), making this a valuable probe for detecting Zn²⁺ influx into neurons through voltage- or glutamate-gated channels.^{46,68,69} When used alongside dyes with dual Ca²⁺/Zn²⁺ sensitivity such as fura-2 and mag-fura-2, Newport Green™ DCF provides confirmation that changes in Zn²⁺ levels, and not Ca²⁺ or Mg²⁺, are being detected.^{70,71} Newport Green™ DCF has been used to identify insulin-producing β-cells from human pancreatic islets based on their high intracellular Zn²⁺ content⁴⁵ (Figure 19.7.9). Newport Green™ DCF has also been used in conjunction with Texas Red® 10,000 MW dextran to create a ratiometric fluorescent PEBBLE (Probe Encapsulated By Biologically Localized Embedding) nanosensor for real-time measurements of intra- and intercellular free zinc.⁷² The responses of Newport Green™ DCF to transition metals, including Zn, Mn, Fe, Co, Cu(I), Cu(II), Ni and Cd, have been characterized.⁵

Newport Green™ PDX⁵³ (N24191) incorporates the same di-(2-picolyl)amine chelator as Newport Green™ DCF but has a higher Zn²⁺ dissociation constant (K_d for Zn²⁺ ~30 μM) and a larger Zn²⁺-free to Zn²⁺-saturated fluorescence intensity increase.

TSQ

Use of the membrane-permeant probe *N*-(6-methoxy-8-quinolyl)-*p*-toluenesulfonamide (TSQ, M688; Figure 19.7.10) in cells was first described by Fredrickson.⁷³ TSQ is selective for Zn²⁺ in the presence of physiological concentrations of Ca²⁺ and Mg²⁺ ions. The complex of TSQ with free Zn²⁺ apparently has a stoichiometry of two dye molecules per metal atom,⁷⁴ but a 1:1 complex may be formed with metalloproteins. The intracellular Zn²⁺ chelator dithizone blocks TSQ binding of Zn²⁺.⁷⁵

Several reports suggest that TSQ can be used to localize Zn²⁺ pools in the central nervous system.^{76–78} Histochemical localization using TSQ identified a broad distribution of Zn²⁺ in neonatal mice, particularly associated with rapidly proliferating tissues, such as skin and gastrointestinal epithelium.⁷⁹ TSQ has also been used to detect Zn²⁺ translocation from presynaptic nerve terminals into postsynaptic nerve terminals when blood flow is constricted in the brain during ischemic events.⁸⁰ TSQ (like Newport Green™ DCF) is a selective nontoxic stain for pancreatic islet cells, which have a high content of Zn²⁺, and may be useful for their flow cytometric isolation.⁸¹

TSQ-based assays for Zn²⁺ in seawater and other biological systems exhibit a detection limit of ~0.1 nM.^{82,83} The simultaneous determination of Zn²⁺ and Cd²⁺ by spectrofluorometry using TSQ in an SDS micelle has also been reported.⁷⁴ TSQ has been used to measure Zn²⁺ levels in artificial lipid vesicles and live sperm cells by flow cytometry.⁸⁴ In this latter study, the fluorescence yield of the TSQ–Zn²⁺ complex was shown to be much higher when bound to lipids than in aqueous solution, indicating that quantitative cell assays for Zn²⁺ based on the fluorescence intensity of TSQ may not be accurate because of uncertainty in the quantum yield of the dye when bound to membranes.

Traditional Ca²⁺ and Mg²⁺ Indicators as Zn²⁺ Indicators

Zn²⁺ binds to most BAPTA-based Ca²⁺ indicators with substantially higher affinity than Ca²⁺.⁸⁵ For example, fura-2 (F1200, F6799; Section 19.2) exhibits a K_d for Zn²⁺ in the absence of Ca²⁺ of 3 nM (Table 19.5). The lack of saturation of fura-2 fluorescence in resting cells is indicative of the low intracellular concentration of free Zn²⁺. Fura-2 remains sensitive to nanomolar

Figure 19.7.12 Dual-color scatter plot showing two populations of Jurkat cells. Jurkat cells were loaded with Leadmium™ Green AM (A10024) and washed. The sample was then incubated in the presence of $1 \mu\text{M}$ PbCl_2 (in saline) and $1 \mu\text{M}$ ionomycin. After washing the sample, it was incubated in the presence of PI. Dual-color fluorescence was collected using 488 nm excitation and 525/10 nm and 610/10 nm bandpass filters. This results in visualization of two populations: dead cells (positive for PI) and live cells that contain lead (positive for Leadmium™ Green dye and negative for PI).

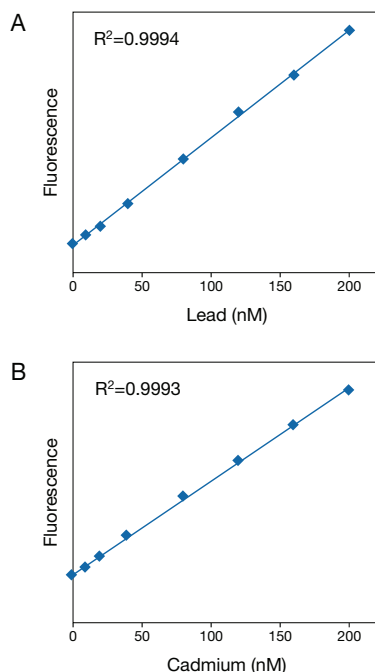

Figure 19.7.13 Linearity and sensitivity of the Measure-iT™ Lead and Cadmium Assay Kit (M36353) for lead (A) and cadmium (B). Triplicate $10 \mu\text{L}$ samples of lead and cadmium were assayed; fluorescence was measured at 490/520 nm and plotted versus lead or cadmium concentration. The variation (CV) of replicate samples was $<2\%$.

P14313) is quenched upon binding Fe^{2+} (Figure 19.7.2) and Fe^{3+} (Figure 19.7.4). The emission intensity of the Phen Green™ FL indicator depends on both the metal ion's concentration and the indicator's concentration.¹⁰³ Phen Green™ SK diacetate has been successfully used to quantitate the intracellular pool of chelatable iron in rat hepatocytes,^{102–104} to directly measure Fe^{2+} transport across chloroplast membranes¹⁰⁵ and to monitor iron uptake in relation to fatigue in mouse skeletal muscle.¹⁰¹

Calcein

Cabantchik and co-workers have exploited the fluorescence quenching of calcein at neutral pH to follow intracellular release of Fe^{2+} from transferrin.^{36,106,107} Using passively loaded calcein AM (C1430, C3099, C3100MP), they were able to measure cytosolic Fe^{2+} concentrations from about $0.1 \mu\text{M}$ to $1.0 \mu\text{M}$. However, more recent studies on the mechanism of iron chelation indicate that quenching of calcein fluorescence is primarily due to Fe^{3+} and is relatively insensitive to Fe^{2+} ¹⁰⁸ (Figure 19.7.4). Nontransferrin-bound iron (NTBI) occurs in the serum of individuals with iron overload and in a variety of other pathological conditions, including thalassemia. A microplate assay based on the fluorescence quenching of calcein by iron has been developed to measure NTBI.¹⁰⁹ The capacity of transition metals such as iron to catalyze the generation of oxidative radicals can be used as a basis for indirect detection using fluorescent ROS sensors (Section 18.2) under conditions where the metal ion is the limiting species. Dihydrorhodamine 123 (D632, D23806; Section 18.2) has been used in this way to detect NTBI in the plasma of healthy and thalassemic patients.¹¹⁰

Indicators for Lead, Cadmium and Mercury

Leadmium™ Green Indicator

Leadmium™ Green dye is a fluorescent indicator supplied in cell-permeant AM ester form (A10024) for selectively detecting lead or cadmium in cells. The calcium-insensitive Leadmium™ Green dye can detect nanomolar levels of lead and micromolar levels of cadmium (Figure 19.7.12). In a typical application, Leadmium™ Green AM was used to assess the effects of *N*-acetylcysteine on intracellular lead levels in oligodendrocyte progenitor cells.¹¹¹

Measure-iT™ Lead and Cadmium Assay Kit

The Measure-iT™ Lead and Cadmium Assay Kit (M36353) provides a fluorescence microplate assay for quantitation of lead or cadmium in solution, with a linear detection range from 5 to 200 nM.¹¹² (Figure 19.7.13). The Measure-iT™ Leadmium™ reagent working solution is mixed with 1–20 μL sample volumes in the wells of a microplate and then immediately analyzed with a fluorescence microplate reader using fluorescein/FITC wavelength settings. The assay is performed at room temperature, and the signal is stable for at least 30 minutes.

Each Measure-iT™ Lead and Cadmium Assay Kit contains:

- Measure-iT™ Leadmium™ reagent
- Concentrated Measure-iT™ Leadmium™ buffer
- Lead standard
- Cadmium standard
- Detailed protocol

Sufficient reagents are provided for 1000 assays using a fluorescence microplate reader.

Phen Green™ FL and Phen Green™ SK Indicators

Our phenanthroline-based Phen Green™ FL and Phen Green™ SK indicators (P14312), which can be passively loaded into cells as their membrane-permeant diacetates (P6763, P14313), are excellent general-purpose heavy metal sensors that are capable of detecting a broad range of metal ions—including Cu^{2+} , Cu^+ and Fe^{2+} —as well as micromolar concentrations of Hg^{2+} , Pb^{2+} , Cd^{2+} , Zn^{2+} and Ni^{2+} (Figure 19.7.4). We have used these versatile sensors

to detect metal ions in a variety of matrices, including seawater and various contaminated solids such as paint sludge and soil. In such samples, Phen Green™ FL and Phen Green™ SK detect only the readily soluble (bioavailable) fraction of the total metal ions. Phen Green™ FL and Phen Green™ SK are well suited for initial field testing of metal ion contamination in aqueous samples; the large fluorescence changes produced by micromolar ion concentrations of these heavy metals are easily visible upon illuminating the sample with a hand-held light source (Figure 19.7.2).

Traditional Ca²⁺ and Mg²⁺ Indicators as Pb²⁺, Cd²⁺ and Hg²⁺ Indicators

The fluorescence of several of our traditional Ca²⁺ and Mg²⁺ indicators is strongly affected by binding of Pb²⁺, Cd²⁺ and Hg²⁺ (Figure 19.7.3). Fura-2 and quin-2 bind Cd²⁺ with extremely high affinity (Table 19.5). The excitation response of fura-2 to Cd²⁺—almost identical to its Ca²⁺ response—has been used to monitor Cd²⁺ uptake by cells and to image intracellular free Cd²⁺.¹¹³ The response is reversed by TPEN (T1210, Section 19.8), which complexes many heavy metals but not Ca²⁺ or Mg²⁺.¹¹⁴ Heavy metal binding by rhod-5N (R14207, Section 19.3) has also been reported; the K_d(Cd²⁺) of rhod-5N was determined to be 1.4 nM.⁹

Mag-fura-2 AM (M1291, M1292; Section 19.6) has proven useful as an intracellular Cd²⁺ indicator,¹¹⁵ and indo-1 AM can be used to simultaneously determine the intracellular concentrations of Ca²⁺ and Cd²⁺ or Ca²⁺ and Ba²⁺.¹¹⁶ Use of fura-2 AM (F1201, F1221, F1225, F14185; Section 19.2) to measure the concentration of cytosolic Ba²⁺ has also been reported,¹¹ as has fluorometric detection of Cd²⁺ at pH 13.3 using calcein¹¹⁷ (C481). Pb²⁺ entry into cells has been monitored using fura-2 or indo-1 as intracellular indicators.^{118–122} Pb²⁺ is efficiently transported into cells with high selectivity by ionomycin¹²³ (I24222, Section 19.8).¹⁹ F NMR can also be used to detect Pb²⁺ uptake by platelets using fluorinated BAPTA derivatives¹²⁴ (Section 19.8).

Indicators for Nickel and Cobalt

Newport Green™ Indicators

Much of the recent interest in Ni²⁺ comes from its use in the detection and isolation of oligohistidine fusion proteins by metal-chelate affinity chromatography. Newport Green™ DCF indicator (N7990) is an exceptionally sensitive probe for Ni²⁺ in solution.⁵ 100 μM Ni²⁺ enhances the fluorescence of the Newport Green™ DCF reagent approximately 13-fold without a spectral shift; Zn²⁺ and Co²⁺ enhance this indicator's fluorescence to a lesser extent (Figure 19.7.4). Newport Green™ DCF diacetate (N7991) has been used to measure the cellular uptake of Ni²⁺ in human monocyte-derived dendritic cells.¹²⁵ Newport Green™ DCF and Newport Green™ DCF diacetate have also been used with flow cytometry to detect Ni²⁺-binding metalloproteins involved in human nickel allergy, the most common form of human contact hypersensitivity.¹²⁶ The AM ester of Newport Green™ PDX (N24191) incorporates the same di-(2-picolyl)amine chelator as Newport Green™ DCF and should prove to have similar utility for detection of Ni²⁺.

Traditional Ca²⁺ and Mg²⁺ Indicators as Ni²⁺ and Co²⁺ Indicators

Co²⁺ enhances the fluorescence of the Calcium Green™-2 indicator at least 20-fold and strongly quenches fluorescence of the Fura Red™ indicator (Figure 19.7.3). Co²⁺ and Ni²⁺, as well as Cu²⁺ and Fe³⁺ (Figure 19.7.4), strongly quench the fluorescence of calcein, even at pH 7.^{127–129} Consequently, it should be possible to follow the kinetics of uptake of these ions into cells loaded with calcein AM (C1430, C3099, C3100MP). Note that the 1:1 stoichiometry of calcein-metal binding will require the use of low loading levels of this probe to achieve significant quenching by limited amounts of metal transport. The efficient quenching of calcein fluorescence by Co²⁺ or Ni²⁺³⁶ has been used to detect liposome fusion¹²⁸ (Assays of Volume Change, Membrane Fusion and Membrane Permeability—Note 14.3). Fura-2 has been used to measure low levels of Ni²⁺ and Co²⁺ in solution.¹⁰

Indicators for Aluminum

Al³⁺ binding has little effect on the fluorescence of most of the traditional Ca²⁺ and Mg²⁺ indicators. However, Al³⁺ is reported to selectively form a fluorescent complex with calcein (C481) at acidic pH that can be detected with micromolar sensitivity.¹³⁰ Quenching of the Al³⁺-calcein complex fluorescence has been used as the basis of a method for fluoride determination, with a detection limit of 0.2 ng/mL.¹³¹

Newport Green™ DCF diacetate (N7991) has also been used to detect the uptake and distribution of several metal ions—including Al³⁺ and Ti³⁺—in human monocyte-derived dendritic cells by flow cytometry and confocal microscopy.¹²⁵ Although the intensities varied, intracellular Cr³⁺, Mo²⁺, Ni²⁺, Ti⁴⁺ and Zr⁴⁺ also produced a fluorescence response with Newport Green™ DCF diacetate.

Indicators for Lanthanides

La³⁺ has a strong effect on the fluorescence of indicators designed for detection of Ca²⁺, Mg²⁺ and Zn²⁺ (Figure 19.7.3). For example, fluo-4 fluorescence increases more than 400-fold in the presence of 100 μM La³⁺, a response that is about twice as large as that generated by Ca²⁺ saturation. Detection of La³⁺ by the prototypical BAPTA-based Ca²⁺ indicator quin-2 has been used to investigate the ion transport selectivity of 4-bromo A-23187 and ionomycin¹³² (B1494, I24222; Section 19.8). These indicators generally exhibit relatively weak responses to Tb³⁺; fluo-3 and fluo-4 are apparently the most sensitive (~40-fold fluorescence enhancement with 1 μM Tb³⁺) (Figure 19.7.3). Long-lived luminescence of Tb³⁺ (from TbCl₃, T1247) is also used to probe Ca²⁺ binding sites of proteins.¹³³ Fluo-5N (F14203; Section 19.3) is a low-affinity Ca²⁺ indicator with subnanomolar affinity for gadolinium (Gd³⁺), enabling its use for determining Gd³⁺-binding affinities of magnetic resonance imaging (MRI) contrast agents via competition titrations.¹³⁴

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- C481 fluorescence is strongly quenched by micromolar concentrations of Fe³⁺, Co²⁺, Ni²⁺ and Cu²⁺ at pH 7. (Am J Physiol (1995) 268:C1354, J Biol Chem (1999) 274:13375)
- K_d(Co²⁺) for calcein is 120 nM, determined in 10 mM HEPES, 1 μM Ca²⁺, 1 mM Mg²⁺, 100 mM KCl. (Anal Biochem (1997) 248:31)
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."

DATA TABLE 19.7 FLUORESCENT INDICATORS FOR Zn²⁺ AND OTHER METAL IONS—continued

- Dissociation constants are known to vary considerably depending on the temperature, pH, ionic strength, viscosity, protein binding, presence of other ions (especially polyvalent ions), instrument setup and other factors. It is strongly recommended that these values be verified under user-specific experimental conditions.
- Spectra measured in aqueous buffers containing zero (H₂O) or a >10-fold excess of free cation X (H₂O/X) relative to the listed dissociation constant (K_d) for cation X.
- This indicator exhibits fluorescence enhancement in response to ion binding, with essentially no change in absorption or emission wavelengths.
- Fluorescence of the free indicator is very weak and is enhanced >100-fold on binding Zn²⁺.
- Fluorescence of this AM ester derivative is very weak and is enhanced only after hydrolytic cleavage followed by binding of divalent cations to the anionic indicator.
- K_d(Zn²⁺) determined in 135 mM NaCl, 1.1 mM EGTA, 20 mM HEPES, pH 7.4, 0 to 10 μM free Zn²⁺ at 22°C. K_d(Zn²⁺) is unchanged in the presence of 1 μM free Ca²⁺. (J Am Chem Soc (2002) 124:776, Cell Calcium (2003) 34:281)
- Fluorescence of M688 is very sensitive to solvent polarity. Em = 495 nm in aqueous buffer (pH 7.4). Fluorescence is enhanced on binding Zn²⁺ (0.01–10 μM) with no change in emission wavelength. (Cytometry (1995) 21:153)
- Fluorescence of Phen Green™ indicators is quenched by Fe²⁺, Fe³⁺, Cu²⁺, Cd²⁺, Hg²⁺ and Pb²⁺ with no change in emission wavelength. The extent of quenching is dependent on the concentration of indicator as well as the ion concentration.
- Spectra measured in 90:10 (v/v) CHCl₃:MeOH.
- Absorption and luminescence of T1247 are extremely weak unless it is chelated. Data are for dipicolinic acid (DPA) chelate. The luminescence spectrum has secondary peak at 490 nm.
- MW is for the hydrated form of this product.

PRODUCT LIST 19.7 FLUORESCENT INDICATORS FOR Zn²⁺ AND OTHER METAL IONS

Cat. No	Product	Quantity
C481	calcein *high purity*	100 mg
C1430	calcein, AM	1 mg
C3099	calcein, AM *1 mg/mL solution in anhydrous DMSO*	1 mL
C3100MP	calcein, AM *special packaging*	20 x 50 μg
F24181	FluoZin™-1, AM *cell permeant*	50 μg
F24180	FluoZin™-1, tripotassium salt *cell impermeant*	500 μg
F24189	FluoZin™-2, AM *cell permeant*	50 μg
F24195	FluoZin™-3, AM *cell permeant*	100 μg
F24194	FluoZin™-3, tetrapotassium salt *cell impermeant*	500 μg
A10024	Leadmium™ Green, AM dye *for intracellular detection of lead and cadmium* *special packaging*	5 x 50 μg
M36353	Measure-iT™ Lead and Cadmium Assay Kit *1000 assays*	1 kit
M688	N-(6-methoxy-8-quinolyl)-p-toluenesulfonamide (TSQ)	25 mg
N7991	Newport Green™ DCF diacetate *cell permeant*	1 mg
N7990	Newport Green™ DCF, dipotassium salt *cell impermeant*	1 mg
N24191	Newport Green™ PDX acetoxymethyl ether	1 mg
P6763	Phen Green™ FL, diacetate *cell permeant*	1 mg
P14313	Phen Green™ SK, diacetate	1 mg
P14312	Phen Green™ SK, dipotassium salt	1 mg
R36351	RhodZin™-3, AM *cell permeant* *special packaging*	10 x 50 μg
R36350	RhodZin™-3, dipotassium salt *cell impermeant*	500 μg
T1247	terbium(III) chloride, hexahydrate	1 g

19.8 Chelators, Calibration Buffers, Ionophores and Cell-Loading Reagents

Caged Calcium and Caged Calcium Chelators

Nitrophenyl EGTA: A Superior Caged Calcium Reagent

As an alternative to solely monitoring Ca²⁺ changes using fluorescent indicators, scientists may want to rapidly raise or lower the intracellular Ca²⁺ concentration and study the physiological response that results. Ellis-Davies and Kaplan have developed a photolabile chelator, *o*-nitrophenyl EGTA (NP-EGTA, N6802) that exhibits a high selectivity for Ca²⁺, a dramatic 12,500-fold decrease in affinity for Ca²⁺ upon UV illumination (its K_d increases from 80 nM to >1 mM) and a high photochemical quantum yield^{1,2} (~0.2). Photolysis of NP-EGTA is slightly faster than that of DMNP-EDTA,³ another "caged Ca²⁺" reagent that is frequently called DM-Nitrophen™. Furthermore, with a K_d for Mg²⁺ of 9 mM, NP-caged EGTA does not bind physiological levels of Mg²⁺ and thus reduces interference from this abundant cation.⁴ Skinned muscle fibers equilibrated with NP-EGTA were shown to contract maximally upon irradiation with a single flash from a frequency-doubled ruby laser⁵ (347 nm illumination). Other suitable ultraviolet light sources for photoactivation of NP-EGTA include mercury arc lamps (365 nm), frequency-tripled Nd:YAG lasers⁶ (355 nm), UV argon-ion laser lines⁷ (351/364 nm) and light-emitting diodes⁸ (LED). NP-EGTA is not suitable for two-photon photoactivation due to its extremely low absorption cross section in the wavelength range accessible with femtosecond pulsed Ti:sapphire laser sources.⁹

We offer the tetrapotassium salt (N6802) and the acetoxymethyl (AM) ester (NP-EGTA AM, N6803) of NP-EGTA. The NP-EGTA salt can be complexed with Ca²⁺ to generate a caged Ca²⁺ reagent that will rapidly deliver Ca²⁺ upon photolysis (Figure 19.8.1). The cell-permeant AM ester of NP-EGTA does not bind Ca²⁺ unless its AM ester groups are removed. NP-EGTA AM can serve as a photolabile buffer in cells because, once converted to NP-EGTA by intracellular esterases, it will bind Ca²⁺ with high affinity until photolyzed with UV light.¹⁰

DMNP-EDTA

The first caged Ca²⁺ reagent to be described by Kaplan and Ellis-Davies was 1-(4,5-dimethoxy-2-nitrophenyl)-EDTA (DMNP-EDTA, D6814), which they named DM-Nitrophen™^{11,12} (now a trademark of Calbiochem-Novabiochem Corp.). Because its structure more closely resembles that of EDTA than EGTA, we named it as a caged EDTA derivative (Figure 19.8.2). Upon illumination, DMNP-EDTA's dissociation constant for Ca²⁺ increases from 5 nM to 3 mM. Thus, photolysis of DMNP-EDTA complexed with Ca²⁺ results in a pulse of free Ca²⁺. Furthermore, DMNP-EDTA has significantly higher affinity for Mg²⁺ (K_d = 2.5 μM) than does NP-EGTA¹¹ (K_d = 9 mM). Because the photolysis product's K_d for Mg²⁺ is ~3 mM, DMNP-EDTA is an effective caged Mg²⁺ source, in addition to its applications for photolytic Ca²⁺ release.^{13,14} Photorelease of Ca²⁺ has been shown to occur in <180 μsec, with even faster photorelease of Mg²⁺.¹⁵ Moreover, DMNP-EDTA is also useful for photolytic release of other divalent cations such as Sr²⁺, Ba²⁺, Mn²⁺, Co²⁺ and Cd²⁺.¹⁶ Unlike NP-EGTA, DMNP-EDTA has a low but finite two-photon absorption cross-section in the wavelength range accessible with femtosecond pulsed Ti:sapphire laser sources⁹ and can therefore be used to produce two-photon activated calcium release with high spatial precision (Figure 19.8.3). Two reviews by Ellis-Davies discuss the uses and limitations of DMNP-EDTA.^{1,17}

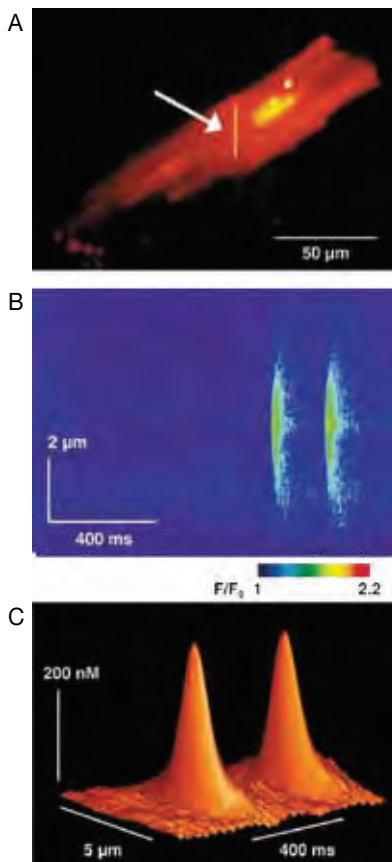

Figure 19.8.3 A) Confocal image of a guinea pig ventricular myocyte filled with fluo-3, pentapotassium salt (F3715). The vertical yellow line (arrow) indicates the region scanned repetitively to generate the line-scan image shown in panel B. B) Two precisely localized Ca²⁺ transients were elicited by two-photon photolysis of DMNP-EDTA (D6814) using ultrafast high-repetition (120 fs, 80 MHz) laser pulses at 700 nm. The color scale bar represents fluo-3 fluorescence intensities corresponding to resting (blue) to high (red) Ca²⁺ concentrations. C) Surface plot of Ca²⁺ concentration plotted against space and time. The spatial spread of the Ca²⁺ transients was about 2 μm at half-maximum amplitude. Images contributed by Ernst Niggli, University of Bern, and reproduced with permission from Nat Cell Biol (1999) 1:323.

Figure 19.8.1 NP-EGTA (N6802) complexed with Ca²⁺. Upon illumination, this complex is cleaved to yield free Ca²⁺ and two iminodiacetic acid photoproducts. The affinity of the photoproducts for Ca²⁺ is ~12,500-fold lower than that of NP-EGTA.

Figure 19.8.2 DMNP-EDTA (D6814) complexed with Ca²⁺. Upon illumination, this complex is cleaved to yield free Ca²⁺ and two iminodiacetic acid photoproducts. The affinity of the photoproducts for Ca²⁺ is ~600,000-fold lower than that of DMNP-EDTA.

Diazo-2: A Photoactivatable Calcium Knockdown Reagent

In contrast to NP-EGTA and DMNP-EDTA, diazo-2 is a photoactivatable Ca²⁺ scavenger. Diazo-2 (D3034, Figure 19.8.4), which was introduced by Adams, Kao and Tsien,^{18,19} is a relatively weak chelator (K_d for Ca²⁺ = 2.2 μM). Following flash photolysis at ~360 nm, however, cytosolic free Ca²⁺ rapidly binds to the high-affinity photolysis product of diazo-2 (K_d = 73 nM). Microinjecting a relatively low concentration of a visible light-excitabile Ca²⁺ indicator—such as fluo-3, fluo-4 or one of our Calcium Green™ or Oregon Green® 488 BAPTA indicators—along with a known quantity of diazo-2 permits measurement of the extent of depletion of cytosolic Ca²⁺ following photolysis. Diazo-2 can be microinjected into larger cells⁴ or electroporated into smaller cells²⁰ as its potassium salt (D3034). Intracellular loading of NP-EGTA, DMNP-EDTA and diazo-2 is best accomplished by patch pipette infusion with the carboxylate salt form of the caged compound added to the internal pipette solution at 1–10 mM.^{21,22}

Figure 19.8.4 Diazo-2, tetrapotassium salt (D3034).

Nonfluorescent Chelators

BAPTA and BAPTA AM

The bis(2-aminophenoxy)ethane tetraacetic acid (BAPTA, Figure 19.8.5) buffers developed by Tsien²³ are highly selective for Ca²⁺ over Mg²⁺ and can be used to control the level of both intracellular and extracellular Ca²⁺ (Table 19.7, Figure 19.8.6). The BAPTA buffers are more selective for Ca²⁺ than EDTA and EGTA, and their metal binding is also much less pH sensitive. Furthermore, BAPTA buffers bind and release Ca²⁺ ions about 50–400 times faster than EGTA. Both BAPTA and its membrane-permeant AM ester are extensively used to clamp intracellular Ca²⁺ concentrations, providing insights on the role of free cytosolic Ca²⁺ in a number of important cell systems.^{24–26} BAPTA AM (or the higher-affinity 5,5'-dimethyl BAPTA AM) is also useful for establishing an intracellular zero free calcium level for *in situ* calibrations of fluorescent indicators (Loading and Calibration of Intracellular Ion Indicators—Note 19.1). BAPTA and its derivatives also exert physiological effects that are somewhat independent of their calcium-binding activity.^{27,28}

BAPTA is available as a cell-impermeant potassium, cesium²⁹ or sodium salt (B1204, B1212, B1214); the Cs⁺ salt of BAPTA has frequently been used for patch-clamp experiments.²⁹ In addition, we offer the cell-permeant BAPTA AM ester in two packaging formats (B1205, B6769). In addition to these products, we offer a polystyrene conjugate of BAPTA for selective removal of Ca²⁺ from solutions, which we call Calcium Sponge™ S (C3047).

Figure 19.8.5 BAPTA, tetrapotassium salt (B1204).

Figure 19.8.6 Absorption spectra of BAPTA (B1204) in solutions containing 0–39.8 μM free Ca²⁺.

Other BAPTA Derivatives

Other BAPTA derivatives are listed in Table 19.7, along with their dissociation constants for Ca²⁺. The most powerful Ca²⁺ chelator among these is 5,5'-dimethyl BAPTA,^{30–33} available as its cell-permeant AM ester (D1207).

BAPTA derivatives with intermediate affinity for Ca²⁺, such as 5,5'-dibromo BAPTA (D1211), have been extensively used to study Ca²⁺ mobilization, spatial Ca²⁺ buffering and Ca²⁺ shuttling in a variety of cells and animal models.^{34–36} 5,5'-Dibromo BAPTA and other lower-affinity chelators protect neurons against excitotoxic and ischemic injury, without markedly attenuating intracellular Ca²⁺ levels.³⁷

Fluorinated BAPTA derivatives, such as the AM ester of 5,5'-difluoro BAPTA (D1209), have been employed for optical imaging studies^{38,39} but are most widely used for NMR analysis of Ca²⁺ in live cells and tissues. The ¹⁹F NMR shifts of the 5,5'-difluoro BAPTA have been reported to correlate with intracellular Ca²⁺ in BALB/c thymocytes,⁴⁰ normal⁴¹ and sickle⁴² erythrocytes and ferret hearts.^{43,44}

Table 19.7 Ca²⁺ affinities of BAPTA chelators.

Chelator	Water-Soluble Salt	Cell-Permeant Ester	K _d for Ca ²⁺

NOTE 19.2**MAXC Computer Program for Calculating Free Ca²⁺ Concentrations**

In solutions that contain several chelating species, or that contain ions such as Zn²⁺ that compete with Ca²⁺ for binding to BAPTA or EGTA, calculating the free Ca²⁺ concentration requires simultaneously solving multiple equilibrium expressions. Except for the simplest cases where analytical solutions are feasible, researchers must use an iterative computer program to complete these calculations. MAXC, a program developed for this purpose,¹ is freely accessible on the Web at www.stanford.edu/~cpatton/maxc.html.

1. *Methods Cell Biol* (1994) 40:3.

Figure 19.8.7 EGTA, tetra (acetoxymethyl ester) (EGTA, AM; E1219).

Figure 19.8.8 (S)-1-p-isothiocyanatobenzyl-diethylenetriaminepentaacetic acid (DTPA isothiocyanate, I24221).

Figure 19.8.9 Tetrakis-(2-pyridylmethyl)ethylenediamine (TPEN, T1210).

EGTA AM

The AM ester derivative of EGTA (E1219, Figure 19.8.7) can be passively loaded into cells to generate intracellular EGTA. The slower on-rate of EGTA relative to the BAPTA-based buffers reduces its ability to inhibit Ca²⁺ diffusion in cells.⁴⁵ Because Ca²⁺ binding by intracellular EGTA is relatively slow it is possible to distinguish between buffering of rapid Ca²⁺ transients, which can occur with BAPTA-derived buffers, and the slower effects of general Ca²⁺ buffering.^{37,46,47}

DTPA Isothiocyanate

DTPA isothiocyanate (I24221) can be coupled to antibodies and other biomolecules by conventional amine-reactive chemistry, thereby introducing a high-affinity binding site for lanthanides and other metal ions. Unlike reactive anhydride forms of DTPA, the isothiocyanate derivative yields conjugates that retain all five carboxylate groups (Figure 19.8.8), resulting in more stable metal complexation.⁴⁸ Antibodies and ligands labeled with the fluorescent lanthanides europium and terbium (T1247, Section 19.7) are widely utilized in time-resolved fluorescence-based assays.⁴⁹ DTPA-gadolinium (Gd³⁺) complexes are extensively used as contrast agents for magnetic resonance imaging.⁵⁰ DTPA isothiocyanate-labeled antibodies also have potentially important therapeutic applications for targeted delivery of radionuclides such as indium-111 and yttrium-90.⁵¹

Calcium Sponge™ Polymer

We offer a biologically compatible conjugate of the BAPTA chelator to selectively remove specific polyvalent ions from solution, as well as from the binding sites of indicators, proteins and polynucleotides. This BAPTA polystyrene conjugate—Calcium Sponge™ S—is selective for Ca²⁺ and certain other ions, including Zn²⁺ and some heavy metals, in the presence of relatively high levels of Mg²⁺. Many contaminating polycations can be selectively removed from aqueous solutions simply by stirring a solution with the water-insoluble Calcium Sponge™ S polymer^{52,53} (BAPTA polystyrene, C3047). For example, free Ca²⁺ can be reduced to less than 40 nM (measured with fura-2) by passing 3 mL of a 100 μM CaCl₂ solution through one gram of Calcium Sponge™ S. The polymer can be regenerated several times by washing it with pH 4 buffer, then readjusting to neutral pH with base.

TPEN

TPEN (T1210, Figure 19.8.9) selectively chelates intracellular heavy metal ions such as Zn²⁺, Cu²⁺ and Fe²⁺ without disturbing Ca²⁺ and Mg²⁺ concentrations, revealing distortions in intracellular Ca²⁺ measurements caused by high-affinity binding of these ions to fluorescent indicators.^{54–57} TPEN has been used to show that the effects of BAPTA on mitotic progression and nuclear assembly are specifically Ca²⁺-mediated and are not attributable to binding of essential heavy metal ions.^{58,59} TPEN has also been used to modulate the effects of Zn²⁺ on enzymatic activity⁶⁰ and protein conformation.⁶¹

Calcium Calibration Buffer Kits

Calibration of fluorescent Ca²⁺ indicators is a prerequisite for accurate Ca²⁺ measurements. We offer kits designed to facilitate this calibration using a laboratory fluorometer or quantitative imaging system. These kits contain buffers and detailed protocols—including methods for calculating K_d, a sample response curve and tables to help determine the exact concentration of free Ca²⁺ under conditions of varying pH, temperature and ionic strength. A discussion of methods to correct the fura-2 dissociation constants for differences in temperature and ionic strength has been published.⁶² A computer program is available online for calculating the free Ca²⁺ concentrations in solutions that contain several chelating species, or that contain ions such as Zn²⁺ that compete with Ca²⁺ for binding to BAPTA or EGTA (MAXC Computer Program for Calculating Free Ca²⁺ Concentrations—Note 19.2).

Calcium Calibration Buffer Kit #1

Because cells contain very low levels of free Ca²⁺, it is essential to use Ca²⁺ buffers such as EGTA to precisely calibrate Ca²⁺ indicators under specific experimental conditions. When the concentrations of Ca²⁺ and EGTA are very close to each other, the only free Ca²⁺ available is the

Ca²⁺ that is in equilibrium with EGTA. Thus, the concentration of free Ca²⁺ is determined by the K_d of CaEGTA at a controlled pH, temperature and ionic strength.⁶³

Calcium Calibration Buffer Kit #1 (C3008MP) contains:

- 10 mM K₂EGTA buffered solution ("zero" free Ca²⁺)
- 10 mM CaEGTA buffered solution (40 μM free Ca²⁺)
- Detailed protocols for calibrating Ca²⁺ indicators

When used according to the protocol provided, each kit provides sufficient reagents for five complete calibrations using 2 mL samples and a standard fluorometer cuvette. Many more calibrations can be done by digital imaging microscopy.^{64,65} This kit employs a reciprocal dilution method—an equal amount of dye is added to a portion of the zero and 40 μM free Ca²⁺ solutions, and the two are then cross-mixed to give a series of solutions with equal dye and varying free Ca²⁺ concentrations. With ratiometric indicators, this method yields a series of curves that exhibit an accurate isosbestic point (see, for example, Figure 19.8.10); it is the method regularly used in our laboratories to determine Ca²⁺ affinities. *In situ* calibrations of intracellular calcium indicators can be carried out using CaEGTA buffer solutions in combination with a suitable ionophore such as ionomycin (I24222).⁶⁶

Fura-2 Calcium Imaging Calibration Kit

The Fura-2 Calcium Imaging Calibration Kit (F6774) is designed to facilitate rapid calibration and standardization of digital imaging microscopes.^{67,68} This kit provides 11 CaEGTA:EGTA buffer solutions with free Ca²⁺ concentrations from zero to 40 μM. Each solution also includes 50 μM fura-2, as well as 15 μm unstained polystyrene microspheres to act both as spacers that ensure uniform separation between the slide and the coverslip and as focusing aids. We also provide a twelfth buffer, identical to the 10 mM CaEGTA standard but lacking fura-2, that serves as a control for background fluorescence.

Figure 19.8.10 Fluorescence excitation spectra of fura-2 (F1200, F6799) in solutions containing 0–39.8 μM free Ca²⁺.

Figure 19.8.12 Adherent CRE BAG 2 cells passively loaded with the membrane-impermeant polar tracer Alexa Fluor[®] 594 hydrazide (A10438, A10442). The image on the left illustrates the relatively uniform, cytoplasmic labeling one can obtain with the Influx[™] pinocytotic cell-loading reagent (I14402), compared to the punctate labeling that results from pinocytotic uptake in normal growth medium (right panel). Both images were acquired using a bandpass filter set appropriate for rhodamine dyes.

Influx[™] Pinocytotic Cell-Loading Reagent

The Influx[™] pinocytotic cell-loading reagent (I14402) facilitates the loading of water-soluble materials into live cells via a rapid and simple technique based on the osmotic lysis of pinocytotic vesicles.⁶⁹ Simply mix the water-soluble probe at high concentration with the Influx[™] reagent blended into growth medium, then incubate the cells in the medium to allow pinocytotic uptake of the surrounding solution. When the cells are subsequently transferred to a slightly hypotonic medium, pinocytotic vesicles within the cells release the trapped material and fill the cytosol with the probe (Figure 19.8.11).

The Influx[™] pinocytotic cell-loading reagent is effective for loading a diverse array of probes—including calcein, Alexa Fluor[®] hydrazides (Figure 19.8.12), dextran conjugates of fluorophores⁷⁰ and ion indicators (Figure 19.8.13), fura-2 salts, Oregon Green[®] 514 dye-labeled tubulin, Alexa Fluor[®] 488 dye-labeled actin, heparin,⁷¹ DNA, siRNAs,⁷² antisense oligonucleotides^{73,74} and Qdot[®] nanocrystals^{75,76}—into a variety of cell lines.

Figure 19.8.11 Principle of the Influx[™] reagent pinocytotic cell-loading method (I14402). Cultured cells are placed in hypertonic Influx[™] loading reagent (A), along with the material to be loaded into the cells (yellow fluid, B), allowing the material to be carried into the cells via pinocytotic vesicles. When the cells are placed in hypotonic medium, the pinocytotic vesicles burst (C), releasing their contents into the cytosol (D).

Figure 19.8.13 Adherent 3T3 fibroblasts labeled with 3000 MW Texas Red[®] dextran (D3329) and 70,000 MW Calcium Green[™]-1 dextran (C3714). Both dextrans were loaded into the fibroblasts using the Influx[™] pinocytotic cell-loading reagent (I14402). The images were acquired using a fluorescence microscope equipped with a cooled CCD camera and bandpass filter sets appropriate for either the Texas Red[®] dye (left image) or fluorescein (right image). The center image represents a composite of the cells labeled with both dextrans. The 3000 MW Texas Red[®] dextran is distributed throughout the cell, but the 70,000 MW Calcium Green[™]-1 dextran is excluded from the nucleus by the nuclear membrane.

In addition to the Influx™ pinocytic cell-loading reagent and cell growth medium, all that is required to perform the loading procedure is sterile deionized water and the fluorescent probe or other polar molecule of interest. Cell labeling can be accomplished in a single 30-minute loading cycle and may be enhanced by repetitive loading. Although most types of cells load quickly and easily, optimal conditions for loading must be determined for each cell type. It is also important to note that cell-to-cell variability in the degree of loading is typical and that higher variability is generally observed when using large compounds, such as >10,000 MW dextrans and proteins.

The Influx™ pinocytic cell-loading reagent is packaged as a set of 10 tubes (I14402), each containing sufficient material to load 50 samples of cells grown on coverslips following the standard protocol supplied. Cells in suspension or in culture flasks may also be easily loaded; however, the number of possible cell loadings will depend on the cell suspension volume or size of culture flask used. The information provided with the Influx™ reagent includes general guidelines and detailed suggestions for optimizing cell loading. Use of the coverslip mini-rack or coverslip maxi-rack (C14784, C24784; Section 23.1) facilitates cell loading and slide handling when using the Influx™ reagent.

Loading P2X Receptor-Expressing Cells

P2X₇ receptor-expressing cells such as macrophages and thymocytes exhibit reversible pore opening that can be exploited to provide an entry pathway for intracellular loading of both cationic and anionic fluorescent dyes with molecular weights of up to 900 daltons.⁷⁷ Pore opening is induced by treatment with 5 mM ATP for five minutes and subsequently reversed by addition of divalent cations (Ca²⁺ or Mg²⁺). Dyes that have been successfully loaded into macrophage cells by this method include:

- Ca²⁺ indicator: fura-2⁷⁸ (F1200, F6799; Section 19.2)
- pH indicator: HPTS⁷⁹ (H348, Section 20.2)
- Aqueous tracers: lucifer yellow CH (L453, L682, L1177, L12926; Section 14.3) and sulforhodamine B⁸⁰ (S1307, Section 14.3)
- Nucleic acid stain: YO-PRO[®]-1^{80,81} (Y3603, Section 8.1)

We offer one of the most potent and widely used P2X receptor agonists, BzBzATP⁸²⁻⁸⁴ (2'-(or 3')-O-(4-benzoylbenzoyl)adenosine 5'-triphosphate, B22358, Section 17.3). BzBzATP has more general applications for site-directed irreversible modification of nucleotide-binding proteins via photoaffinity labeling;^{85,86} see Section 17.3 for more information on nucleotide analogs.

Figure 19.8.14 Chemical structures of the ionophores A-23187 (R = H, A1493) and 4-bromo A-23187 (R = Br, B1494).

Ionophores

A-23187 and 4-Bromo A-23187

The Ca²⁺ ionophore A-23187 (A1493, Figure 19.8.14) is commonly used for *in situ* calibrations of fluorescent Ca²⁺ indicators, to equilibrate intracellular and extracellular Ca²⁺ concentrations and to permit Mn²⁺ to enter the cell to quench intracellular dye fluorescence. Although the intrinsic fluorescence of A-23187 is too high for use with fura-2, indo-1 and quin-2, it is suitable for use with the visible light-excitable indicators, including Calcium Green™, Magnesium Green™, Calcium Orange™, Calcium Crimson™, Oregon Green® 488 BAPTA, fluo-3, fluo-4, rhod-2, X-rhod-1 and Fura Red™ indicator. Brominated A-23187 (4-bromo A-23187, B1494; Figure 19.8.14), which is essentially nonfluorescent, is the best ionophore for use with fura-2, indo-1 and other UV light-excited Ca²⁺ indicators. Like A-23187, 4-bromo A-23187 rapidly transports both Ca²⁺ and Mn²⁺ into cells.⁸⁷ Both A-23187 and 4-bromo A-23187 can also be used to equilibrate intracellular and extracellular Mg²⁺ concentrations, making them useful for calibrating Mg²⁺ indicators (Section 19.6). Furthermore, 4-bromo A-23187 has occasionally been used to equilibrate intracellular Zn²⁺ with controlled extracellular levels for *in situ* calibration of fluorescent indicators.⁸⁸ The zero reference level for intracellular Zn²⁺ calibrations is usually set by addition of TPEN⁸⁹ (K_d for Zn²⁺ = 2.6 × 10⁻¹⁶ M).

Ionomycin

Ionomycin (I24222, Figure 19.8.15) is an effective Ca²⁺ ionophore that is commonly used both to modify intracellular Ca²⁺ concentrations and to calibrate fluorescent Ca²⁺ indicators when studying the regulatory properties of Ca²⁺ in cellular processes. Ionomycin also transports Pb²⁺ and some other divalent cations, as well as several lanthanide series trivalent cations, at efficiencies that are greater than or equal to those for Ca²⁺.^{90,91}

Probenecid: Inhibitor of Organic-Anion Transporters

Probenecid (P36400) is commonly used to inhibit organic-anion transporters located in the cell membrane. Such transporters can extrude dyes and indicators and thus contribute to poor loading or a high background signal in assays based on retention of the dyes or indicators inside cells.⁹² The use of probenecid to block the efflux of intracellular dyes was first reported by Di Virgilio and co-workers.⁹³ Wash steps or masking dyes may be incorporated into fluorescent assays in order to minimize baseline fluorescence. However, washing introduces an extra

Figure 19.8.15 Ionomycin, calcium salt (I24222).

step that is undesirable for high-throughput applications and that may also risk loss of nonadherent cells. Masking dyes, while offering the advantage of homogeneous (one-step, mix-and-read) assays, may interact negatively with some receptor systems of interest.⁹⁴ Our water-soluble probenecid (P36400) has the advantage of being easy to dissolve in physiological buffers, unlike the conventionally used free acid form, which must be initially dissolved in strong base.

Pluronic® F-127 and PowerLoad™ Solutions

Pluronic® F-127

Because acetoxymethyl (AM) esters have low aqueous solubility,⁹⁵ dispersing agents—typically fetal calf serum, bovine serum albumin or Pluronic® F-127—are often used to facilitate cell loading.^{96,97} Pluronic® F-127 has also proven useful as a blocking reagent to prevent cell adhesion to PDMS (polydimethylsiloxane, a silicon-based organic polymer) microfluidic channels.⁹⁸ We provide Pluronic® F-127 in three forms, all of which have low UV absorbance (OD_{280 nm} <0.02 at 10 mg/mL):

- Powder (P6867)
- 10% Solution in water (P6866), filtered through a 0.2 µm-pore size membrane filter for use in tissue culture and other applications
- 20% Solution in DMSO (P3000MP)

Cautioning that Pluronic® F-127 is not necessarily physiologically benign, a recent paper shows a Pluronic® F-127-dependent modulation of depolarization-evoked Ca²⁺ transients in rat dorsal ganglion (DRG) neurons, as detected with fura-2 AM⁹⁹ (F1201, F1221, F1225, F14185; Section 19.2).

PowerLoad™ Concentrate

PowerLoad™ concentrate (P10020) is an optimized formulation of non-ionic Pluronic® surfactants that act to disperse and stabilize water-insoluble dyes in aqueous solution, thereby facilitating cellular uptake from aqueous dispersions.¹⁰⁰ The PowerLoad™ reagent is supplied as a ready-to-use concentrate in sterile water that is mixed with the dye stock solution (typically prepared in DMSO) and then diluted 1:100 into serum-free medium for direct application to adherent cells on coverslips, in microplate wells or in other suitable incubation chambers (Section 23.1).

Notes

- Dissociation constants are known to vary considerably depending on the temperature, pH, ionic strength, viscosity, protein binding, presence of other ions (especially polyvalent ions), instrument setup and other factors. It is strongly recommended that these values be verified under user-specific experimental conditions.
- Dissociation constant determined from absorption measurements in 100 mM KCl, 10 mM MOPS, pH 7.2 at 22°C. Ca²⁺ concentrations below 5 μM were controlled using CaEGTA buffering (Calcium Calibration Buffer Kit #1, C3008MP).
- BAPTA is weakly fluorescent in aqueous solutions (Em = 363 nm, QY = 0.03). (Biochemistry (1980) 19:2396)
- Absorption spectra of BAPTA and its derivatives are Ca²⁺ dependent.
- Abs and EC values determined in Ca²⁺-free solution (100 mM KCl, 10 mM EGTA, 10 mM MOPS, pH 7.2).
- ND = not determined.
- This compound has weaker visible absorption at >300 nm but no discernible absorption peaks in this region.
- Dissociation constant determined in CaEGTA buffers in 100 mM KCl, 10 mM MOPS, pH 7.3. (Biochemistry (1980) 19:2396)
- 5,5'-Difluoro BAPTA dissociation constant determined in 115 mM KCl, 20 mM NaCl, 10 mM MOPS, pH 7.3. (Am J Physiol (1994) 266:C1313, Am J Physiol (1987) 252:C441)
- The Ca²⁺ dissociation constant of diazo-2 is 2200 nM before photolysis and 73 nM after ultraviolet photolysis. The absorption spectrum of the photolysis product is similar to that of B1204. (J Am Chem Soc (1989) 111:7957)
- All photoactivatable probes are sensitive to light. They should be protected from illumination except when photolysis is intended.
- K_d(Ca²⁺) increases from 5 nM to 3 mM after ultraviolet photolysis. K_d values determined in 130 mM KCl, 10 mM HEPES, pH 7.1. (Proc Natl Acad Sci U S A (1988) 85:6571)
- This product is intrinsically a liquid or an oil at room temperature.
- Isothiocyanates are unstable in water and should not be stored in aqueous solution.
- K_d(Ca²⁺) increases from 80 nM to 1 mM after ultraviolet photolysis. K_d values determined in 100 mM KCl, 40 mM HEPES, pH 7.2. (Proc Natl Acad Sci U S A (1994) 91:187)
- N6803 is converted to N6802 via hydrolysis of its acetoxymethyl ester (AM) groups.
- TPEN has very high affinity for Zn²⁺ (K_d = 2.6 × 10⁻¹⁶ M), Fe²⁺ (K_d = 2.4 × 10⁻¹⁵ M) and Mn²⁺ (K_d = 5.4 × 10⁻¹¹ M) but relatively low affinity for Ca²⁺ (K_d = 4.0 × 10⁻⁵ M) and Mg²⁺ (K_d = 2.0 × 10⁻² M). (J Biol Chem (1985) 260:2719)

PRODUCT LIST 19.8 CHELATORS, CALIBRATION BUFFERS, IONOPHORES AND CELL-LOADING REAGENTS

Cat. No.	Product	Quantity
A1493	A-23187 free acid (calcimycin)	10 mg
B1205	BAPTA, AM *cell permeant*	25 mg
B6769	BAPTA, AM *cell permeant* *special packaging*	20 x 1 mg
B1212	BAPTA, tetra cesium salt *cell impermeant*	1 g
B1204	BAPTA, tetrapotassium salt *cell impermeant*	1 g
B1214	BAPTA, tetrasodium salt *cell impermeant*	1 g
B1494	4-bromo A-23187, free acid	1 mg
C3008MP	Calcium Calibration Buffer Kit #1 *zero and 10 mM CaEGTA (2 x 50 mL)*	1 kit
C3047	Calcium Sponge™ S (BAPTA polystyrene)	1 g
D3034	diazo-2, tetrapotassium salt *cell impermeant*	1 mg
D1211	5,5'-dibromo BAPTA, tetrapotassium salt *cell impermeant*	100 mg
D1209	5,5'-difluoro BAPTA, AM *cell permeant*	25 mg
D6814	1-(4,5-dimethoxy-2-nitrophenyl)-1,2-diaminoethane- <i>N,N,N',N'</i> -tetraacetic acid (DMNP-EDTA) *cell impermeant*	5 mg
D1207	5,5'-dimethyl BAPTA, AM *cell permeant*	25 mg
E1219	EGTA, tetra(acetoxymethyl ester) (EGTA, AM)	10 mg
F6774	Fura-2 Calcium Imaging Calibration Kit *zero to 10 mM CaEGTA, 50 μM fura-2 (11 x 1 mL)*	1 kit
I14402	Influx™ pinocytic cell-loading reagent *makes 10 x 5 mL*	1 set
I24222	ionomycin, calcium salt	1 mg
I24221	(S)-1- <i>p</i> -isothiocyanatobenzyl diethylenetriaminepentaacetic acid (DTPA isothiocyanate)	1 mg
N6803	<i>o</i> -nitrophenyl EGTA, AM (NP-EGTA, AM) *cell permeant* *special packaging*	20 x 50 μg
N6802	<i>o</i> -nitrophenyl EGTA, tetrapotassium salt (NP-EGTA) *cell impermeant*	1 mg
P6866	Pluronic® F-127 *10% solution in water* *0.2 μm filtered*	30 mL
P3000MP	Pluronic® F-127 *20% solution in DMSO*	1 mL
P6867	Pluronic® F-127 *low UV absorbance*	2 g
P10020	PowerLoad™ concentrate, 100X	5 mL
P36400	probenecid, water soluble	10 x 77 mg
T1210	tetrakis-(2-pyridylmethyl)ethylenediamine (TPEN)	100 mg

20.1 Overview of pH Indicators

The ability of dyes—notably litmus, phenolphthalein and phenol red—to change their color in response to a pH change has found widespread application in research and industry. Fluorescent dyes, however, provide the increased sensitivity required for optical pH measurements *inside* live cells. They also offer much greater spatial sampling capability when compared with microelectrode techniques.¹ These advantages have spurred the development of improved fluorescent dyes that can sense pH changes within physiological ranges. Of course, many of the same fluorescent pH indicators can also be used as pH sensors in cell-free media.

To quantitatively measure pH, it is essential to match the indicator's pK_a to the pH of the experimental system. Consequently, the following two sections of this chapter are divided into pH indicators for use in environments with near-neutral pH (Section 20.2) and pH indicators for use in relatively acidic environments (Section 20.3). Intracellular pH is generally between ~6.8 and 7.4 in the cytosol and ~4.5 and 6.0 in the cell's acidic organelles. Unlike intracellular free Ca^{2+} concentrations, which can rapidly change by perhaps 100-fold, the pH inside a cell varies by only fractions of a pH unit, and such changes may be quite slow.

We offer a variety of fluorescent pH indicators, pH indicator conjugates and other reagents for pH measurements in biological systems. Among these are several probes with unique optical responses and specialized localization characteristics:

- Visible light–excitable SNARF® pH indicators enable researchers to determine intracellular pH in the physiological range using dual-emission or dual-excitation ratiometric techniques (Section 20.2), thus providing important tools for confocal laser-scanning microscopy and flow cytometry.
- pHrodo™ dye and LysoSensor™ probes, for use in acidic environments such as lysosomes (Section 20.3).
- Fluorescent pH indicators coupled to dextrans are extremely well retained in cells, do not bind to cellular proteins and have a reduced tendency to compartmentalize² (Section 20.4).

Families of Molecular Probes® pH indicators are listed in Table 20.1 in approximate order of decreasing pK_a value.

Table 20.1 Molecular Probes® pH indicator families, in order of decreasing pK_a .

Parent Fluorophore	pH Range	Typical Measurement
SNARF® indicators	6.0–8.0	Emission ratio 580/640 nm
HPTS (pyranine)	7.0–8.0	Excitation ratio 450/405 nm
BCECF	6.5–7.5	Excitation ratio 490/440 nm
Fluoresceins and carboxyfluoresceins	6.0–7.2	Excitation ratio 490/450 nm
LysoSensor™ Green DND-189	4.5–6.0	Single emission 520 nm
Oregon Green® dyes	4.2–5.7	Excitation ratio 510/450 nm or excitation ratio 490/440 nm
LysoSensor™ Yellow/Blue DND-160	3.5–6.0	Emission ratio 450/510 nm
pHrodo™ dye	See below *	Single emission 585 nm

* pHrodo™ succinimidyl ester exhibits a complex pH titration profile. Decreasing pH (from pH 9 to pH 2) produces a continuous (but nonlinear) fluorescence increase. This pH response profile typically changes upon conjugation of the dye to proteins and other biomolecules.

Figure 20.2.3 Loading and retention characteristics of intracellular marker dyes. Cells of a human lymphoid line (GePa) were loaded with the following cell-permeant acetoxymethyl ester (AM) or acetate derivatives of fluorescein: 1) calcein AM (C1430, C3099, C3100MP), 2) BCECF AM (B1150), 3) fluorescein diacetate (FDA, F1303), 4) carboxy-fluorescein diacetate (CFDA, C1354) and 5) CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate, C2925, C7025). Cells were incubated in 4 μM staining solutions in Dulbecco's modified eagle medium containing 10% fetal bovine serum (DMEM+) at 37°C. After incubation for 30 minutes, cell samples were immediately analyzed by flow cytometry to determine the average fluorescence per cell at time zero (0 hours). Retained cell samples were subsequently washed twice by centrifugation, resuspended in DMEM+, maintained at 37°C for 2 hours and then analyzed by flow cytometry. The decrease in the average fluorescence intensity per cell in these samples relative to the time zero samples indicates the extent of intracellular dye leakage during the 2-hour incubation period.

20.2 Probes Useful at Near-Neutral pH

Fluorescein and Fluorescein Derivatives

Fluorescein and many of its derivatives exhibit multiple, pH-dependent ionic equilibria.^{1–5} Both the phenol and carboxylic acid functional groups of fluorescein are almost totally ionized in aqueous solutions above pH 9 (Figure 20.2.1). Acidification of the fluorescein dianion first protonates the phenol ($pK_a \sim 6.4$) to yield the fluorescein monoanion, then the carboxylic acid ($pK_a < 5$) to produce the neutral species of fluorescein. Further acidification generates a fluorescein cation ($pK_a \sim 2.1$).

Only the monoanion and dianion of fluorescein are fluorescent, with quantum yields of 0.37 and 0.93, respectively, although excitation of either the neutral or cationic species is reported to produce emission from the anion with effective quantum yields of 0.31 and 0.18, respectively.² A further equilibrium involves formation of a colorless, nonfluorescent lactone (Figure 20.2.1). The lactone is not formed in aqueous solution above pH 5 but may be the dominant form of neutral fluorescein in solvents such as acetone. The pH-dependent absorption spectra of fluorescein (Figure 20.2.2) clearly show the blue shift and decreased absorptivity indicative of the formation of protonated species. However, the fluorescence emission spectrum of most fluorescein derivatives, even in acidic solution, is dominated by the dianion, with only small contributions from the monoanion. Consequently, the wavelength and shape of the emission spectra resulting from excitation close to the dianion absorption peak at 490 nm are relatively independent of pH, but the fluorescence intensity is dramatically reduced at acidic pH (Figure 20.2.2).

We offer a broad variety of fluorescein-derived reagents and fluoresceinated probes that can serve as sensitive fluorescent pH indicators in a wide range of applications. Chemical substitutions of fluorescein may shift absorption and fluorescence maxima and change the pK_a of the dye; however, the effects of acidification on the spectral characteristics illustrated in Figure 20.2.2 are generally maintained in all fluorescein derivatives.

Fluorescein and Its Diacetate

The cell-permeant fluorescein diacetate (FDA, F1303) is still occasionally used to measure intracellular pH,⁶ as well as to study cell adhesion⁷ or, in combination with propidium iodide (P1304MP, P3566, P21493; Section 8.1), to determine cell viability.^{8,9} However, fluorescein (F1300), which is formed by intracellular hydrolysis of FDA, rapidly leaks from cells (Figure 20.2.3). Thus, other cell-permeant dyes such as the acetoxymethyl (AM) esters of BCECF and calcein are now preferred for intracellular pH measurements and cell viability assays (Section 15.2).

Figure 20.2.1 Ionization equilibria of fluorescein.

Carboxyfluorescein and Its Cell-Permeant Esters

Fluorescein's high leakage rate out of cells makes it very difficult to quantitate intracellular pH, because the decrease in the cell's fluorescence due to dye leakage cannot be easily distinguished from that due to acidification. The use of carboxyfluorescein diacetate (CFDA, C195) for intracellular pH measurements partially addresses this problem.^{10,11} CFDA is moderately permeant to most cell membranes and, upon hydrolysis by intracellular nonspecific esterases, forms carboxyfluorescein (5(6)-FAM, C194, C1904), which has a pH-dependent spectral response very similar to that of fluorescein. As compared with fluorescein, carboxyfluorescein contains an extra negative charge and is therefore better retained in cells¹² (Figure 20.2.3). The mixed-isomer preparation of CFDA (C195) is usually adequate for intracellular pH measurements because the single isomers of carboxyfluorescein exhibit essentially identical pH-dependent spectra with a $pK_a \sim 6.5$. For experiments requiring a pure isomer, the single-isomer preparations of carboxyfluorescein (C1359, C1360; Section 1.5) and CFDA (C1361, C1362; Section 15.2) are available. In addition, we offer the AM ester of CFDA (5-CFDA, AM, C1354), which is electrically neutral and facilitates cell loading. Upon hydrolysis by intracellular esterases, this AM ester also yields carboxyfluorescein.^{13–15}

BCECF and Its AM Ester

Although carboxyfluorescein is better retained in cells than is fluorescein, its pK_a of ~ 6.5 is lower than the cytosolic pH of most cells (pH ~ 6.8 – 7.4). Consequently, its fluorescence change is less than optimal for detecting small pH changes above pH 7. Since its introduction by Roger Tsien in 1982,^{16,17} the polar fluorescein derivative BCECF (B1151) and its membrane-permeant AM ester (B1150, B1170, B3051) have become the most widely used fluorescent indicators for estimating intracellular pH. Also, a flow cytometric assay has been developed that uses BCECF to estimate the concentration of intracellular K^+ .¹⁸ BCECF's four to five negative charges at pH 7–8 improve its retention in cells (Figure 20.2.3), and its pK_a of 6.98 is ideal for typical intracellular pH measurements.

As with fluorescein and carboxyfluorescein, absorption of the phenolate anion (basic form) of BCECF is red-shifted and has increased molar absorptivity relative to the protonated (acidic) form (Figure 20.2.4); there is little pH-dependent shift in the fluorescence emission spectrum of BCECF upon excitation at 505 nm. BCECF is typically used as a dual-excitation ratiometric pH indicator. Signal errors caused by variations in concentration, path length, leakage and photobleaching are greatly reduced with ratiometric methods (Loading and Calibration of Intracellular Ion Indicators—Note 19.1). Intracellular pH measurements with BCECF are made by determining the pH-dependent ratio of emission intensity (detected at 535 nm) when the dye is excited at ~ 490 nm versus the emission intensity when excited at its isosbestic point of ~ 440 nm (Figure 20.2.4, Figure 20.2.5). Because BCECF's absorption at 440 nm is quite weak, increasing the denominator wavelength to ~ 450 nm provides improved signal-to-noise characteristics for ratio imaging applications.^{19–21} As with other intracellular pH indicators, *in situ* calibration of BCECF's fluorescence response is usually accomplished using 10–50 μM nigericin (N1495) in the presence of 100–150 mM K^+ to equilibrate internal and external pH.^{22,23} Alternative calibration methods have also been reported.^{24–26}

Figure 20.2.5 Fluorescence excitation (detected at 535 nm) and emission (excited at 490 nm) spectra of BCECF in pH 9.0 and pH 5.5 buffers.

Figure 20.2.4 The pH-dependent spectra of BCECF (B1151): **A**) absorption spectra, **B**) emission spectra and **C**) excitation spectra. The fluorescence excitation spectra on the left in panel C have been enlarged 10X to reveal BCECF's 439 nm isosbestic point. Note that the isosbestic point of the excitation spectra of BCECF is different from that of the absorption spectra (compare panels A and C).

Figure 20.2.10 5-(and-6)-carboxynaphthofluorescein (C652).

Loading of live cells for measurement of intracellular pH is readily accomplished by incubating cell suspensions or adherent cells in a 1–10 μM solution of the AM ester of BCECF. At least three different molecular species can be obtained in synthetic preparations of the AM ester of BCECF; however, all three forms shown in Figure 20.2.6 appear to be converted to the same product—BCECF acid (B1151, Figure 20.2.7)—by intracellular esterase hydrolysis. Although we can readily prepare the pure tri(acetoxymethyl) ester form (Form I in Figure 20.2.6), some researchers have found that cell loading with a mixture of the lactone Forms II and III is more efficient. Consequently, we produce BCECF AM predominantly as a mixture of Forms II and III with a typical percentage composition ratio of 45:55, as determined by HPLC, NMR and mass spectrometry. The AM ester of BCECF is available in a single 1 mg vial (B1150), specially packaged as a set of 20 vials that each contains 50 μg (B1170) and as a 1 mg/mL solution (~ 1.6 mM) in anhydrous dimethylsulfoxide (DMSO) (B3051). We highly recommend purchasing the set of 20 vials in order to reduce the potential for product deterioration caused by exposure to moisture.

Our bibliography for BCECF AM lists more than 1200 journal citations, including references for the use of BCECF AM to investigate:

The cell-impermeant BCECF acid (B1151) is useful for pH measurements in intercellular spaces of epithelial cell monolayers,⁵⁰ interstitial spaces of normal and neoplastic tissue^{51,52} and isolated cell fractions.⁵³ BCECF has also been employed for two-photon fluorescence lifetime imaging of the skin stratum corneum to detect aqueous acid pockets within the lipid-rich extracellular matrix.⁵⁴ The free acid of BCECF can be loaded into cells by microinjection²⁶ or electroporation or by using our Influx™ pinocytic cell-loading reagent (I14402, Section 19.8). It has also been loaded into bacterial cells by brief incubation at pH ~ 2 .^{55,56} In addition to the cell-permeant BCECF AM and cell-impermeant BCECF acid, we offer dextran conjugates of BCECF (D1878, D1880; Section 20.4).

Fluorescein Sulfonic Acid and Its Diacetate

The fluorescein-5-(and 6)-sulfonic acid (F1130, Figure 20.2.8) is much more polar than carboxyfluorescein. Consequently, once inside cells or liposomes, it is relatively well retained. Some cells can be loaded directly with 5-sulfofluorescein diacetate^{57–60} (SFDA, S1129). Direct ratio-metric measurement of the pH in the trans-Golgi of live human fibroblasts was achieved by simultaneously microinjecting liposomes loaded with both fluorescein sulfonic acid and sulforhodamine 101⁶¹ (S359, Section 14.3). Fluorescein-5-(and 6)-sulfonic acid is more commonly used to measure barrier permeability of membranes^{62,63} (Section 14.3).

Chemically Reactive Fluorescein Diacetates

One means for overcoming the cell leakage problem common to the above pH indicators, including BCECF, is to trap the indicator inside the cell via conjugation to intracellular constituents. CellTracker™ Green CMFDA (C2925, C7025; Figure 20.2.9) and chloromethyl SNARF®-1 (C6826) incorporate a thiol-reactive chloromethyl moiety that reacts with intracellular thiols, including glutathione and proteins, to yield well-retained products (Figure 20.2.3). Cleavage of the acetate groups of the CMFDA conjugate by intracellular esterases yields a conjugate that retains the pH-dependent spectral properties of fluorescein. Because of its superior retention as compared with SNARF® AM and BCECF AM, CellTracker™ Green CMFDA was employed to monitor the intracellular pH response to osmotic stress in CHO, HEK 293 and Caco-2 cells.⁶⁴ Similarly, the amine-reactive succinimidyl ester of CFDA (CFSE, C1157) can be used for long-term pH studies of live cells, producing a conjugate with the pH-sensitive properties of carboxyfluorescein.⁶⁵

Figure 20.2.12 5-(and-6)-carboxy SNARF®-1 (C1270).

Carboxynaphthofluorescein

Carboxynaphthofluorescein (C652, Figure 20.2.10) has pH-dependent red fluorescence (excitation/emission maxima ~598/668 nm at pH >9) with a relatively high pK_a of ~7.6. The long-wavelength pH-dependent spectra of carboxynaphthofluorescein have been exploited in the construction of fiber-optic pH sensors.^{66,67} This long-wavelength pH indicator is also available in membrane-permeant diacetate form (C13196) for passive intracellular loading and as an amine-reactive succinimidyl ester (C653, Section 20.4) for preparing pH-sensitive conjugates.

SNARF® pH Indicator

The seminaphthorhodafluors (SNARF® dyes) are visible light-excitabile fluorescent pH indicators.⁶⁸ The SNARF® indicators have both dual-emission and dual-excitation properties, making them particularly useful for confocal laser-scanning microscopy⁶⁹⁻⁷² (Figure 20.2.11), flow cytometry^{21,73-75} and microplate reader-based measurements.⁷⁶ The dual-emission properties of the SNARF® indicators make them preferred probes for use in fiber-optic pH sensors.⁷⁷⁻⁷⁹ These pH indicators can be excited by the 488 or 514 nm spectral lines of the argon-ion laser and are sensitive to pH values within the physiological range. Dextran conjugates of the SNARF® dyes are described in Section 20.4.

Carboxy SNARF®-1 Dye and Its Cell-Permeant Ester

The carboxy SNARF®-1 dye (C1270, Figure 20.2.12), which is easily loaded into cells as its cell-permeant AM ester acetate (C1271, C1272), has a pK_a of about 7.5 at room temperature and between 7.3 and 7.4 at 37°C. Thus, carboxy SNARF®-1 is useful for measuring pH changes

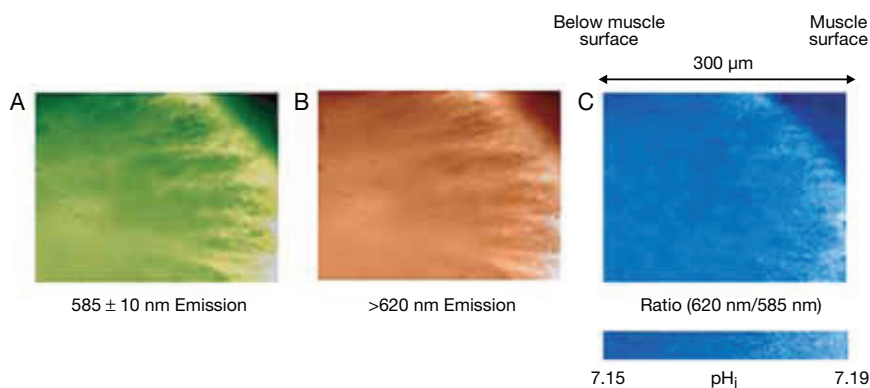

Figure 20.2.11 Confocal fluorescence images of rabbit papillary muscle loaded by perfusion with carboxy SNARF®-1 AM acetate (C1271, C1272). The first two images (A and B) were acquired through 585 ± 10 nm bandpass and >620 nm longpass emission filters, respectively. The 620 nm/585 nm fluorescence ratio image in the third image (C) is more uniform than the component images A and B due to cancellation of intensity variations resulting from heterogeneous uptake of the fluorescent indicator. Images contributed by Barbara Muller-Borer and John Lemasters, University of North Carolina, and reprinted with permission from *Am J Physiol* (1998) 275:H1937.

Figure 20.2.13 The pH-dependent absorption spectra of carboxy SNARF[®]-1 (C1270).

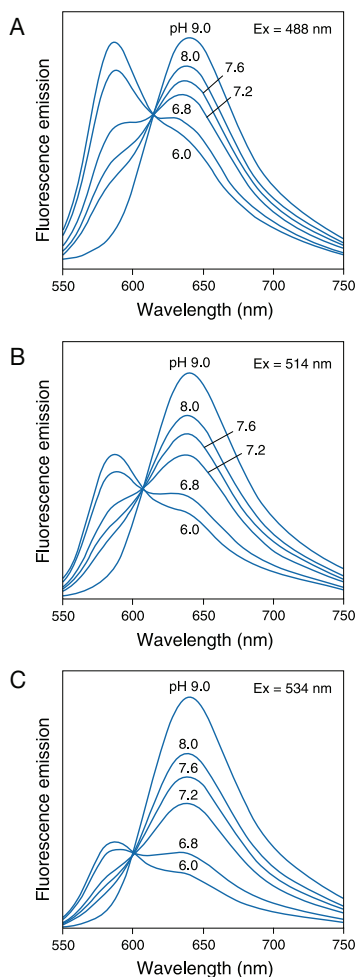

Figure 20.2.14 The pH-dependent emission spectra of carboxy SNARF[®]-1 (C1270) when excited at A) 488 nm, B) 514 nm and C) 534 nm.

between pH 7 and pH 8. Like fluorescein and BCECF, the absorption spectrum of the carboxy SNARF[®]-1 pH indicator undergoes a shift to longer wavelengths upon deprotonation of its phenolic substituent (Figure 20.2.13). In contrast to the fluorescein-based indicators, however, carboxy SNARF[®]-1 also exhibits a significant pH-dependent emission shift from yellow-orange to deep-red fluorescence as conditions become more basic (Figure 20.2.14, Figure 20.2.15). This pH dependence allows the ratio of the fluorescence intensities from the dye at two emission wavelengths—typically 580 nm and 640 nm—to be used for quantitative determinations of pH (Loading and Calibration of Intracellular Ion Indicators—Note 19.1) (Figure 20.2.11). For practical purposes, it is often desirable to bias the detection of carboxy SNARF[®]-1 fluorescence towards the less fluorescent acidic form by using an excitation wavelength between 488 nm and the excitation isosbestic point at ~530 nm, yielding balanced signals for the two emission ratio components (Figure 20.2.14, Figure 20.2.16). When excited at 488 nm, carboxy SNARF[®]-1 exhibits an emission isosbestic point of ~610 nm and a lower fluorescent signal than obtained with 514 nm excitation.⁷² Alternatively, when excited by the 568 nm spectral line of the Ar-Kr laser found in some confocal laser-scanning microscopes, carboxy SNARF[®]-1 exhibits a fluorescence increase at 640 nm as the pH increases and an emission isosbestic point at 585 nm.⁷² As with other ion indicators, intracellular environments may cause significant changes to both the spectral properties and pK_a of carboxy SNARF[®]-1,^{80–83} and the indicator should always be calibrated in the system under study.

The spectra of carboxy SNARF[®]-1 are well resolved from those of fura-2^{84,85} and indo-1⁸⁶ (Section 19.2), as well as those of the fluo-3,^{85,87,88} fluo-4, Calcium Green[™] and Oregon Green[™] 488 BAPTA Ca²⁺ indicators (Section 19.3), permitting simultaneous measurements of intracellular pH and Ca²⁺ (Figure 20.2.17). Carboxy SNARF[®]-1 has also been used in combination with the Na⁺ indicator SBFI (S1262, S1263, S1264; Section 21.1) to simultaneously detect pH and Na⁺ changes.⁸⁹ The relatively long-wavelength excitation and emission characteristics of carboxy SNARF[®]-1 facilitate studies in autofluorescent cells⁹⁰ and permit experiments that employ ultraviolet light-photoactivated caged probes⁹¹ (Section 5.3). Incubation of cells for several hours after loading with carboxy SNARF[®]-1 AM ester acetate results in compartmentally selective retention of the dye, allowing *in situ* measurements of mitochondrial pH⁹² (Figure 20.2.18).

SNARF[®]-4F and SNARF[®]-5F Dyes and Their Cell-Permeant Esters

Although the carboxy SNARF[®]-1 indicator possesses excellent spectral properties, its pK_a of ~7.5 may be too high for measurements of intracellular pH in some cells. For quantitative measurements of pH changes in the typical cytosolic range (pH ~6.8–7.4), we now recommend SNARF[®]-5F carboxylic acid (Figure 20.2.19), which has a pK_a value of ~7.2, as the indicator with the optimal spectral properties for estimating cytosolic pH (Figure 20.2.20). SNARF[®]-4F carboxylic acid (Figure 20.2.21) has a somewhat more acidic pH sensitivity maximum (pK_a ~6.4) but retains its dual-emission spectral properties (Figure 20.2.22). SNARF[®]-4F has been used for pH imaging in kidney tissues using two-photon excitation (780 nm) microscopy; the pH-dependent emission shift response was observed to be essentially the same as seen with one-photon

Figure 20.2.15 Absorption and fluorescence emission (excited at 514 nm) spectra of carboxy SNARF[®]-1 in pH 9.0 and pH 6.0 buffers.

Figure 20.2.16 Absorption and fluorescence emission (excited at 488 nm) spectra of carboxy SNARF[®]-1 in pH 9.0 and pH 6.0 buffers.

excitation.⁹³ This study also reported nigericin calibrations that yielded different pK_a values (6.8 versus 7.4) in the kidney cortex and kidney ileum, respectively, emphasizing the importance of performing *in situ* calibrations. Both SNARF[®]-4F and SNARF[®]-5F⁹⁴ allow dual-excitation and dual-emission ratiometric pH measurements, making them compatible with the same instrument configurations used for carboxy SNARF[®]-1 in ratio imaging and flow cytometry applications. SNARF[®]-4F and SNARF[®]-5F are available as free carboxylic acids (S23920, S23922) and as cell-permeant AM ester acetate derivatives (S23921, S23923).

Amine- and Thiol-Reactive SNARF[®] Dyes

Our 5-(and 6)-chloromethyl SNARF[®]-1 acetate (C6826, Figure 20.2.23) contains a chloromethyl group that is mildly reactive with intracellular thiols, forming adducts that improve cellular retention of the SNARF[®] fluorophore (Figure 20.2.24). As with CellTracker™ Green CMFDA, improved retention of this conjugate in cells may permit monitoring of intracellular pH over longer time periods than is possible with other intracellular pH indicators. Similarly, amine-reactive SNARF[®]-1 succinimidyl ester (S22801, Section 20.4) is useful as an intracellular pH indicator⁹⁵ in addition to its more common application as a cell tracer.⁹⁶

8-Hydroxypyrene-1,3,6-Trisulfonic Acid (HPTS)

8-Hydroxypyrene-1,3,6-trisulfonic acid (HPTS, also known as pyranine; H348; Figure 20.2.25) is an inexpensive, highly water-soluble, membrane-impermeant pH indicator with a pK_a of ~ 7.3 in aqueous buffers.⁹⁷ The pK_a of HPTS is reported to rise to 7.5–7.8 in the cytosol of some cells.⁹⁸ Unlike indicators based on the SNARF[®] and fluorescein dyes, there is no membrane-permeant form of HPTS available. Consequently, HPTS must be introduced into cells by microinjection, electroporation⁹⁹ or liposome-mediated delivery,^{100–102} through ATP-gated ion channels¹⁰³ or by other relatively invasive means (Table 14.1, Section 14.1). HPTS exhibits a pH-dependent absorption shift (Figure 20.2.26), allowing ratiometric measurements using an excitation ratio of 450/405 nm.^{49,104} Because the excited state of HPTS is much more acidic than the ground state,¹⁰⁵ it is frequently used as a photoactivated source of H^+ in mechanistic studies of bacteriorhodopsin and other proton pumps.^{106–108}

Nigericin

Intracellular calibration of the fluorescence response of cytosolic pH indicators is typically performed using the K^+/H^+ ionophore nigericin (N1495), which causes equilibration of intracellular and extracellular pH in the presence of a depolarizing concentration of extracellular K^+ ^{22,23} (Loading and Calibration of Intracellular Ion Indicators—Note 19.1). Nett and Deitmer have compared this technique with calibrations performed by direct insertion of pH-sensitive microelectrodes in leech giant glial cells.²⁶

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

* Cat. No. of product generated *in situ* in typical intracellular applications.

Notes

- MW value is approximate. BCECF, AM is a mixture of molecular species.
- pK_a values may vary considerably depending on the temperature, ionic strength, viscosity, protein binding and other factors. Unless otherwise noted, values listed have been determined from pH-dependent fluorescence measurements at 22°C.
- Spectra are in aqueous buffers adjusted to >1 pH unit above and >1 pH unit below the pK_a.
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- Data on pH dependence of C652 spectra obtained in our laboratories. Additional relevant data are reported elsewhere. (Mikrochim Acta (1992) 108:133)
- Values of pK_a for these SNARF® indicators are as reported in published references. (Anal Biochem (1991) 194:330)
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- Acetate hydrolysis of this compound yields a fluorescent product with pH-dependent spectral characteristics similar to C1904.
- C6826 and S22801 are converted to fluorescent products with spectra similar to C1270 after acetate hydrolysis.
- The pK_a for H348 was determined in 0.066 M phosphate buffers at 22°C. (Fresenius Z Anal Chem (1983) 314:119)

PRODUCT LIST 20.2 PROBES USEFUL AT NEAR-NEUTRAL pH

Cat. No.	Product	Quantity
B1151	2',7'-bis-(2-carboxyethyl)-5-(and-6)-carboxyfluorescein (BCECF acid) *mixed isomers*	1 mg
B1150	2',7'-bis-(2-carboxyethyl)-5-(and-6)-carboxyfluorescein, acetoxymethyl ester (BCECF, AM)	1 mg
B3051	2',7'-bis-(2-carboxyethyl)-5-(and-6)-carboxyfluorescein, acetoxymethyl ester (BCECF, AM) *1 mg/mL solution in anhydrous DMSO*	1 mL
B1170	2',7'-bis-(2-carboxyethyl)-5-(and-6)-carboxyfluorescein, acetoxymethyl ester (BCECF, AM) *special packaging*	20 x 50 µg
C1270	5-(and-6)-carboxy SNARF®-1	1 mg
C1271	5-(and-6)-carboxy SNARF®-1, acetoxymethyl ester, acetate	1 mg
C1272	5-(and-6)-carboxy SNARF®-1, acetoxymethyl ester, acetate *special packaging*	20 x 50 µg
C194	5-(and-6)-carboxyfluorescein *mixed isomers*	5 g
C1904	5-(and-6)-carboxyfluorescein (5(6)-FAM) *FluoroPure™ grade* *mixed isomers*	100 mg
C195	5(6)-CFDA (5-(and-6)-carboxyfluorescein diacetate) *mixed isomers*	100 mg
C1354	5-CFDA, AM (5-carboxyfluorescein diacetate, acetoxymethyl ester)	5 mg
C1157	5(6)-CFDA, SE; CFSE (5-(and-6)-carboxyfluorescein diacetate, succinimidyl ester) *mixed isomers*	25 mg
C652	5-(and-6)-carboxynaphthofluorescein *mixed isomers*	100 mg
C13196	5-(and-6)-carboxynaphthofluorescein diacetate	10 mg
C6826	5-(and-6)-chloromethyl SNARF®-1, acetate *mixed isomers* *special packaging*	20 x 50 µg
H348	8-hydroxypyrene-1,3,6-trisulfonic acid, trisodium salt (HPTS; pyranine)	1 g
C2925	CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate)	1 mg
C7025	CellTracker™ Green CMFDA (5-chloromethylfluorescein diacetate) *special packaging*	20 x 50 µg
F1303	FDA (fluorescein diacetate)	1 g
F1300	fluorescein *reference standard*	1 g
F1130	fluorescein-5-(and-6)-sulfonic acid, trisodium salt	100 mg
N1495	nigericin, free acid	10 mg
S1129	SFDA (5-sulfofluorescein diacetate, sodium salt)	25 mg
S23920	SNARF®-4F 5-(and-6)-carboxylic acid	1 mg
S23921	SNARF®-4F 5-(and-6)-carboxylic acid, acetoxymethyl ester, acetate *special packaging*	20 x 50 µg
S23922	SNARF®-5F 5-(and-6)-carboxylic acid	1 mg
S23923	SNARF®-5F 5-(and-6)-carboxylic acid, acetoxymethyl ester, acetate *special packaging*	20 x 50 µg

20.3 Probes Useful at Acidic pH

Eukaryotic cells contain compartments with different degrees of acidity. For example, biomolecules brought into cells by receptor-mediated endocytosis or phagocytosis (Section 16.1) are initially processed through organelles of decreasing pH, and specialized organelles such as plant vacuoles and the acrosome of spermatozoa are intrinsically acidic. A low intracompartamental pH activates enzymes and other protein functions—such as iron release from transferrin—that would be too slow at neutral pH, thereby facilitating cellular metabolism. Abnormal lysosomal or endosomal acidification is associated with various pathological conditions. For example, lysosomes in some tumor cells have

been reported to have a lower pH than normal lysosomes,¹ whereas other tumor cells contain lysosomes with higher pH.²

The fluorescent pH indicators used to detect acidic organelles and to follow trafficking through acidic organelles must have a lower pK_a than those described in Section 20.2. Also, unlike most pH indicators for cytosolic measurements, pH indicators for acidic organelles need not be intrinsically permeant to membranes. Often they are covalently attached to large biomolecules that are actively taken up and processed through acidic organelles by the cell's own endocytic mechanisms (Chapter 16).

Table 20.2 Summary of the pH response of our LysoSensor™ probes.

Cat. No.	LysoSensor™ Probe	Abs/Em* (nm)	pK_a †	Useful pH Range †
L7533	LysoSensor™ Blue DND-167	373/425	5.1	4.5–6.0
L7534	LysoSensor™ Green DND-153	442/505	7.5	6.5–8.0
L7535	LysoSensor™ Green DND-189	443/505	5.2	4.5–6.0
L7545	LysoSensor™ Yellow/Blue DND-160	384/540 ‡; 329/440 §	4.2	3.5–6.0

* Absorption (Abs) and fluorescence emission (Em) maxima at pH 5; values may vary somewhat in cellular environments. † All pK_a values were determined *in vitro*; values are likely to be different in cells. ‡ At pH 3. § At pH 7.

LysoSensor™ Probes

LysoSensor™ probes are weak bases that are selectively concentrated in acidic organelles as a result of protonation (Table 20.2). This protonation also relieves the fluorescence quenching of the dye that results from photoinduced electron transfer (PET) by its weak-base side chain. Thus, unlike most other pH indicators in this chapter, the LysoSensor™ dyes become *more* fluorescent in acidic environments. Because accumulation of LysoSensor™ probes also appears to cause lysosomal alkalization, pH measurements should be made rapidly using the lowest practicable concentration of dye.

LysoSensor™ Yellow/Blue Dye

LysoSensor™ Yellow/Blue DND-160 (L7545, Figure 20.3.1) undergoes a pH-dependent emission shift to longer wavelengths in acidic environments when illuminated near its excitation isosbestic point (~360 nm) (Figure 20.3.2). It also undergoes a pH-dependent excitation shift when detected near its emission isosbestic point (~490 nm) (Figure 20.3.2). These properties can be exploited for dual-emission ratio imaging of lysosomal pH³ (Figure 20.3.3) (emission ratio ~450/510 nm, excitation ~365 nm). Yellow-fluorescent staining by LysoSensor™ Yellow/Blue DND-160 has been used to identify lysosomes as the accumulation site for anthracyclines in a drug-resistant cell line.⁴ LysoSensor™ Yellow/Blue DND-160, frequently referred to by the acronym PDMPO, has been widely used as a tracer of silica deposition and transport in marine diatoms.^{5–8} We also offer a 10,000 MW dextran conjugate of the LysoSensor™ Yellow/Blue dye (L22460, Section 20.4).

LysoSensor™ Green and LysoSensor™ Blue Dyes

The green-fluorescent LysoSensor™ Green dyes are available with optimal pH sensitivity in either the acidic or neutral range ($pK_a \sim 5.2$ or ~ 7.5). The blue-fluorescent LysoSensor™ Blue DND-167 has a pK_a of ~ 5.1 (Figure 20.3.4). With their low pK_a values, LysoSensor™ Green DND-189 (L7535, Figure 20.3.5) and LysoSensor™ Blue DND-167 (L7533) are almost non-fluorescent except when inside acidic compartments, whereas LysoSensor™ Green DND-153 (L7534, Figure 20.3.6) is brightly fluorescent, even at neutral pH. LysoSensor™ Green DND-189 has been used to monitor the dissipation of neurite vesicle transmembrane pH gradients by bafilomycin A1.⁹

Figure 20.3.4 The pH titration curve of LysoSensor™ Blue DND-167 (L7533), which exhibits a $pK_a \sim 5.1$.

Figure 20.3.5 LysoSensor™ Green DND-189 (L7535).

Figure 20.3.6 LysoSensor™ Green DND-153 (L7534).

Figure 20.3.1 LysoSensor™ Yellow/Blue DND-160 (PDMPO, L7545).

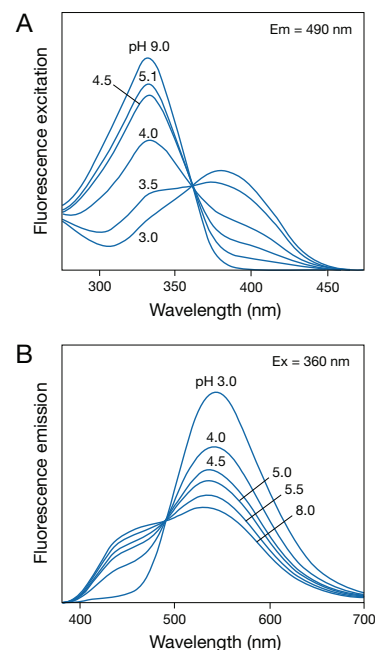

Figure 20.3.2 The pH-dependent spectral response of LysoSensor™ Yellow/Blue DND-160 (L7545): A) fluorescence excitation spectra and B) fluorescence emission spectra.

Figure 20.3.3 Dual-emission ratiometric measurement of lysosomal pH using LysoSensor™ Yellow/Blue DND-160 (L7545). Madin-Darby canine kidney cells were exposed to pH-calibration buffers (pH 4.5 or 7.0) in the presence of nigericin (N1495) and monensin. These pseudocolored images were constructed from two emission images at 450 ± 33 nm and 510 ± 20 nm, both excited at 365 ± 8 nm.

pHrodo™ pH Indicator

pHrodo™ pH indicator is an aminorhodamine dye that exhibits increasing fluorescence as the pH of its surroundings becomes more acidic¹⁰ (Figure 20.3.7). Consequently, pHrodo™ fluorescence (excitation/emission ~560/585 nm) provides a positive indication of processes such as phagocytic ingestion and lysosomal sequestration, in contrast to the negative indication generated by fluorescein and Oregon Green® dyes.^{11–13} Because the pHrodo™ dye has more than one protolytically ionizable substituent, it exhibits a complex pH titration profile that typically changes upon conjugation to proteins and other biomolecules. We currently offer an amine-reactive succinimidyl ester form of the pHrodo™ dye (P36600, Section 20.4) and various bioconjugates (Section 20.4, Section 16.1). In cases where the nonreactive carboxylic acid form of the dye is required, pHrodo™ carboxylic acid can be obtained by mild alkaline hydrolysis of the succinimidyl ester (e.g., 12-hour incubation in aqueous solution at pH 8 in the dark will yield >99.9% hydrolysis; higher pH will give a more rapid reaction).

Figure 20.3.7 The pH sensitivity of pHrodo™ dextran. pHrodo™ dextran (P10361) was reconstituted in HEPES (20 mM)-buffered PBS and adjusted to pH values from pH 4 to pH 10. The intensity of fluorescence emission increases with increasing acidity, particularly in the pH 5–8 range.

Figure 20.3.11 9-amino-6-chloro-2-methoxyacridine (ACMA, A1324).

Oregon Green® and Dichlorofluorescein Derivatives

Introduction of electron-withdrawing groups into fluorescein dyes lowers the pK_a of the phenolic group to 5 or below, as exemplified by our Oregon Green® dyes and their insensitivity to pH changes in the near-neutral pH range.¹⁴ However, these fluorinated fluorescein dyes are still pH sensitive in moderately acidic solutions, with pK_a values of ~4.7 (Figure 20.3.8). With the exception of their lower pK_a values, the pH-dependent spectral characteristics of the Oregon Green® dyes closely parallel those of other fluorescein-based dyes, allowing dual-excitation ratiometric measurements with the same general configuration used for BCECF (Section 20.2).

Oregon Green® 514 carboxylic acid (O6138, Figure 20.3.9), Oregon Green® 488 carboxylic acid (O6146, Figure 20.3.10) and 5-(and 6-)carboxy-2',7'-dichlorofluorescein (C368) do not readily enter cells but may be useful as fluid phase markers for endocytosis. These fluorinated and chlorinated fluorescein derivatives will likely be most useful in the form of conjugates that are endocytosed and processed through acidic organelles (Section 20.4); dextran conjugates of the Oregon Green® 488 and Oregon Green® 514 dyes are described in Section 20.4.

Cell-permeant diacetate derivatives of carboxydichlorofluorescein (carboxy-DCFDA, C369) and carboxydifluorofluorescein (carboxy-DFFDA, O6151) are also available. Carboxy-DCFDA has been used to measure the pH in acidic organelles,¹⁵ as well as in the cytosol and vacuoles of plants and yeast.^{16,17} Furthermore, the mechanism of vacuolar pH rectification following exposure to ammonia has been investigated in rice and maize root hair cells loaded with carboxy-DFFDA.¹⁸

Other pH Indicators for Acidic Environments

9-Amino-6-Chloro-2-Methoxyacridine (ACMA)

The nucleic acid stain 9-amino-6-chloro-2-methoxyacridine (ACMA, A1324; Figure 20.3.11) apparently binds to membranes in the energized state, and its fluorescence becomes quenched if a pH gradient forms.¹⁹ Mechanistically, this probe resembles the membrane potential-sensitive carbocyanines (Section 22.3) more than the other probes in this chapter. ACMA is primarily employed to detect the proton-translocating activity of *Escherichia coli* ATP synthase^{20–23} and yeast vacuolar H^+ -ATPase.^{24–26}

8-Hydroxypyrene-1,3,6-Trisulfonic Acid (HPTS)

Although 8-hydroxypyrene-1,3,6-trisulfonic acid (HPTS, H348; Section 20.2) has a $pK_a \sim 7.3$ and is primarily used as a pH indicator in the near-neutral range, it offers several advantages for monitoring intraorganellar pH in endosomal/lysosomal pathways:²⁷

- The highly polar character that results from its three sulfonic acid groups prevents leakage across intracellular membranes.
- Uptake by fluid-phase endocytosis is efficient and easily accomplished.
- Determination of excitation ratios allows pH measurements that are independent of vesicular size and indicator concentration.
- Precise calibration permits pH values as low as 4.4 to be accurately measured.
- HPTS is nontoxic and does not perturb normal physiological function.

HPTS can be introduced into cells by microinjection, electroporation or liposome-mediated delivery or through ATP-gated ion channels.²⁸ HPTS has also been loaded into cells using a patch pipette.²⁹ HPTS has been reported to be less phototoxic than BCECF.²⁸

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. Absorption and fluorescence spectra of the protonated and deprotonated forms of A1324 are quite similar. This observation, and the listed pK_a value, are reported in published references. (*Eur Biophys J* (1986) 13:251) Accumulation of the probe in the presence of transmembrane pH gradients results in fluorescence quenching. (*Biochim Biophys Acta* (1983) 722:107)
2. Spectra of this compound are in methanol acidified with a trace of HCl.
3. pK_a values may vary considerably depending on the temperature, ionic strength, viscosity, protein binding and other factors. Unless otherwise noted, values listed have been determined from pH-dependent fluorescence measurements at 22°C.
4. Spectra are in aqueous buffers adjusted to >1 pH unit above and >1 pH unit below the pK_a .
5. C369 is converted to a fluorescent product (C368) after acetate hydrolysis.
6. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
7. This LysoSensor™ dye exhibits increasing fluorescence as pH decreases with no spectral shift. L7533 has additional absorption and fluorescence emission peaks at Abs = 394 nm and Em = 401 nm.
8. The pK_a value for this product is determined from the pH-dependent variation of the absorption spectrum.
9. The fluorescence lifetime (τ) of the Oregon Green® 514 dye in pH 9.0 buffer at 20°C is 4.2 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon, Inc.
10. The fluorescence lifetime (τ) of the Oregon Green® 488 dye in pH 9.0 buffer at 20°C is 4.1 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon, Inc.
11. Acetate hydrolysis of this compound yields a fluorescent product with spectral characteristics similar to O6146.

PRODUCT LIST 20.3 PROBES USEFUL AT ACIDIC pH

Cat. No.	Product	Quantity
A1324	9-amino-6-chloro-2-methoxyacridine (ACMA)	100 mg
C368	5-(and-6)-carboxy-2',7'-dichlorofluorescein *mixed isomers*	100 mg
C369	5-(and-6)-carboxy-2',7'-dichlorofluorescein diacetate (carboxy-DCFDA) *mixed isomers*	100 mg
L7533	LysoSensor™ Blue DND-167 *1 mM solution in DMSO* *special packaging*	20 x 50 µL
L7534	LysoSensor™ Green DND-153 *1 mM solution in DMSO* *special packaging*	20 x 50 µL
L7535	LysoSensor™ Green DND-189 *1 mM solution in DMSO* *special packaging*	20 x 50 µL
L7545	LysoSensor™ Yellow/Blue DND-160 (PDMPO) *1 mM solution in DMSO*	20 x 50 µL
O6146	Oregon Green® 488 carboxylic acid *5-isomer*	5 mg
O6151	Oregon Green® 488 carboxylic acid diacetate (carboxy-DFFDA) *6-isomer*	5 mg
O6138	Oregon Green® 514 carboxylic acid	5 mg

20.4 pH Indicator Conjugates

This section includes our selection of pH indicators conjugated to dextrans and lipids, as well as our chemically reactive pH indicators for preparing new pH-sensitive conjugates. The pH indicator conjugates described below include both those useful at near-neutral pH and those useful in acidic environments.

- Attachment to a dextran significantly decreases the likelihood that the indicator will become compartmentalized, thereby avoiding a substantial problem associated with cell-permeant acetoxymethyl (AM) ester derivatives.¹

The properties of some of the most useful pH indicator dextrans are listed in Table 20.3 in approximate order of decreasing pK_a value. Our numerous labeled dextrans are discussed in Section 14.5 and listed in Table 14.4.

pH Indicator Dextrans

The pH-sensitive properties of the pH indicators described in Section 20.2 and Section 20.3 are usually not significantly affected upon conjugation to dextrans. However, coupling of pH indicators to these inert polysaccharides changes several other properties of the dyes:

- Conjugates have high water solubility and therefore must be loaded into cells by microinjection, whole-cell patch-clamping, endocytosis or liposome fusion or by using the Influx™ pinocytotic cell loading reagent (I14402, Section 19.8).
- Once loaded, dextrans are retained in viable cells for long periods and (at least those dextrans with average molecular weights above 3000) will not pass through gap junctions.

pHrodo™ Dextran

The 10,000 MW pHrodo™ dextran (P10361) is a superior alternative to other fluorescent dextran conjugates (e.g., BCECF and tetramethylrhodamine) for live-cell imaging of endocytosis² (Section 16.1). pHrodo™ dextran possesses a pH-sensitive fluorescence emission that increases in intensity with increasing acidity (Figure 20.4.1). pHrodo™ dextran is essentially nonfluorescent in the extracellular environment; however, upon internalization, the acidic environment of the endosomes elicits a bright, red-fluorescent signal from this dextran conjugate. The minimal fluorescent signal from the pHrodo™ dextran conjugate at neutral pH prevents the detection of noninternalized and nonspecifically bound

Table 20.3 Molecular Probes® pH indicator dextrans, in order of decreasing pK_a.

Dye	Cat. No.	pK _a *	Measurement Wavelengths	Application Notes
SNARF®	D3303, D3304	~7.5	Emission ratio 580/640 nm excited at 514 or 488 nm	• Best conjugate for ratiometric emission measurements
BCECF	D1878, D1880	~7.0	Excitation ratio 490/440 nm detected at 530 nm	• Best conjugate for ratiometric excitation measurements
Fluorescein	D1821, D1823, D1844, D3305	~6.4	Excitation ratio 490/450 nm detected at 520 nm	• Fluorescence is strongly quenched upon uptake into acidic organelles
Fluorescein and tetramethylrhodamine	D1951	~6.4	Excitation ratio 495/555 nm detected at 580 nm †	• Conjugate incorporating both pH-sensitive and pH-insensitive fluorescent dyes
pHrodo™	P10361	NA ‡	Emission at 585 nm when excited at 540–560 nm	• Best conjugate for measurements requiring broad-range pH sensitivity
Oregon Green® 488	D7170, D7172	~4.7	Excitation ratio 490/440 nm detected at 520 nm	• Good photostability • Optimum pH sensitivity for measurements in lysosomes and late endosomes
Oregon Green® 514	D7176	~4.7	Excitation ratio 510/450 nm detected at 530 nm	• Excellent photostability • Optimum pH sensitivity for measurements in lysosomes and late endosomes
LysoSensor™ Yellow/Blue	L22460	~4.2	Excitation ratio 340/400 nm detected at 520 nm; emission ratio 450/510 nm excited at 365 nm	• Options for dual excitation or dual emission ratio measurements • Optimum pH sensitivity for measurements in lysosomes and late endosomes

* pK_a values are those determined for the free dyes. Actual values for dextran conjugates may differ by up to ± 0.3 pH units and may vary with production lots. † Ratiometric emission measurements at 520/580 nm (with excitation at 495 nm) are also possible in principle; however, the response may be complicated by fluorescence resonance energy transfer. NA = Not applicable. ‡ pHrodo™ pH indicator exhibits a complex pH titration profile. Decreasing pH (from pH 9 to pH 2) produces a continuous (but nonlinear) fluorescence increase.

conjugates and eliminates the need for quenching reagents and extra wash steps, thus providing a simple fluorescent assay for endocytic activity (Figure 20.4.2). pHrodo™ dextran can be used to study or monitor endocytosis on a variety of platforms including fluorescence microscopy, flow cytometry and automated imaging and analysis (also known as high-content imaging or HCS). pHrodo™ dextran's excitation and emission maxima of 560 and 585 nm, respectively, facilitate multiplexing with other fluorophores including Alexa Fluor® 488 and Alexa Fluor® 647 dyes as well as Green Fluorescent Protein (GFP).

BCECF and SNARF® Indicator Dextrans for Measuring Near-Neutral pH

Our 10,000 MW and 70,000 MW BCECF dextrans (D1878, D1880) are important dual-excitation pH indicator conjugates for pH measurements near pH 7.0. BCECF dextran-labeled Swiss 3T3 cells have been shown to produce much more stable fluorescent signals, reduced probe compartmentalization and 10-fold greater resistance to light-induced damage when compared with BCECF AM-labeled cells.³ The 10,000 MW BCECF dextran (D1878) has been used to monitor intracellular pH increases during developmental processes^{4–6} and to measure pH in submucosal gland secretions from human lung tissues.⁷ Cytoplasmic Ca²⁺/H⁺ buffering in green algae has been investigated using BCECF dextran in combination with fura dextran⁸ (F3029, Section 19.4).

A dextran conjugate of the carboxy SNARF®-1 pH indicator (D3303, D3304) has been microinjected into rhizoid cells of the alga

Pelvetia fastigata and used with ratiometric imaging to measure pH gradients associated with polar tip growth.⁹ SNARF®-1 dextran has also been used to detect cytosolic alkalization associated with multidrug transporter activity¹⁰ and to investigate pH regulation of connexin 43 channels.¹¹ SNARF® dextran conjugates have been scrape-loaded into the cytosol of MDF-7/ADR cells. It was found that the 70,000 MW SNARF® dextran conjugate remained exclusively cytosolic, whereas the 10,000 MW conjugate reported the pH of both cytosolic and nuclear compartments.¹²

Oregon Green® and LysoSensor™ Yellow/Blue Dextrans

Although the fluorescein, BCECF and SNARF® dextrans are intended for pH measurements between pH ~6 and 8, these dextrans are also useful for detecting uptake into acidic organelles, such as occurs during endocytosis. In particular, when these indicator dextrans enter moderately acidic compartments (pH <5.5):

- Fluorescence of the fluorescein and BCECF dextrans is strongly quenched^{13–15} (Section 2.2).
- The 520/570 nm emission intensity ratio of the double-labeled fluorescein–tetramethylrhodamine dextran (D1951) decreases¹⁶ (Figure 20.4.3).
- The 580/640 nm emission ratio of the SNARF®-1 dextrans increases (Section 20.2).
- The fluorescein, BCECF and SNARF® dextrans are useful for detecting translocation into compartments that have an acidic pH; however, the relative insensitivity of their fluorescence below pH ~6 limits quantitative pH estimation. The lower pK_a values of the Oregon Green® 488 and Oregon Green® 514 dextran conjugates (Table 20.3) make them more suitable indicators for estimating the pH of relatively acidic lysosomal environments. Moreover, the shift in their excitation spectra in acidic media permits ratiometric pH measurements.

We have also developed a 10,000 MW dextran conjugate of the LysoSensor™ Yellow/Blue dye (L22460), which can be used to quickly and accurately estimate the pH of lysosomes. As this labeled dextran is taken up by the cells and moves through the endocytic pathway, the fluorescence of the LysoSensor™ probe changes from blue in the near-neutral endosomes to yellow in the acidic lysosomes.¹⁷ The greatest change in

Figure 20.4.1 The pH sensitivity of pHrodo™ dextran. pHrodo™ dextran (P10361) was reconstituted in HEPES (20 mM)-buffered PBS and adjusted to pH values from pH 4 to pH 10. The intensity of fluorescence emission increases with increasing acidity, particularly in the pH 5–8 range.

Figure 20.4.2 Tracking endocytosis inhibition with pHrodo™ dextran conjugates. HeLa cells were plated in 96-well format and treated with dynasore for 3 hr at 37°C prior to the pHrodo™ assay. Then, 40 μg/mL pHrodo™ dextran synthesized from pHrodo™ succinimidyl ester (P36600) and amine-reactive 10,000 MW dextran (D1860) was incubated for 30 min at 37°C. Cells were stained with HCS NuclearMask™ Blue stain (H10325) for 10 min to reveal total cell number and demarcation for image analysis. Images were acquired on the BD Pathway™ 855 High-Content Bioimager (BD Biosciences).

Figure 20.4.3 The excitation spectra of double-labeled fluorescein–tetramethylrhodamine dextran (D1951), which contains pH-dependent (fluorescein) and pH-independent (tetramethylrhodamine) dyes.

Figure 20.4.4 Dual-emission ratiometric measurement of lysosomal pH using LysoSensor™ Yellow/Blue dextran (L22460). MDCK cells labeled with the fluorescent dextran were exposed to pH-calibration buffers (pH 3.5 or pH 6.0) in the presence of nigericin (N1495) and monensin. Pseudocolored images were constructed from two emission images at 450 ± 33 nm and 510 ± 20 nm, both excited at 365 ± 8 nm. (Chem Biol (1999) 6:411).

Figure 20.4.5 Fluorescein DHPE (*N*-(fluorescein-5-thio-carbamoyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt, F362).

Figure 20.4.6 Oregon Green® 488 DHPE (Oregon Green® 488 1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, O12650).

fluorescence emission occurs near the pK_a of the dye at pH ~ 4.2 . The pH in lysosomes can be measured with LysoSensor™ Yellow/Blue dextran using fluorescence microscopy (Figure 20.4.4) or flow cytometry.

Lipophilic pH Indicators

Measurement of the pH adjacent to membrane surfaces is often complicated by electrostatic charge and solvation effects on the pK_a of surface-bound indicators.^{18,19} The pK_a of membrane-intercalated fluorescein DHPE (F362, Figure 20.4.5) is ~ 6.2 , quite close to that of free fluorescein.¹⁸ Researchers have used the pH-dependent fluorescence of fluorescein DHPE to measure lateral proton conduction along lipid monolayers.^{20–23} This fluorescein-labeled phospholipid has also been used to follow proton translocation from internal compartments in phospholipid vesicles.²⁴ For more acidic environments, Oregon Green® 488 DHPE (O12650, Figure 20.4.6) has potentially similar applications. Other related lipophilic fluorescein derivatives, including 5-dodecanoylamino-fluorescein (D109) and 5-hexadecanoylamino-fluorescein (H110), are described in Section 13.5.

Reactive Dyes for Preparing pH-Sensitive Conjugates

Amine-Reactive pHrodo™ pH Indicator

pHrodo™ dye is an aminorhodamine pH indicator that increases in fluorescence as the pH of its surroundings becomes more acidic (Figure 20.4.1). The amine-reactive succinimidyl ester form of the dye (P36600) provides access to a wide variety of user-defined bioconjugates by following the detailed protocols provided in the accompanying product information sheet. pHrodo™ dye is extremely sensitive to its local environment; therefore, the pH response of each bioconjugate must be individually determined. pHrodo™ succinimidyl ester has been used to label dexamethasone-treated thymocytes for flow cytometric analysis of phagocytosis by splenic or peritoneal macrophages²⁵ and for live-cell confocal imaging of antigen transfer from human B lymphocytes to macrophages.²⁶

To study endocytosis in a high-throughput format, we have used pHrodo™ conjugates to create dose response curves for the inhibition of endocytosis by dynasore, a dynamin-specific inhibitor. pHrodo™ succinimidyl ester was conjugated to an amine-derivatized 10,000 MW dextran, and cells were treated with serial dilutions of dynasore to create dose response curves for endocytosis inhibition (Figure 20.4.2). The loss of pHrodo™ dextran accumulation in punctuate structures within the cell was observed as a function of dynasore concentration.

Other Amine-Reactive Dyes

Many of the pH indicators described in Section 20.2 and Section 20.3 can be conjugated to biological molecules in order to generate pH-sensitive tracers. The resulting conjugates are useful for following endocytosis, phagocytosis, organelle trafficking and other processes, as described in Section 16.1. For example, the pH sensitivity of fluorescein-labeled transferrin (T2871, Section 16.1) has frequently been exploited to detect pH changes associated with the endocytic processing of this important iron-transporting glycoprotein.^{27–30}

For these types of applications, fluorescein conjugates are less than optimal because they have little sensitivity in the pH range below pH 5.5. The response range can be extended using conjugates of our Oregon Green® 488 dye, which has a much lower pK_a than fluorescein (4.7 compared with 6.4, Figure 20.4.7) but essentially identical spectra. Our collaborators, Dr. Elizabeth Simons and her co-workers, have labeled fungi (*Cryptococcus neoformans*) with FITC (F143, F1906, F1907; Section 1.5) or Oregon Green® 488 isothiocyanate (O6080, Section 1.5) and used them to study the influence of phagosomal pH on the fungicidal and fungistatic activity of human monocyte-derived macrophages.³¹ At pH levels evoked by phagocytosis of live and heat-killed fungi (pH 4.7–5.7), standard curves of the 498/450 nm fluorescence excitation ratio as a function of pH (Figure 20.4.8) illustrate the greater sensitivity of the Oregon Green® 488 conjugates. Vergne and co-workers have used zymosan (heat-killed yeast) double-labeled with the succinimidyl esters of Oregon Green® 488 carboxylic acid (O6147) and carboxytetramethylrhodamine (C1171, Section 1.6) to measure phagosomal pH in J774 macrophages using dual-emission (530/585 nm) flow cytometry; they were able to estimate pH values as low as 4.0.³²

Many of the reagents or methods required to prepare conjugates have been described in Chapter 1. The most common method of producing a useful conjugate is the reaction of amines with succinimidyl ester or isothiocyanate derivatives of the pH indicator. Examples of amine-reactive pH indicators include the succinimidyl esters of the carboxy SNARF[®]-1 and carboxynaphthofluorescein dyes (S22801, C653). The succinimidyl ester of the chlorinated fluorescein derivative 6-JOE (pK_a ~11.5, C6171MP; Section 1.5) can be used to prepare conjugates that are responsive to alkaline pH levels. When the amine-reactive pH indicator is not available, sulfosuccinimidyl esters can generally be prepared *in situ* simply by dissolving the carboxylic acid dye in a buffer that contains *N*-hydroxysulfosuccinimide and 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (NHSS, H2249; EDAC, E2247; Section 3.4); this method was used to activate SNARF[®]-4F carboxylic acid (S23920, Section 20.2) for labeling 5'-amine-modified oligonucleotides.³³ Addition of NHSS to the buffer has been shown to enhance the yield of carbodiimide-mediated conjugations.³⁴ Suitable amine-reactive pH indicators or dyes that can be made reactive using EDAC/NHSS are listed in Table 20.4.

Table 20.4 Reactive pH indicator dyes.

pH Indicator	Preferred Reactive Form
BCECF	BCECF (B1151, Section 20.2) *
Carboxyfluorescein	5-(and 6-)carboxyfluorescein, succinimidyl ester (C1311, Section 1.5)
6-JOE	6-carboxy-4',5'-dichloro-2',7'-dimethoxyfluorescein, succinimidyl ester (C6171MP, Section 1.5)
Naphthofluorescein	5-(and 6-)carboxynaphthofluorescein, succinimidyl ester (C653)
Oregon Green [®] 488	Oregon Green [®] 488 carboxylic acid, succinimidyl ester (O6147, O6149)
Oregon Green [®] 514	Oregon Green [®] 514 carboxylic acid, succinimidyl ester (O6139)
pHrodo [™]	pHrodo [™] succinimidyl ester (P36600)
SNARF [®] -1	SNARF [®] -1 carboxylic acid, acetate, succinimidyl ester (S22801) 5-(and 6-)carboxy SNARF [®] -1 (C1270, Section 20.2) *
SNARF [®] -4F	SNARF [®] -4F carboxylic acid (S23920, Section 20.2) *
SNARF [®] -5F	SNARF [®] -5F carboxylic acid (S23922, Section 20.2) *

* Carboxylic acids require activation with EDAC/NHSS before reaction with amines.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

- Notes**
1. Spectra are in aqueous buffers adjusted to >1 pH unit above and >1 pH unit below the pK_a.
 2. Spectral data for this product represents the unreacted succinimidyl ester. The pK_a value and the spectral data for acidic solutions have been estimated based on the spectra of the parent carboxylic acid.
 3. The molecular weight is nominally as specified in the product name but may have a broad distribution.
 4. ND = not determined.
 5. Abs, Em and pK_a values listed for this dextran conjugate are those obtained for the free dye. Values for actual conjugates are typically very similar, with slight variations between different production lots.
 6. These conjugates contain both pH-sensitive fluorescein (Abs = 495, Em = 520 nm) and pH-insensitive tetramethylrhodamine (Abs = 555 nm, Em = 575 nm) fluorophores.
 7. The pK_a values of lipophilic pH indicators may vary considerably depending on the electrostatic properties of membrane surfaces. (Biochemistry (1993) 32:10057, J Phys Chem (1977) 81:1755, Biochim Biophys Acta (1988) 939:289) The pK_a values listed are for electrostatically neutral liposomes or micelles. Spectra are in MeOH containing a trace of HCl (MeOH/H⁺) or a trace of KOH (MeOH/OH⁻).
 8. Chloroform is the most generally useful solvent for preparing stock solutions of phospholipids (including sphingomyelins). Glycerophosphocholines are usually freely soluble in ethanol. Most other glycerophospholipids (phosphoethanolamines, phosphatidic acids and phosphoglycerols) are less soluble in ethanol, but solutions up to 1–2 mg/mL should be obtainable, using sonication to aid dispersion if necessary. Labeling of cells with fluorescent phospholipids can be enhanced by addition of cyclodextrins during incubation. (J Biol Chem (1999) 274:35359)
 9. pHrodo™ succinimidyl ester (P36600) exhibits a complex pH titration profile. Decreasing pH (from pH 9 to pH 2) produces a continuous (but nonlinear) fluorescence increase. This pH response profile typically changes upon conjugation of the dye to proteins and other biomolecules.
 10. S22801 is converted to fluorescent products with spectra similar to C1270 (Section 20.2) after acetate hydrolysis.

PRODUCT LIST 20.4 pH INDICATOR CONJUGATES

Cat. No.	Product	Quantity

21.1 Fluorescent Na⁺ and K⁺ Indicators

Sodium and potassium channels are ion-selective protein pores that span the cell's plasma membrane and serve to establish and regulate membrane potential. They are typically classified according to their response mechanism: voltage-gated channels open or close in response to changes in membrane potential,¹ whereas ligand-gated or ion-activated channels are triggered by ligand or ion binding.² In excitable cells such as neurons and myocytes, these channels function both to create the action potential and to reset the cell's resting membrane potential.

In this section, we describe sodium- and potassium-selective fluorescent indicators, as well as the FluxOR™ Thallium Detection Kits, which provide a fluorescence-based method for assaying potassium ion channel and transporter activities. The next section describes fluorescent indicators for intracellular and extracellular chloride, together with an assortment of analytical reagents and methods for direct or indirect quantitation of other inorganic anions.

SBFI and PBFI

Properties of SBFI and PBFI

SBFI³ and PBFI^{3,4} are fluorescent indicators for sodium and potassium, respectively. Although the selectivity of SBFI and PBFI for their target ions is less than that of calcium indicators such as fura-2, it is sufficient for the detection of physiological concentrations of Na⁺ and K⁺ in the presence of other monovalent cations.³ Furthermore, the spectral responses of SBFI and PBFI upon ion binding permit excitation ratio measurements (Loading and Calibration of Intracellular Ion Indicators—Note 19.1), and these indicators can be used with the same optical filters and equipment used for fura-2.^{5,6}

SBFI (Figure 21.1.1) and PBFI (Figure 21.1.2) comprise benzofuranyl fluorophores linked to a crown ether chelator. The cavity size of the crown ether confers selectivity for Na⁺ versus K⁺ (or *vice versa* in the case of PBFI). When an ion binds to SBFI or PBFI, the indicator's fluorescence quantum yield increases, its excitation peak narrows and its excitation maximum shifts to shorter wavelengths (Figure 21.1.3), causing a significant change in the ratio of fluorescence intensities excited at 340/380 nm (Figure 21.1.4, Figure 21.1.5). This fluorescence signal is slightly sensitive to changes in pH between 6.5 and 7.5,^{7,8} but it is strongly affected by ionic strength⁹ and viscosity.¹⁰ Researchers have described the use of SBFI for emission ratio detection¹¹ (410/590 nm, excited at

Figure 21.1.1 SBFI, tetraammonium salt (S1262).

Figure 21.1.2 PBFI, tetraammonium salt (P1265MP).

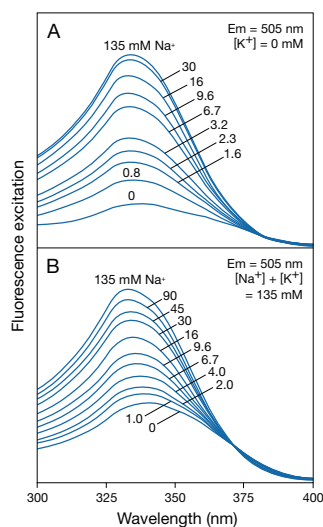

Figure 21.1.4 The excitation spectral response of SBFI (S1262) to Na⁺: **A**) in K⁺-free solution and **B**) in solutions containing K⁺ with the combined Na⁺ and K⁺ concentration equal to 135 mM. The scale on the vertical axis is the same for both panels.

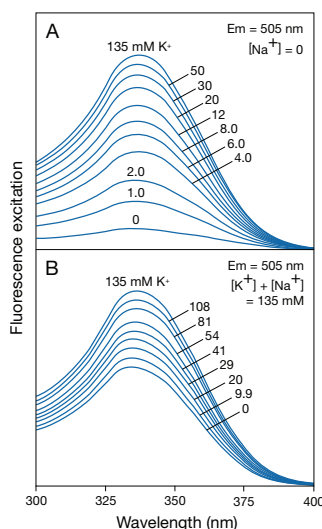

Figure 21.1.5 The excitation spectral response of PBFI (P1265MP) to K⁺: **A**) in Na⁺-free solution and **B**) in solutions containing Na⁺ with the combined K⁺ and Na⁺ concentration equal to 135 mM. The scale on the vertical axis is the same for both panels.

Figure 21.1.3 Fluorescence excitation (detected at 505 nm) and emission (excited at 340 nm) spectra of SBFI in pH 7.0 buffer containing 135 mM **A**) or 0 mM **B**) Na⁺.

340 nm). More recently, the implementation of two-photon excitation of SBFI with infrared light has been reported for Na⁺ imaging in spines and fine dendrites of central neurons^{12,13} (Figure 21.1.6).

Although SBFI is quite selective for the Na⁺ ion, K⁺ has some effect on the native affinity of SBFI for Na⁺ (Figure 21.1.4). The dissociation constant (K_d) of SBFI for Na⁺ is 3.8 mM in the absence of K⁺, and 11.3 mM in solutions with a combined Na⁺ and K⁺ concentration of 135 mM, which approximates physiological ionic strength. SBFI is ~18-fold more selective for Na⁺ than for K⁺. Likewise, the K_d of PBFI for K⁺ is strongly dependent on whether Na⁺ is present (Figure 21.1.5), with a value of 5.1 mM in the absence of Na⁺ and 44 mM in solutions with a combined Na⁺ and K⁺ concentration of 135 mM. In buffers in which the Na⁺ is replaced by tetramethylammonium chloride, the K_d of PBFI for K⁺ is 11 mM; choline chloride and *N*-methylglucamine are two other possible replacements for Na⁺ in the medium. Although PBFI is only 1.5-fold more selective for K⁺ than for Na⁺, this selectivity is often sufficient because intracellular K⁺ concentrations are normally about 10 times higher than Na⁺ concentrations.

The K_d of all ion indicators depends on factors such as pH, temperature, ionic strength, concentrations of other ions and dye-protein interactions. Due to these environmental factors, the K_d determined *in situ* for intracellular SBFI is substantially higher than that determined in cell-free buffer solutions. K_d (Na⁺) values of 29 mM, 26.6 mM and 18.0 mM have been determined for SBFI in lizard peripheral axons, porcine adrenal chromaffin cells and rat hippocampal neurons, respectively.^{7,14} Consequently, intracellular SBFI should be calibrated using the pore-forming antibiotic gramicidin⁵ (G6888). Palytoxin, an ionophoric toxin isolated from marine coelenterates, is much more effective than gramicidin for equilibrating intracellular and extracellular Na⁺.¹⁴ Intracellular PBFI should be calibrated using the K⁺ ionophore valinomycin¹⁵ (V1644).

Figure 21.1.6 CA1 pyramidal neuron in a hippocampal slice filled with SBFI (S1262) delivered from a patch pipette (visible on the right). The image was obtained using two-photon excitation of SBFI at 790 nm. Image contributed by Christine R. Rose, Physiological Institute, University of Munich.

Cell Loading with SBFI and PBFI

SBFI and PBFI are available both as cell-impermeant acid salts (S1262, P1265MP) and as cell-permeant acetoxymethyl (AM) esters (S1263, S1264, P1267MP). The anionic acid forms can be loaded into cells using our Influx™ pinocytic cell-loading reagent (I14402, Section 19.8), or by microinjection, patch-pipette infusion or electroporation. For AM ester loading (Loading and Calibration of Intracellular Ion Indicators—Note 19.1), addition of the Pluronic® F-127 (P3000MP, P6866, P6867) or PowerLoad™ (P10020) dispersing agents as well as relatively long incubation times—up to four hours—are typically necessary.⁵ ATP-induced permeabilization reportedly produces increased uptake of SBFI AM by bovine pulmonary arterial endothelial cells¹⁶ (BPAEC). Somewhat higher working concentrations of PBFI and SBFI than those used for fura-2 may be required because of the lower fluorescence quantum yields of these indicators. AM ester loading sometimes produces intracellular compartmentalization of SBFI.^{10,17} As with other AM esters, reducing the incubation temperature below 37°C may inhibit compartmentalization. Other practical aspects of loading and calibrating SBFI have been reviewed by Negulescu and Machen.⁵

Applications of SBFI

SBFI has been employed to estimate Na⁺ gradients in isolated mitochondria,^{17–19} as well as to measure intracellular Na⁺ levels or Na⁺ efflux in cells from a variety of tissues:

- Blood—platelets,²⁰ monocytes²¹ and lymphocytes²²
- Brain—astrocytes,²³ neurons,^{12,24} and presynaptic terminals^{25,26}
- Muscle—perfused heart,^{27,28} cardiomyocytes^{29–32} and smooth muscle^{33,34}
- Secretory epithelia^{35–37}
- Plants³⁸

SBFI has also been used in combination with other fluorescent indicators to correlate changes in intracellular Na⁺ with Ca²⁺ and Mg²⁺ concentrations,^{24,39,40} intracellular pH and membrane potential.²¹

Applications of PBFI

PBFI⁴ has fewer documented applications than SBFI. Renewed interest has been prompted by the observation that intracellular K⁺ levels appear to be a controlling factor in apoptotic cell death pathways.⁴¹ Flow cytometric measurements using UV argon-ion laser excitation (351 nm and 364 nm) of PBFI indicate that K⁺ efflux induces shrinkage of apoptotic cells and is a trigger for caspase activation.^{42–45} Furthermore, PBFI provides a potential alternative to radiometric ⁸⁶Rb efflux assays for quantitating K⁺ transport.¹⁵ Other applications of PBFI include:

- Detecting adrenoceptor-stimulated decreases of intracellular K⁺ concentration in astrocytes and neurons⁴⁶
- Evaluating the mediating effects of K⁺ depletion on monocytic cell necrosis⁴⁷
- Investigating the relationship between cytoplasmic K⁺ concentrations and NMDA excitotoxicity⁴⁸
- Measuring intracellular K⁺ fluxes associated with apoptotic cell shrinkage^{49,50}
- Monitoring mitochondrial K_{ATP} channel activation^{51–53}
- Quantitating K⁺ in isolated cochlear outer hair cells⁵⁴ and in mammalian ventricles using patch-clamp techniques⁵⁵

- Detecting elevated intracellular K⁺ levels associated with HIV-induced cytopathology⁵⁶
- Measuring K⁺ levels in plant cells and vacuoles⁵⁷

Sodium Green™ Na⁺ Indicator

The Sodium Green™ indicator can be excited at 488 nm (Figure 21.1.7), providing a valuable alternative to the UV light-excitable SBFI for use with confocal laser-scanning microscopes⁵⁸ and flow cytometers.⁵⁹ We offer the cell-impermeant tetra(tetramethylammonium) salt of the Sodium Green™ indicator (S6900), as well as its cell-permeant tetraacetate (S6901).

The Sodium Green™ indicator comprises two 2',7'-dichlorofluorescein dyes linked to the nitrogen atoms of a crown ether (Figure 21.1.8) with a cavity size that confers selectivity for the Na⁺ ion. Upon binding Na⁺, the Sodium Green™ indicator exhibits an increase in fluorescence emission intensity with little shift in wavelength (Figure 21.1.9). Although the Sodium Green™ indicator lacks the direct ratiometric readout capability of SBFI, fluorescence intensity fluctuations due to cell size variability can be compensated to some extent by using forward light scatter as a reference signal in flow cytometry.⁵⁹

As compared with SBFI, the Sodium Green™ indicator shows greater selectivity for Na⁺ than K⁺ (~41-fold versus ~18-fold) and displays a much higher fluorescence quantum yield (0.2 versus 0.08) in Na⁺-containing solutions. The longer-wavelength absorption of the Sodium Green™ indicator results in reduction of the potential for

photodamage to the cell because the energy of the excitation light is lower than that of the UV light required for excitation of SBFI. The K_d of the Sodium Green™ indicator for Na⁺ is about 6 mM in K⁺-free solution and about 21 mM in solutions with combined Na⁺ and K⁺ concentration of 135 mM, approximating physiological ionic strength. Because its K_d may be shifted due to intracellular ionic strength, the Sodium Green™ indicator should be calibrated *in situ* using the pore-forming antibiotic gramicidin⁵⁹ (G6888). In some cases, dye-protein interactions may cause severe dampening or even complete elimination of the Na⁺-dependent fluorescence response of intracellular Sodium Green™ indicator. Nevertheless, flow cytometric measurements in Chinese hamster ovary (CHO) cells are well correlated with spectrofluorometric measurements using SBFI.⁵⁹ Other applications include:

- Assessing the regulation of Na⁺/K⁺-ATPase by persistent Na⁺ accumulation in rat thalamic neurons⁶⁰
- Confocal imaging of Na⁺ transport in rat colonic mucosa⁶¹ and cochlear hair cells by flow cytometry⁶²
- Detecting anoxia-induced Na⁺ influx in neurons⁶³
- Determining intracellular Na⁺ concentration in crayfish presynaptic terminals using an area-ratio method⁶⁴
- Fluorescence lifetime imaging of intracellular Na⁺^{65–67}
- Measuring intracellular Na⁺ concentration in bacterial cells⁶⁸ and green algae⁶⁹
- Determining voltage-gated sodium channel NaV1.5-driven endosomal Na⁺ levels in macrophages²¹

Figure 21.1.7 Absorption and fluorescence emission spectra of Sodium Green™ indicator in pH 7.0 buffer containing 135 mM Na⁺.

Figure 21.1.8 Sodium Green™, tetra(tetramethylammonium) salt (S6900).

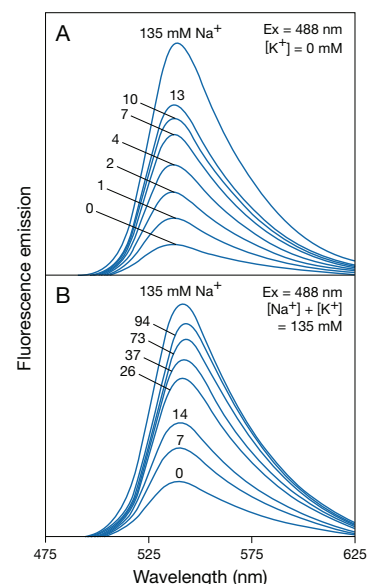

Figure 21.1.9 Emission spectral response of the Sodium Green™ indicator (S6900) to Na⁺: **A**) in K⁺-free solution and **B**) in solutions containing K⁺ with the combined Na⁺ and K⁺ concentration equal to 135 mM. The scale on the vertical axis is the same for both panels.

Figure 21.1.10 Fluorescence emission spectra of the CoroNa™ Green indicator (C36675, C36676) in 50 mM MOPS, pH 7.0 (adjusted with tetramethylammonium hydroxide), containing 100 mM K⁺ and variable concentrations of Na⁺ as indicated.

Figure 21.1.11 CoroNa™ Green (C36675).

Figure 21.1.12 CoroNa™ Green, AM (C36676).

Figure 21.1.13 CoroNa™ Red chloride (C24430).

CoroNa™ Na⁺ Indicators

CoroNa™ Green Na⁺ Indicator

The CoroNa™ Green dye is a green-fluorescent Na⁺ indicator that exhibits an increase in fluorescence emission intensity upon binding Na⁺ (excitation/emission = 492/516 nm), with little shift in wavelength (Figure 21.1.10). Similar to our SBF1 and Sodium Green™ Na⁺ indicators, the CoroNa™ Green indicator allows spatial and temporal resolution of Na⁺ concentrations in the presence of physiological concentrations of other monovalent cations.^{70–73} CoroNa™ Green Na⁺ indicator has been co-loaded with Alexa Fluor® 594 dextran (an ion-insensitive reference) via suction pipettes into live rat optic nerves for confocal imaging of intracellular Na⁺ levels; calcium measurements were also made using fluo-4 dextran and Alexa Fluor® 594 dextran.⁷⁴

Comprising a fluorescein molecule linked to a crown ether with a cavity size that confers selectivity for the Na⁺ ion (Figure 21.1.11), the CoroNa™ Green indicator is less than half the size of the Sodium Green™ indicator⁷⁵ (molecular weight 586 and 1668, respectively). This smaller size appears to help the cell-permeant CoroNa™ Green AM (Figure 21.1.12) load cells more effectively than the Sodium Green™ tetraacetate. Furthermore, the CoroNa™ Green indicator responds to a broader range of Na⁺ concentration, with a K_d of ~80 mM. The cell-impermeant CoroNa™ Green indicator (C36675) is supplied in a unit size of 1 mg. The cell-permeant AM ester of the CoroNa™ Green indicator (C36676) is supplied as a set of 20 vials, each containing 50 µg of the indicator.

CoroNa™ Red Na⁺ Indicator

CoroNa™ Red chloride is based on a crown ether that has structural similarity to the Ca²⁺ chelator BAPTA (Figure 21.1.13). Unlike SBF1 and the Sodium Green™ indicator, the net positive charge of CoroNa™ Red chloride targets the indicator to mitochondria (Figure 21.1.14), and therefore loading of cells does not require use of a permeant ester derivative of the dye. Cells are typically loaded by adding 0.5–1.0 µM CoroNa™ Red chloride from a 1 mM stock solution in DMSO, incubating for 10–30 minutes at 37°C and finally washing with dye-free medium before commencing fluorescence analysis. The CoroNa™ Red indicator is only weakly fluorescent in the absence of Na⁺ and its fluorescence increases ~15-fold upon binding Na⁺ (Figure 21.1.15). Despite its relatively high K_d for Na⁺ of ~200 mM, the CoroNa™ Red indicator exhibits sensitive responses to cellular Na⁺ influxes through voltage-gated channels and ATP-gated cation pores. Verkman and co-workers have immobilized the CoroNa™ Red indicator on polystyrene microspheres and used this complex to measure Na⁺ concentrations around 100 mM in the tracheal airway–surface liquid (ASL) of cultured epithelial cells and human lung tissues.^{76,77} The CoroNa™ Red indicator has also been employed to investigate the Na⁺ channel permeation pathway using polyhistidine-tagged and pore-only constructs of a voltage-dependent Na⁺ channel.⁷⁸ The CoroNa™ Red indicator is available as a single 1 mg vial (C24430) or as a set of 20 vials, each containing 50 µg of the indicator (C24431).

Figure 21.1.14 Images of an NIH 3T3 cell showing colocalization of the CoroNa™ Red sodium indicator (left panel; C24430, C24431) with the MitoTracker™ Green FM® mitochondrial marker (right panel, M7514). A cell loaded with both dyes was imaged consecutively using Omega® Optical bandpass filter set XF41 for CoroNa™ Red sodium indicator and set XF23 for MitoTracker™ Green FM®.

FluxOR™ Potassium Ion Channel Assay

Assaying K⁺ Channels with the FluxOR™ Potassium Ion Channel Assay Kit

The FluxOR™ Potassium Ion Channel Assay Kits (F10016, F10017) provide a fluorescence-based assay for high-throughput screening (HTS) of potassium ion channel and transporter activities.^{79–81} The FluxOR™ Potassium Ion Channel Assay Kits take advantage of the well-described permeability of potassium channels to thallium (Tl⁺) ions. When thallium is present in the extracellular solution containing a stimulus to open potassium channels, channel activity is detected with a cell-permeant thallium indicator dye that reports large increases in fluorescence emission at 525 nm as thallium flows down its concentration gradient and into the cells (Figure 21.1.16). In this way, the fluorescence reported in the FluxOR™ system becomes a surrogate indicator of activity for any ion channel or transporter that is permeable to thallium, including the human ether-a-go-go-related gene (hERG) channel, one of the human cardiac potassium channels. The FluxOR™ potassium ion channel assay has been validated for homogeneous high-throughput profiling of hERG channel inhibition using BacMam-mediated transient expression of hERG.⁸⁰ The FluxOR™ Potassium Ion Channel Assay Kits can also be used to study potassium co-transport processes that accommodate the transport of thallium into cells.⁸² Furthermore, resting potassium channels and inward rectifier potassium channels like Kir2.1 can be assayed by adding stimulus buffer with thallium alone, without any depolarization to measure the signal.

The FluxOR™ reagent, a thallium indicator dye, is loaded into cells as a membrane-permeable AM ester. The FluxOR™ dye is dissolved in DMSO and further diluted with FluxOR™ assay buffer, a physiological HBSS (Hank's balanced salt solution), for loading into cells. Loading is assisted by the proprietary PowerLoad™ concentrate, an optimized formulation of nonionic Pluronic® surfactant polyols that act to disperse and stabilize AM ester dyes for optimal loading in aqueous solution. This PowerLoad™ concentrate is also available separately (P10020) to aid the solubilization of water-insoluble dyes and other materials in physiological media.

Once inside the cell, the nonfluorescent AM ester of the FluxOR™ dye is cleaved by endogenous esterases into a weakly fluorescent (basal fluorescence), thallium-sensitive indicator. The thallium-sensitive form is retained in the cytosol, and its extrusion is inhibited by water-soluble probenecid (P36400, Section 19.8), which blocks organic anion pumps. For most applications, cells are loaded with the dye at room temperature. For best results, the dye-loading buffer is then replaced with fresh, dye-free assay buffer (composed of physiological HBSS containing probenecid), and cells are ready for the HTS assay.

Each FluxOR™ Potassium Ion Channel Assay Kit contains:

- FluxOR™ reagent
- FluxOR™ assay buffer
- PowerLoad™ concentrate
- Probenecid
- FluxOR™ chloride-free buffer
- Potassium sulfate (K₂SO₄) concentrate
- Thallium sulfate (Tl₂SO₄) concentrate
- Dimethylsulfoxide (DMSO)
- Detailed protocols

Figure 21.1.16 Thallium redistribution in the FluxOR™ assay. Basal fluorescence from cells loaded with FluxOR™ reagent (provided in the FluxOR™ Potassium Ion Channel Assay Kits; F10016, F10017) is low when potassium channels remain unstimulated, as shown in the left panel. When thallium is added to the assay with the stimulus, the thallium flows down its concentration gradient into the cells, activating the dye as shown in the right panel.

Figure 21.1.15 Fluorescence emission spectra of the CoroNa™ Red indicator (C24430, C24431) in 50 mM MOPS (pH 7.0, adjusted with tetramethylammonium hydroxide) containing 100 mM K⁺ and variable concentrations of Na⁺ as indicated.

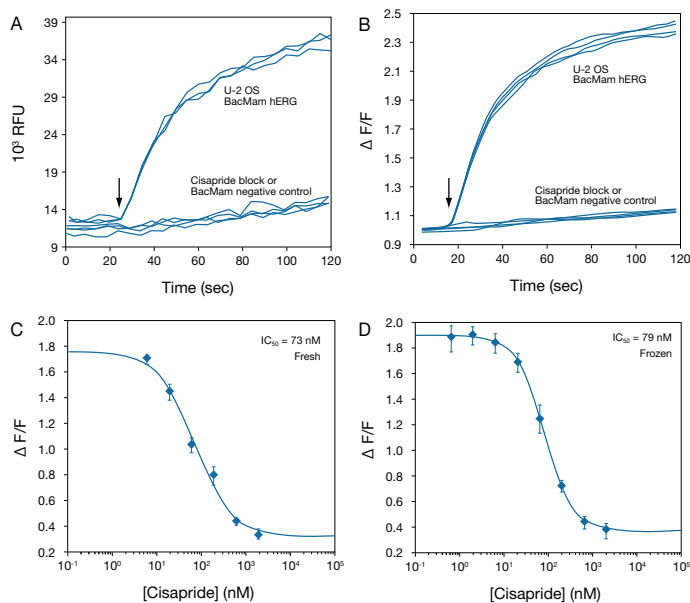

Figure 21.1.17 FluxOR™ potassium ion channel assays (F10016, F10017) performed on fresh and frozen U2OS cells transduced with the BacMam hERG reagent (B10019, B10033). **A**) Raw data (RFU = relative fluorescence units) obtained in the FluxOR™ assay determination of thallium flux in U2OS cells, which had been transduced with BacMam-hERG and kept frozen until the day of use. The arrow indicates the addition of the thallium/potassium stimulus, and upper and lower traces indicate data taken from the minimum and maximum doses of cisapride used in the determination of the dose-response curves. **B**) Raw pre-stimulus peak and baseline values were boxcar averaged and normalized to indicate the fold increase in fluorescence over time. **C**) Data generated in a dose-response determination of cisapride block on BacMam hERG expressed in U2OS cells freshly prepared from overnight expression after viral transduction. **D**) Parallel data obtained from cells transduced with BacMam-hERG, stored for 2 weeks in liquid nitrogen, thawed and plated 4 hours prior to running the assay. Error bars indicate standard deviation, n = 4 per determination.

The FluxOR™ Kits provide a concentrated thallium solution along with sufficient dye and buffers to perform ~4000 (F10016) or ~40,000 (F10017) assays in a 384-well microplate format. These kits allow maximum target flexibility and ease of operation in a homogeneous format. The FluxOR™ potassium ion channel assay has been demonstrated for use with CHO and HEK 293 cells stably expressing hERG, as well as U2OS cells transiently transduced with the BacMam hERG reagent⁸⁰ (B10019, B10033; see below) (Figure 21.1.17). More information is available at www.invitrogen.com/handbook/fluxorpotassium.

Using BacMam Technology for Transient Expression of K⁺ Channels

Potassium channel cDNAs that have been engineered into a baculovirus gene delivery/expression system using BacMam technology (BacMam Gene Delivery and Expression Technology—Note 11.1) are also available for use with the FluxOR™ Potassium Ion Channel Assay Kits, including the human ether-a-go-go related gene⁸⁰ (hERG) (Figure 21.1.18), several members of the voltage-gated K⁺ channel (Kv) gene family and two members of the inwardly rectifying K⁺ channel (Kir) gene family:

- BacMam hERG (for 10 microplates, B10019; for 100 microplates, B10033)
- BacMam Kv1.1 (for 10 microplates, B10331)
- BacMam Kv1.3 (for 10 microplates, B10332)
- BacMam Kv2.1 (for 10 microplates, B10333)
- BacMam Kv7.2 and Kv7.3 (for 10 microplates, B10147)
- BacMam Kir1.1 (for 10 microplates, B10334)
- BacMam Kir2.1 (for 10 microplates, B10146)

The BacMam system uses a modified insect cell baculovirus as a vehicle to efficiently deliver and express genes in mammalian cells with minimum effort and toxicity. The use of BacMam delivery in mammalian cells is relatively new, but well described, and has been used extensively in a drug discovery setting.⁸³ Constitutively expressed ion channels and other cell surface proteins have been shown to contribute to cell toxicity in some systems, and may be subject to clonal drift and other inconsistencies that hamper successful experimentation and screening. Thus, inducible, division-arrested or transient expression systems such as BacMam technology are increasingly methods of choice to decrease variability of expression in such assays.

U2OS cells (ATCC number HTB-96) have been shown to demonstrate highly efficient expression of BacMam-delivered targets in a null background ideal for screening in a heterologous expression system. The U2OS cell line is recommended for use if your particular cell line does not efficiently express the BacMam targets. Examples of other cell lines that are efficiently transduced by BacMam technology include HEK 293, HepG2, BHK, Cos-7 and Saos-2.

Figure 21.1.18 BacMam-hERG gene delivery and expression. This schematic depicts the mechanism of BacMam-mediated gene delivery into a mammalian cell and expression of the hERG gene (B10019, B10033). The hERG gene resides within the baculoviral DNA, downstream of a CMV promoter that drives its expression when introduced into a mammalian target cell. BacMam viral particles are taken up by endocytic pathways into the cell, and the DNA within them is released for transcription and expression. The translated protein is then folded for insertion into the membrane, forming functional hERG ion channels. This process begins within 4–6 hours and in many cell types is completed after an overnight period.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

* For "Low Ion" spectra, the concentration of Na⁺ or K⁺ is zero. For "High Ion" spectra, the concentration of Na⁺ or K⁺ is in excess of that required to saturate the response of the indicator.

† Cat. No. of product generated *in situ* in typical intracellular application.

Notes

- Dissociation constant values vary considerably depending on presence of other ions, temperature, pH, ionic strength, viscosity, protein binding and other factors. It is essential that the spectral response of the probe be calibrated in your system.
- This indicator exhibits fluorescence enhancement in response to ion binding, with essentially no change in absorption or emission wavelengths.
- K_d determined in 50 mM MOPS, pH 7.0 (adjusted with tetramethylammonium hydroxide) containing 40% DMSO at 22°C.
- Spectra measured in aqueous buffers containing 40% DMSO and 0 M (H₂O) or 1 M Na⁺ (H₂O/Na⁺).
- Spectra measured in aqueous buffers containing 0 M (H₂O) or a >10-fold excess of free cation X (H₂O/X) relative to the listed dissociation constant (K_d) for cation X.
- K_d(Na⁺) determined in 50 mM MOPS, pH 7.0 (adjusted with tetramethylammonium hydroxide) at 22°C.
- K_d(K⁺) has been determined in 10 mM MOPS, pH 7.0 (adjusted with tetramethylammonium hydroxide) at 22°C. K_d(K⁺) is strongly dependent on the concentration of Na⁺. In solutions with Na⁺ + K⁺ = 135 mM, K_d(K⁺) = 44 mM.
- Fluorescence of SBFI AM and PBFI AM is very weak.
- K_d(Na⁺) has been determined in 10 mM MOPS, pH 7.0 (adjusted with tetramethylammonium hydroxide) at 22°C. Na⁺ dissociation constants for these indicators are dependent on K⁺ concentration. In solutions with total Na⁺ + K⁺ = 135 mM, K_d(Na⁺) = 11.3 mM (S1262) and 21 mM (S6900).

PRODUCT LIST 21.1 FLUORESCENT Na⁺ AND K⁺ INDICATORS

Cat. No.	Product	Quantity
B10019	BacMam-hERG *for 10 microplates*	1 kit
B10033	BacMam-hERG *for 100 microplates*	1 kit
B10334	BacMam Kir1.1 *for 10 microplates*	1 kit
B10146	BacMam Kir2.1 *for 10 microplates*	1 kit
B10331	BacMam Kv1.1 *for 10 microplates*	1 kit
B10332	BacMam Kv1.3 *for 10 microplates*	1 kit
B10333	BacMam Kv2.1 *for 10 microplates*	1 kit
B10147	BacMam Kv7.2 and Kv7.3 *for 10 microplates*	1 kit
C36675	CoroNa™ Green *cell impermeant*	1 mg
C36676	CoroNa™ Green, AM *cell permeant* *special packaging*	20 x 50 µg
C24430	CoroNa™ Red chloride	1 mg
C24431	CoroNa™ Red chloride *special packaging*	20 x 50 µg
F10016	FluxOR™ Potassium Ion Channel Assay *for 10 microplates*	1 kit
F10017	FluxOR™ Potassium Ion Channel Assay *for 100 microplates*	1 kit
G6888	gramicidin	100 mg
P1267MP	PBFI, AM *cell permeant* *special packaging*	20 x 50 µg
P1265MP	PBFI, tetraammonium salt *cell impermeant*	1 mg
P6866	Pluronic® F-127 *10% solution in water* *0.2 µm filtered*	30 mL
P3000MP	Pluronic® F-127 *20% solution in DMSO*	1 mL
P6867	Pluronic® F-127 *low UV absorbance*	2 g
P10020	PowerLoad™ concentrate, 100X	5 mL
S1263	SBFI, AM *cell permeant*	1 mg
S1264	SBFI, AM *cell permeant* *special packaging*	20 x 50 µg
S1262	SBFI, tetraammonium salt *cell impermeant*	1 mg
S6901	Sodium Green™ tetraacetate *cell permeant* *special packaging*	20 x 50 µg
S6900	Sodium Green™, tetra(tetramethylammonium) salt *cell impermeant*	1 mg
V1644	valinomycin	25 mg

21.2 Detecting Chloride, Phosphate, Nitrite and Other Anions

This section describes fluorescent indicators for intracellular and extracellular chloride together with an assortment of analytical reagents and methods for direct or indirect quantitation of other inorganic anions, including bromide, iodide, hypochlorite, cyanide, nitrite, nitrate, phosphate, pyrophosphate and selenide.¹

Fluorescent Chloride Indicators

Most of the fluorescent chloride indicators are 6-methoxyquinolinium derivatives, the prototype of which is 6-methoxy-*N*-(3-sulfopropyl)quinolinium^{2,3} (SPQ, Figure 21.2.1). Cl⁻ detection sensitivity has been improved by modifications of the quinolinium *N* substituent.^{4,5} Our current range of Cl⁻ indicators consists of:

- 6-Methoxy-*N*-(3-sulfopropyl)quinolinium (SPQ, M440)
- *N*-(Ethoxycarbonylmethyl)-6-methoxyquinolinium bromide (MQAE, E3101)
- 6-Methoxy-*N*-ethylquinolinium iodide (MEQ, M6886)
- Lucigenin (L6868)

All of these indicators detect Cl⁻ via diffusion-limited collisional quenching.⁶ This detection mechanism is different from that of fluorescent indicators for Ca²⁺, Mg²⁺, Zn²⁺, Na⁺ and K⁺. It involves a transient interaction between the excited state of the fluorophore and a halide ion—no ground-state complex is formed. Quenching is not accompanied by spectral shifts (Figure 21.2.2) and, consequently, ratio measurements are not directly feasible. Quenching by other halides, such as Br⁻ and I⁻, and other anions, such as thiocyanate, is more efficient than Cl⁻ quenching.⁶ Fortunately, physiological concentrations of non-chloride ions do not significantly affect the fluorescence of SPQ and other methoxyquinolinium-based Cl⁻ indicators. With some exceptions,⁷ fluorescence of these indicators is not pH sensitive in the physiological range.⁴ Because Cl⁻-dependent fluorescence quenching is a diffusional process, it is quite sensitive to solution viscosity and volume. Exploiting this property, SPQ has been used to measure intracellular volume changes.⁸

The efficiency of collisional quenching is characterized by the Stern–Volmer constant (K_{SV}), defined as the reciprocal of the ion concentration that produces 50% of maximum quenching. For SPQ, K_{SV} is reported to be 118 M⁻¹ in aqueous solution and 12 M⁻¹ inside cells.⁹ For MQAE, *in situ* K_{SV} values of 25–28 M⁻¹ have been determined in various cell types,^{10,11} compared with the solution value of 200 M⁻¹. Intracellular Cl⁻ indicators are generally calibrated using high-K⁺ buffers and the K⁺/H⁺ ionophore nigericin (N1495) in conjunction with tributyltin chloride, an organometallic compound that acts as a Cl⁻/OH⁻ antiporter.^{4,12} With the exception of diH-MEQ, Cl⁻ indicators must be loaded into cells by long-term incubation (up to eight hours) in the presence of a large excess of dye or by brief hypotonic permeabilization. Because membranes are slightly permeable to the indicator, rapid leakage may occur. Experimentally determined estimates of leakage vary quite widely.^{10–12}

Measurement of intracellular Cl⁻ concentrations and the study of Cl⁻ channels have been stimulated by the discovery that cystic fibrosis is caused by mutations in a gene encoding a Cl⁻ transport channel, which is known as the cystic fibrosis transmembrane conductance regulator¹³ (CFTR). Cl⁻ permeability assays are used to detect activity of the CFTR and other anion transporters.^{14–17} In these assays, SPQ- or MQAE-loaded cells are successively perfused with chloride-containing extracellular medium followed by medium in which the Cl⁻ content is replaced by nitrate (NO₃⁻). NO₃⁻ is used in this assay protocol because it produces no fluorescence quenching of the indicator, yet its channel permeability is essentially the same as that of Cl⁻^{14,15} (Figure 21.2.3).

Figure 21.2.1 6-methoxy-*N*-(3-sulfopropyl)quinolinium, inner salt (SPQ, M440).

Figure 21.2.2 Fluorescence emission spectra of MQAE (E3101) in increasing concentrations of Cl⁻.

Figure 21.2.3 Detection of cystic fibrosis transmembrane conductance regulator (CFTR) activity using 6-methoxy-*N*-(3-sulfopropyl)quinolinium, inner salt (SPQ, M440). Fluorescence of intracellular SPQ is quenched by collision with chloride ions, indicated by $F_0/F > 1$ (F_0 = fluorescence intensity in absence of chloride, F = fluorescence intensity at time points indicated on the x-axis). Upon addition of cyclic AMP to initiate channel opening, and exchange of extracellular Cl⁻ (135 mM) for nitrate (NO₃⁻), SPQ quenching decreases in CFTR-expressing cells (filled circles) as CFTR-mediated anion transport results in replacement of intracellular Cl⁻ with nonquenching NO₃⁻. Control cells with no CFTR expression (open circles) show no response.

SPQ

SPQ (M440, Figure 21.2.1) is currently in widespread use for detecting CFTR activity using the Cl⁻/NO₃⁻ exchange technique described above.^{16,18–24} SPQ has also been employed to investigate Cl⁻ fluxes through several other transporters such as the GABA_A receptor,^{25,26} erythrocyte Cl⁻/HCO₃⁻ exchangers^{27,28} and the mitochondrial uncoupling protein.^{29–31} Although SPQ requires UV excitation (as do MQAE and MEQ), techniques for flow cytometric detection and calibration of the indicator using argon-ion laser excitation at 351 nm and 364 nm have been successfully demonstrated.¹²

MQAE

MQAE (E3101, Figure 21.2.4) has greater sensitivity to Cl⁻^{4,5} and a higher fluorescence quantum yield than SPQ; consequently, it is currently the more widely used of the two indicators. However, the ester group of MQAE may slowly hydrolyze inside cells, resulting in a change in its fluorescence response.³² MQAE has been used in a fluorescence-based microplate assay that has potential for screening compounds that modify Cl⁻ ion-channel activity.¹⁰ Other applications have included Cl⁻ measurements in cytomegalovirus-infected fibroblasts,³³ smooth muscle cells³² and salivary glands,¹⁷ as well as in reconstituted membranes containing the GABA_A receptor²⁶ or the mitochondrial-uncoupling protein^{34,35} (UCP-1).

MEQ and Cell-Permeant Dihydro-MEQ

The Cl⁻ indicator 6-methoxy-*N*-ethylquinolinium iodide (MEQ) can be rendered cell-permeant by masking its positively charged nitrogen to create a lipophilic, Cl⁻-insensitive compound, 6-methoxy-*N*-ethyl-1,2-dihydroquinoline³⁶ (dihydro-MEQ). This reduced quinoline derivative can then be loaded noninvasively into cells, where it is rapidly reoxidized in most cells to the cell-impermeant, Cl⁻-sensitive MEQ (Figure 21.2.5). Using this technique, researchers have loaded live brain slices and hippocampal neurons with MEQ for confocal imaging of Cl⁻ responses to GABA_A receptor activation and glutamatergic

Figure 21.2.4 *N*-(ethoxycarbonylmethyl)-6-methoxyquinolinium bromide (MQAE, E3101).

Figure 21.2.5 Intracellular delivery of the fluorescent chloride indicator 6-methoxy-*N*-ethylquinolinium iodide (MEQ, M6886), via oxidation of the membrane-permeant precursor dihydro-MEQ.

excitotoxicity.^{37–41} Quenching of intracellular MEQ fluorescence by Cl⁻ has a K_{SV} of 19 M⁻¹, a value that is slightly higher than that reported for SPQ in fibroblasts. MEQ is available in solid form (M6886) and is supplied with a simple protocol for reducing it to dihydro-MEQ with sodium borohydride (not supplied) just prior to cell loading.

Lucigenin

The fluorescence of lucigenin (L6868, Figure 21.2.6) is quantitatively quenched by high levels of Cl⁻ with a reported K_{SV} = 390 M⁻¹.⁴² Lucigenin absorbs maximally at both 368 nm ($EC = 36,000 \text{ cm}^{-1}\text{M}^{-1}$) and 455 nm ($EC = 7400 \text{ cm}^{-1}\text{M}^{-1}$), with an emission maximum at 505 nm. Its fluorescence emission has a quantum yield of ~0.6 and is insensitive to nitrate, phosphate and sulfate. Lucigenin is a useful Cl⁻ indicator in liposomes and reconstituted membrane vesicles; however, because its fluorescence is reported to be unstable in the cytoplasm, it may not always be suitable for determining intracellular Cl⁻.⁴² Lucigenin has been used to detect chloride uptake in tonoplast vesicles⁴³ and to measure Cl⁻ influx across the pleural surface in perfused mouse lungs.⁴⁴

Alternative Detection Techniques for Halides

As mentioned above, the fluorescence of SPQ and related Cl⁻ indicators is quenched by collision with a variety of anions, including (in order of increasing quenching efficiency) Cl⁻, Br⁻, I⁻ and thiocyanate⁴⁵ (SCN⁻). For example, fluorescence of SPQ is partially quenched by the anionic pH buffer TES (*N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid) but not by the protonated TES zwitterion, a property that has been exploited to measure proton efflux from proteoliposomes.^{31,46} Anion detectability using diffusional fluorescence quenching of these fluorophores is typically limited to the millimolar range. I⁻ quenches many other fluorophores and is commonly used to determine the accessibility of fluorophores to quenching in proteins and membranes.^{47,48}

In addition, halides can be oxidized to hypohalites (OCl⁻, OBr⁻, OI⁻), which react with rhodamine 6G (R634, Section 12.2) to yield chemiluminescent products.^{49,50} A cell produces OCl⁻ by oxidizing Cl⁻ within

Figure 21.2.6 Lucigenin (bis-*N*-methylacridinium nitrate, L6868).

Figure 21.2.7 Detection of reactive oxygen species (ROS) with 3'-(*p*-hydroxyphenyl) fluorescein (HPF, H36004) and 3'-(*p*-aminophenyl) fluorescein (APF, A36003).

the phagocytose.^{51,52} ⁻OCl also reacts with fluorescein (F1300, Section 1.5) to yield fluorescent products,⁵³ permitting analysis of ⁻OCl levels in water.

Alternatively, 3'-(*p*-aminophenyl) fluorescein (APF) and 3'-(*p*-hydroxyphenyl) fluorescein (HPF) (A36003, H36004; Section 18.2) can be used for the selective detection of ⁻OCl. Both of these fluorescein derivatives are essentially nonfluorescent until they react with the hydroxyl radical (HO[•]) or peroxyxynitrite anion (ONOO⁻) (Figure 21.2.7). APF will also react with the hypochlorite anion (⁻OCl), making it possible to use APF and HPF together to selectively detect hypochlorite anion. In the presence of these specific ROS, both APF and HPF yield a bright green-fluorescent product (excitation/emission maxima ~490/515 nm) and are compatible with all fluorescence instrumentation capable of visualizing fluorescein. Using APF, researchers have been able to detect the ⁻OCl generated by activated neutrophils, a feat that has not been possible with traditional ROS indicators.⁵⁴

Premo™ Halide Sensor

The fluorescent protein-based Premo™ Halide Sensor (P10229) is a pharmacologically relevant sensor for functional studies of ligand- and voltage-gated chloride channels and their modulators in cells. Chloride channels are involved in cellular processes as critical and diverse as transepithelial ion transport, electrical excitability, cell volume regulation and ion homeostasis. Given their physiological significance, it follows that defects in their activity can have severe implications, including such conditions as cystic fibrosis and neuronal degeneration. Thus, chloride channels represent important targets for drug discovery.⁵⁵

The Premo™ Halide Sensor combines a Yellow Fluorescent Protein (YFP) variant sensitive to halide ions with the efficient and noncytotoxic BacMam delivery and expression technology (BacMam Gene Delivery and Expression Technology—Note 11.1), yielding a highly sensitive, robust and easy-to-use tool for efficiently screening halide ion channels and transporter modulators in their cellular models of choice. The Premo™ Halide Sensor is based on the Venus variant of *Aequorea victoria* Green Fluorescent Protein (GFP), which displays enhanced fluorescence, increased folding, and reduced maturation time when compared with YFP.⁵⁶ Additional mutations (H148Q and I152L) were made within the Venus sequence to increase the sensitivity of the Venus fluorescent protein to changes in local halide concentration, in particular iodide ions.⁵⁷ Because chloride channels are also permeable to the iodide ion (I⁻), iodide can be used as a surrogate of chloride. Upon stimulation, a chloride channel or transporter opens and iodide flows down the concentration gradient into the cells, where it quenches the fluorescence of the expressed Premo™ Halide Sensor protein (Figure 21.2.8). The decrease in Premo™ Halide Sensor fluorescence is directly proportional to the ion flux, and therefore the chloride channel or transporter activity. The Premo™ Halide Sensor shows a similar excitation and emission profile to YFP (Figure 21.2.9) and can be detected using standard GFP/FITC or YFP filter sets. Halide-sensitive YFP-based constructs in conjunction with iodide quenching have been used in high-throughput screening (HTS) to identify modulators of calcium-activated chloride channels.⁵⁸

Figure 21.2.8 Principle of Premo™ Halide Sensor (P10229): Iodide redistribution upon chloride channel activation. Basal fluorescence from Premo™ Halide Sensor is high when chloride channels are low. Upon activation (opening) of chloride channels, the iodide ions enter the cell, down its concentration gradient, and quench the fluorescence from Premo™ Halide Sensor.

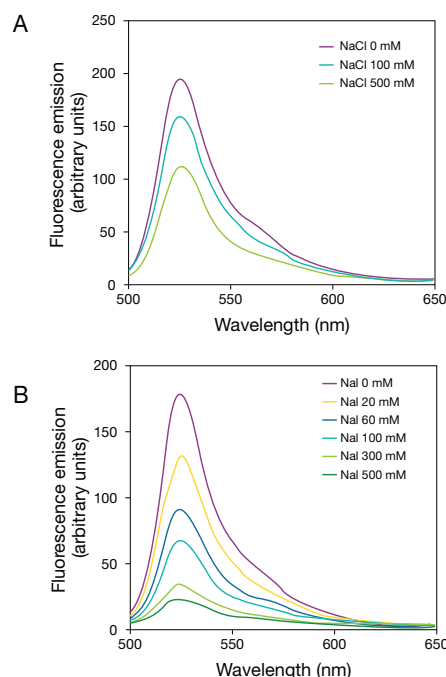

Figure 21.2.9 Quenching of Premo™ Halide Sensor fluorescence by increasing concentrations of iodide and chloride. U2OS cells were transfected with Premo™ Halide Sensor. After 24 hours, cells were trypsinized and lysed by resuspension in sterile distilled water. Fluorescence quenching of the lysate was examined using increasing concentrations of NaCl (A) and NaI (B). Iodide induces substantially greater quenching of Premo™ Halide Sensor fluorescence than chloride.

Figure 21.2.10 Fluorogenic amine-derivatization reaction of *o*-phthalaldehyde (OPA, P2331MP).

Figure 21.2.11 Fluorogenic amine-derivatization reaction of naphthalene-2,3-dicarboxaldehyde (NDA, N1138).

Figure 21.2.12 Fluorogenic amine-derivatization reaction of CBQCA (A6222, A2333).

Figure 21.2.13 Linearity and sensitivity of the Measure-iT™ high-sensitivity nitrite assay. Triplicate 10 μ L samples of nitrite were assayed using the Measure-iT™ High-Sensitivity Nitrite Assay Kit (M36051). Fluorescence was measured using excitation/emission of 365/450 nm and plotted versus picomoles of nitrite. Background fluorescence was not subtracted. The variation (CV) of replicate samples was <2%.

The Premo™ Halide Sensor (P10229) is pre-packaged and ready for immediate use. It contains all components required for cellular delivery and expression—including the baculovirus carrying the genetically encoded biosensor, BacMam enhancer and stimulus buffer containing iodide—in ten 96- or 384-well plates. The Premo™ Halide Sensor has been demonstrated to transduce multiple cell lines including BHK, U2OS, HeLa, CHO, and primary human bronchial epithelial cells (HBEC), providing the flexibility to assay chloride-permeable channels in a wide range of cellular models. More information is available at www.invitrogen.com/handbook/premohalide.

Cyanide Detection

The homologous aromatic dialdehydes, *o*-phthalaldehyde⁵⁹ (OPA, P2331MP) and naphthalene-2,3-dicarboxaldehyde⁶⁰ (NDA, N1138), are essentially nonfluorescent until reacted with a primary amine in the presence of excess cyanide or a thiol, such as 2-mercaptoethanol, 3-mercaptopropionic acid or the less obnoxious sulfite,⁶¹ to yield a fluorescent isoindole (Figure 21.2.10, Figure 21.2.11). Modified protocols that use an excess of an amine and limiting amounts of other nucleophiles permit the determination of cyanide in blood, urine and other samples.^{62–65}

We also offer the ATTO-TAG™ CBQCA (A6222) and ATTO-TAG™ FQ (A10192) reagents, which are similar to OPA and NDA in that they react with primary amines in the presence of cyanide or thiols to form highly fluorescent isoindoles^{66–74} (Figure 21.2.12). The ATTO-TAG™ CBQCA and ATTO-TAG™ FQ reagents should also be useful for detecting cyanide in a variety of biological samples.

We have found that our Thiol and Sulfide Quantitation Kit (T6060, Section 2.1) also provides an ultrasensitive enzymatic assay for cyanide, with a detection limit of ~5 nanomoles. In this case, interference would be expected from thiols, sulfides, sulfites and other reducing agents.

Nitrite, Nitrate and Nitric Oxide Detection

With the discovery of the role of nitric oxide in signal transduction (Section 18.3), assays for nitrite (NO₂⁻) have assumed new importance. Because inorganic nitrite is spontaneously produced by air oxidation of nitric oxide, the same reagents that have been utilized to detect nitric oxide production in cells should be useful for detecting nitrite in aqueous samples. Furthermore, inorganic nitrate (NO₃⁻) can be reduced to NO₂⁻ by both chemical and enzymatic means, permitting the quantitative analysis of NO₃⁻ in samples.

Measure-iT™ High-Sensitivity Nitrite Assay Kit

The Measure-iT™ High-Sensitivity Nitrite Assay Kit (M36051) provides an easy and accurate method for quantitating nitrite. This kit has an optimal range of 20–500 picomoles nitrite (Figure 21.2.13), making it up to 50 times more sensitive than colorimetric methods utilizing the Griess reagent. Nitrates may be analyzed after quantitative conversion to nitrites through enzymatic reduction.⁷⁵

Each Measure-iT™ High-Sensitivity Nitrite Assay Kit contains:

- Measure-iT™ nitrite quantitation reagent (100X concentrate in 0.62 M HCl)
- Measure-iT™ nitrite quantitation developer (2.8 M NaOH)
- Measure-iT™ nitrite quantitation standard (11 mM sodium nitrite)
- Detailed protocols

Simply dilute the reagent 1:100, load 100 μL into the wells of a microplate, add 1–10 μL sample volumes and mix. After a 10-minute incubation at room temperature, add 5 μL of developer and read the fluorescence. The assay signal is stable for at least 3 hours, and common contaminants are well tolerated in the assay. The Measure-iT™ High-Sensitivity Nitrite Assay Kit provides sufficient material for 2000 assays, based on a 100 μL assay volume in a 96-well microplate format; this nitrite assay can also be adapted for use in cuvettes or 384-well microplates.

Griess Reagent Kit

Under physiological conditions, NO is readily oxidized to NO₂⁻ and NO₃⁻ or it is trapped by thiols as an *S*-nitroso adduct. The Griess reagent provides a simple and well-characterized colorimetric assay for nitrites—and nitrates that have been reduced to nitrites—with a detection limit of about 100 nM.^{75–77} The Griess assay is suitable for measuring the activity of nitrate reductase in a microplate.⁷⁸ Nitrite reacts with the Griess reagent to form a purple azo derivative that can be monitored by absorbance at 548 nm (Figure 21.2.14).

The Griess Reagent Kit (G7921) contains all of the reagents required for NO₂⁻ quantitation, including:

- *N*-(1-Naphthyl)ethylenediamine dihydrochloride
- Sulfanilic acid in 5% H₃PO₄
- A concentrated nitrite quantitation standard for generating calibration curves
- Detailed protocols for spectrophotometer- and microplate reader-based assays

Both the *N*-(1-naphthyl)ethylenediamine dihydrochloride and the sulfanilic acid in 5% H₃PO₄ are provided in convenient dropper bottles for easy preparation of the Griess reagent. Sample pretreatment with nitrate reductase and glucose 6-phosphate dehydrogenase is reported to reduce NO₃⁻ without producing excess NADPH, which can interfere with the Griess reaction.⁷⁹ NO that has been trapped as an *S*-nitroso derivative can also be analyzed with the Griess Reagent Kit after first releasing the NO from its complex using mercuric chloride or copper (II) acetate.^{80,81}

DAF-FM Reagent

DAF-FM⁸² (4-amino-5-methylamino-2',7'-difluorofluorescein, D23841; Figure 21.2.15) and its diacetate derivative (DAF-FM diacetate, D23842, D23844; Section 18.3) have significant utility for measuring nitric oxide and nitrite production in live cells and solutions. The fluorescence quantum yield of DAF-FM is reported to be 0.005 but increases about 160-fold to 0.81 after reacting with nitrite⁸² (Figure 21.2.16). DAF-FM has some important advantages over the similar nitric oxide sensor, DAF-2, and other aromatic diamines:

- Spectra of the NO (NO₂⁻) adduct of DAF-FM are independent of pH above pH 5.5.⁸²
- NO₂⁻ adduct of DAF-FM is significantly more photostable than that of DAF-2.⁸²
- DAF-FM is a more sensitive reagent for NO₂⁻ than is DAF-2; the NO and NO₂⁻ detection limit for DAF-FM is ~3 nM⁸² versus ~5 nM for DAF-2.⁸³
- The higher absorptivity and greater water solubility of the NO₂⁻ adduct of DAF-FM should make this assay much more sensitive than detection with 2,3-diaminonaphthalene or other aromatic diamines.

Figure 21.2.14 Principle of nitrite quantitation using the Griess Reagent Kit (G7921). Formation of the azo dye is detected via its absorbance at 548 nm.

Figure 21.2.15 DAF-FM (4-amino-5-methylamino-2',7'-difluorofluorescein, D23841).

Figure 21.2.16 Fluorescence emission spectra of DAF-FM (D23841, D23842, D23844) in solutions containing 0–1.2 μM nitric oxide (NO).

Figure 21.2.17 2,3-diaminonaphthalene (D7918).

Figure 21.2.19 Detection of inorganic phosphate using the P_iPer™ Phosphate Assay Kit (P22061). Each reaction contained 50 μM Amplex® Red reagent, 2 U/mL maltose phosphorylase, 1 mM maltose, 1 U/mL glucose oxidase and 0.2 U/mL HRP in 1X reaction buffer. Reactions were incubated at 37°C. After 60 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. Data points represent the average of duplicate reactions, and a background value of 43 (arbitrary units) was subtracted from each reading.

Figure 21.2.18 Principle of the P_iPer™ Phosphate Assay Kit (P22061). In the presence of inorganic phosphate, maltose phosphorylase converts maltose to glucose 1-phosphate and glucose. Then, glucose oxidase converts the glucose to gluconolactone and H₂O₂. Finally, with horseradish peroxidase (HRP) as a catalyst, the H₂O₂ reacts with the Amplex® Red reagent to generate the highly fluorescent resorufin. The resulting increase in fluorescence or absorption is proportional to the amount of P_i in the sample.

Because the reaction of DAF-FM with NO requires a preliminary nonspecific oxidation step, it is important to also perform control experiments with nitric oxide synthase inhibitors to confirm the source of the fluorescent species.⁸⁴

2,3-Diaminonaphthalene

We also offer 2,3-diaminonaphthalene (D7918, Figure 21.2.17), which reacts with NO₂⁻ to form the fluorescent product 1*H*-naphthotriazole. A rapid, quantitative fluorometric assay that employs 2,3-diaminonaphthalene can reportedly detect from 10 nM to 10 μM NO₂⁻, and is compatible with a 96-well microplate format.⁸⁵ Nitrate (NO₃⁻) does not interfere with this assay; however, NO₃⁻ can be reduced to NO₂⁻ by bacterial nitrate reductase and then detected using the same reagent.⁸⁶ A detailed protocol for measuring the stable products of the nitric oxide pathway (NO₂⁻ and NO₃⁻) using 2,3-diaminonaphthalene has been published and is shown to be approximately 50 times more sensitive than the Griess assay.⁸⁶

NBD Methylhydrazine

NBD methylhydrazine (*N*-methyl-4-hydrazino-7-nitrobenzofurazan, M20490) has been used to measure NO₂⁻ in water.⁸⁷ Reaction of NBD methylhydrazine with NO₂⁻ in the presence of mineral acids leads to formation of fluorescent products with excitation/emission maxima of ~468/537 nm. This reaction serves as the principle behind a selective fluorogenic method for the determination of NO₂⁻. The assay is suitable for measurements by absorption or fluorescence spectroscopy or by fluorescence-detected HPLC.⁸⁷

Other Nitrate Detection Reagents

Rhodamine 110 (R6479) has proven useful in a fluorescence quenching method for determining trace nitrite.⁸⁸ This sensitive assay takes advantage of the reaction of the green-fluorescent rhodamine 110 with nitrite at acidic pH to form a nitroso product that exhibits much weaker fluorescence. With a linear range of 1 × 10⁻⁸ to 3 × 10⁻⁷ moles/L and a detection limit of 7 × 10⁻¹⁰ moles/L, this assay has been used to measure nitrite in tap water and lake water without any prior extraction procedures.

Efficient quenching of SPQ or MQAE fluorescence (M440, E3101; see above) by nitrite (but not nitrate) has been used for direct measurement of NO₂⁻ transport across erythrocyte membranes⁸⁹ and for functional assays of bacterial nitrite extrusion transporters.⁹⁰

Phosphate and Pyrophosphate Detection

P_iPer™ Phosphate Assay Kit

The P_iPer™ Phosphate Assay Kit (P22061) provides an ultrasensitive assay that detects free phosphate in solution through formation of the fluorescent product resorufin. Because resorufin also has strong absorption, the assay can be performed either fluorometrically or spectrophotometrically. This kit can be used to detect inorganic phosphate (P_i) in a variety of samples or to monitor the kinetics of phosphate release by a variety of enzymes, including ATPases, GTPases, 5'-nucleotidase, protein phosphatases, acid and alkaline phosphatases and phosphorylase kinase. Furthermore, the assay can be modified to detect virtually any naturally occurring organic phosphate molecule by including an enzyme that can specifically digest the organic phosphate to liberate inorganic phosphate.

In the P_iPer™ phosphate assay (Figure 21.2.18), maltose phosphorylase converts maltose (in the presence of P_i) to glucose 1-phosphate and glucose. Then glucose oxidase converts the glucose to gluconolactone and H₂O₂. Finally, with horseradish peroxidase as a catalyst, the H₂O₂ reacts with the Amplex® Red reagent (10-acetyl-3,7-dihydroxyphenoxazine) to generate resorufin, which has absorption/emission maxima of ~571/585 nm.^{91,92} The resulting increase in fluorescence or absorption is proportional to the amount of P_i in the sample. This kit can be used to detect as little as 0.2 μM P_i by fluorescence (Figure 21.2.19) or 0.4 μM P_i by absorption.

The P_iPer™ Phosphate Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Concentrated reaction buffer
- Recombinant maltose phosphorylase from *Escherichia coli*
- Maltose
- Glucose oxidase from *Aspergillus niger*
- Horseradish peroxidase
- Phosphate standard
- Hydrogen peroxide
- Detailed protocols for detecting phosphatase activity

Each kit provides sufficient reagents for approximately 1000 assays using a reaction volume of 100 μL per assay and either a fluorescence or absorbance microplate reader.

P_iPer™ Pyrophosphate Assay Kit

The P_iPer™ Pyrophosphate Assay Kit (P22062) provides a sensitive fluorometric or colorimetric method for measuring the inorganic pyrophosphate (PP_i) in experimental samples or for monitoring the kinetics of PP_i release by a variety of enzymes, including DNA and RNA polymerases, adenylate cyclase and S-acetyl coenzyme A synthetase. In the P_iPer™ pyrophosphate assay, inorganic pyrophosphatase hydrolyzes PP_i to two molecules of inorganic phosphate (P_i). The P_i then enters into the same cascade of reactions as it does in the P_iPer™ Phosphate Assay Kit (Figure 21.2.18). In this case, the resulting increase in fluorescence or absorption is proportional to the amount of PP_i in the sample. This kit can be used to detect as little as 0.1 μM PP_i by fluorescence or 0.2 μM PP_i by absorption (Figure 21.2.20).

The P_iPer™ Pyrophosphate Assay Kit contains:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Concentrated reaction buffer
- Recombinant maltose phosphorylase from *Escherichia coli*
- Maltose
- Glucose oxidase from *Aspergillus niger*
- Horseradish peroxidase
- Inorganic pyrophosphatase from baker's yeast
- Pyrophosphate standard
- Detailed protocols for detecting pyrophosphatase activity

Each kit provides sufficient reagents for approximately 1000 assays using a reaction volume of 100 μL per assay and either a fluorescence or absorbance microplate reader.

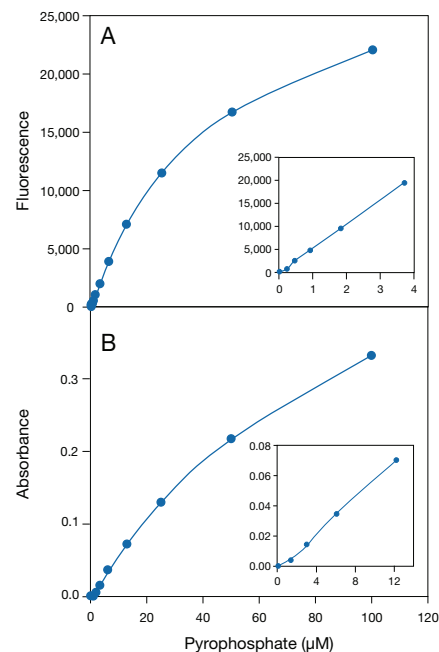

Figure 21.2.20 Detection of pyrophosphate using the P_iPer™ Pyrophosphate Assay Kit (P22062). Each reaction contained 50 μM Amplex® Red reagent, 0.01 U/mL inorganic pyrophosphatase, 2 U/mL maltose phosphorylase, 0.2 mM maltose, 1 U/mL glucose oxidase and 0.2 U/mL HRP in 1X reaction buffer. Reactions were incubated at 37°C. After 60 minutes, A) fluorescence was measured in a fluorescence-based microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm or B) absorbance was measured in an absorption-based microplate reader at 576 ± 5 nm. Data points represent the average of duplicate reactions. In panel A, a background value of 78 (arbitrary units) was subtracted from each reading; in panel B, a background absorbance of 0.011 was subtracted from each reading.

Figure 21.2.21 Enzymatic conversion of 2-amino-6-mercapto-7-methylpurine riboside (MESG) to ribose 1-phosphate and 2-amino-6-mercapto-7-methylpurine by purine nucleoside phosphorylase (PNP), reagents supplied in the EnzChek[®] Phosphate Assay Kit (E6646). The accompanying change in the absorption maximum (Abs_{max}) allows quantitation of inorganic phosphate (P_i) consumed in the reaction.

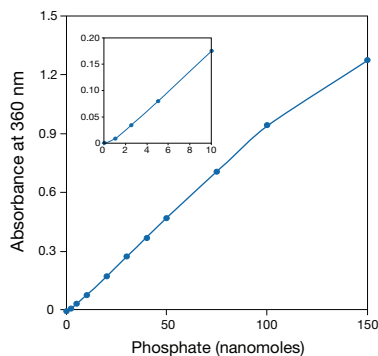

Figure 21.2.22 Quantitative analysis of inorganic phosphate using the EnzChek[®] Phosphate Assay Kit (E6646). KH₂PO₄ was used as the source for the inorganic phosphate, and the absorbance at 360 nm was corrected for background absorbance. The inset shows an enlargement of the standard curve, demonstrating the lower range of the assay; the units are the same.

EnzChek[®] Phosphate Assay Kit

The EnzChek[®] Phosphate Assay Kit (E6646), which is based on a method originally described by Webb,^{93,94} provides an easy enzymatic assay for detecting P_i from multiple sources through formation of a chromophoric product (Figure 21.2.21). Although this kit is usually used to determine the P_i produced by a wide variety of enzymes such as ATPases, kinases and phosphatases (Section 10.3), it can also be used to specifically quantitate P_i with a sensitivity of ~2 μM P_i (~0.2 μg/mL) (Figure 21.2.22). Moreover, this colorimetric assay has proven useful for determining the level of P_i contamination in the presence of high concentrations of acid-labile phosphates using a microplate reader.⁹⁵ Because the sulfate anion competes with P_i for binding to purine nucleoside phosphorylase (PNP), this kit can be adapted for measurement of sulfate concentrations between 0.1 and 10 mM in the presence of a low (<100 μM) fixed P_i concentration.⁹⁶

The EnzChek[®] Phosphate Assay Kit contains:

- 2-Amino-6-mercapto-7-methylpurine riboside (MESG)
- Purine nucleoside phosphorylase (PNP)
- Concentrated reaction buffer
- KH₂PO₄ standard
- Detailed protocols for detecting and quantitating P_i

Each kit provides sufficient reagents for about 100 phosphate assays using 1 mL assay volumes and standard cuvettes.

EnzChek[®] Pyrophosphate Assay Kit

In the EnzChek[®] Pyrophosphate Assay Kit (E6645), we have adapted the method provided in the EnzChek[®] Phosphate Assay Kit to permit the sensitive spectrophotometric detection of PP_i, which is converted by the enzyme pyrophosphatase to P_i.⁹⁷ Because two moles of P_i are released per mole of PP_i consumed, the sensitivity limit of the EnzChek[®] Pyrophosphate Assay Kit is 1 μM PP_i (~0.2 μg/mL). This assay has been modified to continuously detect several enzymes that liberate PP_i^{98–101} such as aminoacyl-tRNA synthetase,¹⁰² luciferase, cytidyl transferase¹⁰³ and S-acetyl coenzyme A synthetase⁹⁷ and potentially DNA and RNA polymerases, adenylate cyclase and guanylyl cyclase.¹⁰⁴

The EnzChek[®] Pyrophosphate Assay Kit contains:

- Inorganic pyrophosphatase
- 2-Amino-6-mercapto-7-methylpurine riboside (MESG)
- Purine nucleoside phosphorylase (PNP)
- Concentrated reaction buffer
- Na₂P₂O₇ standard
- Detailed protocols for detecting and quantitating PP_i

Each kit provides sufficient reagents for about 100 PP_i assays using standard 1 mL assay volumes and standard cuvettes.

Notes

- Spectral data are for the reaction product with glycine in the presence of cyanide. Unreacted reagent in MeOH: Abs = 254 nm (EC = 46,000 cm⁻¹M⁻¹), nonfluorescent.
- ND = not determined.
- Solubility in methanol is improved by addition of base (e.g., 1–5% (v/v) 0.2 M KOH).
- Spectral data are for the reaction product with glycine in the presence of cyanide. Unreacted reagent in MeOH: Abs = 282 nm (EC = 21,000 cm⁻¹M⁻¹), nonfluorescent.
- Fluorescence of D7918 is weak. Reaction with nitrite yields highly fluorescent 1H-naphthotriazole (Abs = 365 nm, Em = 415 nm in H₂O (pH 12)). (Methods Enzymol (1996) 268:105)
- DAF-FM fluorescence is very weak. Reaction with nitrite or nitric oxide generates a highly fluorescent benzotriazole derivative with Abs = 495 nm (EC = 73,000 cm⁻¹M⁻¹), Em = 515 nm in pH 7.4 buffer. (Angew Chem Int Ed Engl (1999) 38:3209)
- Values of K_{SV} are taken from published references. (Anal Biochem (1994) 219:139, Am J Physiol (1992) 262:C242, Biochemistry (1991) 30:7879, Anal Biochem (1989) 178:355)
- K_{SV} is the Stern-Volmer quenching constant for Cl⁻ ions (units are M⁻¹), representing the reciprocal of the ion concentration that produces 50% fluorescence quenching. The quenching constant is very dependent on viscosity and is usually significantly lower in cells. These indicators are quenched more effectively by bromide, iodide and certain other anions.
- This quinolinium dye also has a slightly stronger (~50%) absorption peak 25–30 nm shorter than the listed Abs wavelength.
- This product undergoes Cl⁻-dependent fluorescence quenching with essentially no change in absorption or emission wavelengths.
- Data represent the substrate component of this kit.
- Enzymatic phosphorylation of this substrate yields 2-amino-6-mercapto-7-methylpurine (Abs = 355 nm). (Proc Natl Acad Sci U S A (1992) 89:4884)
- L6868 has much stronger absorption at shorter wavelengths (Abs = 368 nm (EC = 36,000 cm⁻¹M⁻¹)).
- This compound emits chemiluminescence upon oxidation in basic aqueous solutions. Emission peaks are at 425 nm (L8455) and 470 nm (L6868).
- M6886 may be chemically reduced to cell-permeant diH-MEQ. (Biochemistry (1991) 30:7879)
- NBD methylhydrazine reacts with nitrite in the presence of strong acid to form fluorescent N-methyl-4-amino-7-nitrobenzofurazan (Abs = 459 nm, Em = 537 nm in MeCN). (Anal Chem (1999) 71:3003)
- Spectral data are for the reaction product with glycine in the presence of cyanide, measured in pH 7.0 buffer/MeCN (40:60). (Anal Chem (1987) 59:1102) Unreacted reagent in MeOH: Abs = 279 nm (EC = 5500 cm⁻¹M⁻¹), Em = 330 nm.
- Spectral data are for the reaction product of P2331MP with alanine and 2-mercaptoethanol. The spectra and stability of the adduct depend on the amine and thiol reactants. (Biochim Biophys Acta (1979) 576:440) Unreacted reagent in H₂O: Abs = 257 nm (EC = 1000 cm⁻¹M⁻¹).

22.1 Introduction to Potentiometric Probes

Potentiometric optical probes enable researchers to perform membrane potential measurements in organelles and in bacterial cells that are too small for microelectrodes. Moreover, in conjunction with imaging techniques, these probes can be employed to map variations in membrane potential across excitable cells, in perfused organs¹ and ultimately in the brain *in vivo*,²⁻⁵ with spatial resolution and sampling frequency that cannot be obtained using microelectrodes.

Applications for Potentiometric Probes

The plasma membrane of a cell typically has a transmembrane potential of approximately -70 mV (negative inside) as a consequence of K^+ , Na^+ and Cl^- concentration gradients that are maintained by active transport processes. Potentiometric probes offer an indirect method of detecting the translocation of these ions, whereas the fluorescent ion indicators discussed in Chapter 21 can be used to directly measure changes in specific ion concentrations.

Increases and decreases in membrane potential—referred to as membrane hyperpolarization and depolarization, respectively—play a central role in many physiological processes, including nerve-impulse propagation, muscle contraction, cell signaling and ion-channel gating. Potentiometric probes are important tools for studying these processes, as well as for visualizing mitochondria (which exhibit transmembrane potentials of approximately -150 mV, negative inside matrix) (Section 12.2), for assessing cell viability (Section 15.2) and for high-throughput screening of new drug candidates.

Potentiometric probes include the cationic or zwitterionic styryl dyes, the cationic carbocyanines and rhodamines, the anionic and hybrid oxonols and merocyanine 540. The class of dye determines factors such as accumulation in cells, response mechanism and toxicity. Surveys of techniques and applications using membrane potential probes can be found in several reviews.^{2,4,6-8}

Selecting a Potentiometric Probe

Selecting the best potentiometric probe for a particular application can be complicated by the substantial variations in their optical responses, phototoxicity and interactions with other molecules. Probes can be divided into two categories based on their response mechanism:

- Fast-response probes (usually styrylpyridinium dyes, Section 22.2) operate by means of a change in their electronic structure, and consequently their fluorescence properties, in response to a change in the surrounding electric field (Figure 22.1.1). Their optical response is sufficiently fast to detect transient (millisecond) potential changes in excitable cells, including single neurons, cardiac cells and intact brains. However, the magnitude of their potential-dependent fluorescence change is often small; fast-response probes typically show a 2–10% fluorescence change per 100 mV.
- Slow-response probes (Section 22.3) exhibit potential-dependent changes in their transmembrane distribution that are accompanied by a fluorescence change (Figure 22.1.1). The magnitude of their

A. Fast-response probe

B. Slow-response probe

Figure 22.1.1 Response mechanisms of membrane potential-sensitive probes. Fast-response probes undergo electric field-driven changes of intramolecular charge distribution that produce corresponding changes in the spectral profile or intensity of their fluorescence (represented by color changes in the illustration). Slow-response probes are lipophilic anions (in this illustration) or cations that are translocated across membranes by an electrophoretic mechanism. Fluorescence changes associated with transmembrane redistribution (represented by color changes in the illustration) result from sensitivity of the probe to intracellular and extracellular environments. Thus, potentiometric response speeds directly reflect the time constants of the underlying processes—fast intramolecular redistribution of electrons versus relatively slow transmembrane movement of entire molecules.

optical responses is much larger than that of fast-response probes (typically a 1% fluorescence change per mV). Slow-response probes, which include cationic carbocyanines and rhodamines and anionic oxonols, are suitable for detecting changes in average membrane potentials of nonexcitable cells caused by respiratory activity, ion-channel permeability, drug binding and other factors.

Calibration of potentiometric probes can be accomplished by imposing a transmembrane potential using valinomycin or gramicidin (V1644, G6888; Section 21.1) in conjunction with externally applied K^+ solutions.^{9,10} The ultimate test of calibration veracity is quantitative agreement with electrophysiological measurements.^{5,11}

22.2 Fast-Response Probes

Figure 22.2.3 Detection of action potentials in intact rabbit hearts using the fast potentiometric probe di-4-ANEPPS (D1199). Excised rabbit hearts were loaded with di-4-ANEPPS by perfusion with dye-containing medium. Fluorescence was excited at 488 nm by an argon-ion laser. Emission components at 540 ± 6 nm (green) and >610 nm (red) were detected simultaneously by two photomultipliers (panel A). The ratio of the green to red signals (panel B) displayed a larger fractional change during action potential cycles than either of the component signals; it also followed transmembrane voltage contours recorded simultaneously by an intracellular microelectrode (panel C). In addition, fluorescence ratio measurements reduce the motion artifacts that typically distort optical signals detected from contracting hearts. Figure reproduced with permission from Am J Physiol Heart Circ Physiol (2000) 279:H1421.

Our fast-response potential-sensitive probes (see Figure 22.1.1A in Section 22.1) are listed in Table 22.1, along with their charges, optical responses and selected applications.

ANEP Dyes

Di-4-ANEPPS and Di-8-ANEPPS

The ANEP (AminoNaphthylEthynylPyridinium) dyes developed by Leslie Loew and colleagues¹ are among the most sensitive of the fast-response probes. Zwitterionic di-4-ANEPPS (D1199, Figure 22.2.1) and di-8-ANEPPS (D3167, Figure 22.2.2) exhibit fairly uniform 10% per 100 mV changes in fluorescence intensity in a variety of tissue, cell and model membrane systems.^{2,3} The millisecond-range temporal characteristics of the ANEP dyes compensate for this modest response amplitude (Figure 22.2.3). Di-4-ANEPPS is internalized in the cell rather rapidly, precluding its use in all but very short-term experiments, whereas di-8-ANEPPS is better retained in the outer leaflet of the plasma membrane. In addition, although both ANEP dyes exhibit good photostability and low toxicity, di-8-ANEPPS is reported to be slightly more photostable and significantly less phototoxic than di-4-ANEPPS.⁴⁻⁶

Like other styryl dyes, the ANEP dyes are essentially nonfluorescent in aqueous solutions and exhibit spectral properties that are strongly dependent on their environment.⁷ When bound to phospholipid vesicles, di-8-ANEPPS has absorption/emission maxima of $\sim 467/631$ nm (Figure 22.2.4), as compared with $\sim 498/713$ nm in methanol. The fluorescence excitation/emission maxima of di-4-ANEPPS bound to neuronal membranes are $\sim 475/617$ nm.⁸

Both di-4-ANEPPS and di-8-ANEPPS respond to increases in membrane potential (hyperpolarization) with a decrease in fluorescence excited at approximately 440 nm and an increase in fluorescence excited at 530 nm.^{7,9} These spectral shifts permit the use of ratiometric methods (Loading and Calibration of Intracellular Ion Indicators—Note 19.1) to correlate the change in fluorescence signal with membrane potential.² Using di-8-ANEPPS, Loew and colleagues were able to follow changes in membrane potential along the surface of a single mouse neuroblastoma cell in their study of the mechanisms underlying cathode-directed neurite elongation¹⁰ and to define differences between transmembrane potentials of neurites and somata.¹¹ Potential-dependent fluorescence emission ratio measurements (ratio of emission intensities at 560 nm and 620 nm following excitation at 475 nm) have also been reported using both di-4-ANEPPS and di-8-ANEPPS¹²⁻¹⁵ (Figure 22.2.3). Some other applications are listed in Table 22.1.

Figure 22.2.1 di-4-ANEPPS (D1199).

Figure 22.2.2 di-8-ANEPPS (D3167).

Cationic ANEP Dyes

In collaboration with Leslie Loew and Joe Wuskell of the University of Connecticut, we offer a series of potential-sensitive cationic ANEP dyes.^{16–18} The water-soluble di-2-ANEPEQ¹⁹ (JPW 1114, D6923; Figure 22.2.5) can be either microinjected into cells, a mode of delivery that intensifies the staining of remote neuronal processes, or applied topically to deeply stain brain tissue.²⁰ Microinjection of di-2-ANEPEQ into neurons in ganglia of the snail *Helix aspersa* produced an approximately 50-fold improvement in voltage-sensitive signals from distal processes over that obtained with conventional absorption- and fluorescence-based staining methods.²¹ Di-12-ANEPPQ (D6927) is useful for potential-sensitive retrograde labeling of neurons^{17,22} using techniques similar to those employed for lipophilic carbocyanine and aminostyryl tracers (Section 14.4). Di-3-ANEPPDHQ (D36801, Figure 22.2.6) and di-4-ANEPPDHQ (D36802, Figure 22.2.7) both exhibit very low rates of internalization and good signal-to-noise ratios, and are useful for neural network analysis.²³ Di-4-ANEPPDHQ has proven useful for visualizing cholesterol-enriched lipid domains in model membranes.²⁴

RH Dyes

Originally synthesized by Rina Hildesheim, the RH dyes include an extensive series of dialkylaminophenylpolyenylpyridinium dyes that are principally used for functional imaging of neurons (Table 22.1). The existence of numerous RH dye analogs reflects the observation that no single dye provides the optimal response under all experimental conditions.^{5,25,26} Currently, the most widely used RH dyes are RH 237 (S1109, Figure 22.2.8), RH 414 (T1111, Figure 22.2.9), RH 421 (S1108) and RH 795 (R649, Figure 22.2.10). Physiological effects of staining with different analogs are not equivalent. For example, staining of the cortex with RH 414 causes arterial constriction, whereas staining with RH 795 does not.²⁷ RH 795 produced negligible side effects

when tested *in vitro* using hippocampal slices and *in vivo* using single-unit recordings in cat and monkey visual cortices.²⁸ Electrophysiological measurements indicate a broadening of action potentials that is attributable to the staining of cultured neurons with RH 237.²⁹

Like the ANEP dyes, the RH dyes exhibit varying degrees of fluorescence excitation and emission spectral shifts in response to membrane potential changes.⁸ Their absorption and fluorescence spectra are also strongly dependent on the environment.³⁰ Spectra of RH 414 bound to phospholipid vesicles are similar to those obtained on neuronal plasma membranes.⁸ Using the RH dyes in conjunction with fluorescent Ca²⁺ indicators allowed the simultaneous optical mapping of membrane potential (with RH 237) and intracellular calcium (with rhod-2 AM; R1245MP, R1244; Section 19.3) in cardiomyocyte monolayers; rhod-FF (R23983, Section 19.3) was used to check for buffering of calcium dynamics by the high-affinity rhod-2 indicator.³¹

FRET-Pair Membrane Potential Sensors

Fluorescence resonance energy transfer (FRET) between a mobile lipophilic anion in the membrane interior and a static donor fluorophore on the membrane surface provides a potential-sensing mechanism that generates a more sensitive fluorescence response than electrochromic dyes and a more rapid temporal response than intracellular-extracellular ion translocation.^{32,33} A particularly effective implementation of this concept uses DiOC₁₈(3) or DiOC₁₆(3) (D275, V22886, D1125; Section 14.4) as the static reference marker in combination with the mobile anion dipicrylamine. Characterization of this approach by Bradley and co-workers³⁴ demonstrated depolarization-induced fluorescence changes of >50% per 100 mV with submillisecond time constants in whole-cell patch-clamped HEK293 cells. In neuronal cultures and brain slices, action potentials generated fluorescence increases relative to the resting baseline signal of >25% per 100 mV.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Abs and Em of styryl dyes are at shorter wavelengths in membrane environments than in reference solvents such as methanol. The difference is typically 20 nm for absorption and 80 nm for emission, but varies considerably from one dye to another. Styryl dyes are generally nonfluorescent in water.
- The fluorescence excitation/emission maxima of di-4-ANEPPDHQ (D36802) bound to dioleoylphosphatidylcholine (DOPC) bilayer membranes are 468/635 nm. Em is sensitive to membrane cholesterol content. (Biophys J (2006) 90:2563)
- Abs/Em for these dyes adsorbed on neuronal plasma membranes are 493/638 nm (S1108) and 506/687 nm (S1109). (Biochim Biophys Acta (1993) 1150:111)

PRODUCT LIST 22.2 FAST-RESPONSE PROBES

Cat. No.	Product	Quantity
D6923	di-2-ANEPEQ (JPW 1114)	5 mg
D36801	di-3-ANEPPDHQ	1 mg
D36802	di-4-ANEPPDHQ	1 mg
D6927	di-12-ANEPPQ	5 mg
D1199	di-4-ANEPPS	5 mg
D3167	di-8-ANEPPS	5 mg
R649	RH 795	1 mg
S1109	N-(4-sulfobutyl)-4-(4-(4-(dibutylamino)phenyl)hexatrienyl)pyridinium, inner salt (RH 237)	5 mg
S1108	N-(4-sulfobutyl)-4-(4-(4-(dipentylamino)phenyl)butadienyl)pyridinium, inner salt (RH 421)	25 mg
T1111	N-(3-triethylammoniumpropyl)-4-(4-(4-(diethylamino)phenyl)butadienyl)pyridinium dibromide (RH 414)	5 mg

22.3 Slow-Response Probes

Our slow-response potential-sensitive probes¹ (see Figure 22.1.1B in Section 22.1) are listed in Table 22.2, along with their charges, optical responses and selected applications.

Carbocyanines

DiI, DiS and DiO Derivatives

Indo- (DiI), thia- (DiS) and oxa- (DiO) carbocyanines with short alkyl tails (<7 carbon atoms) were among the first potentiometric fluorescent probes developed.² These cationic dyes accumulate on hyperpolarized membranes and are translocated into the lipid bilayer.³ Aggregation within the confined membrane interior usually results in decreased fluorescence, although the magnitude and even the direction of the fluorescence response is strongly dependent on the concentration of the dye and its structural characteristics.^{1,4} While the distribution of extracellularly applied dye is dependent on both the plasma and mitochondrial membrane potentials, the primary determinant is the latter. Very low applied concentrations (<100 nM) are required to obtain mitochondrial signal specificity and avoid potential-independent background derived from staining of the endoplasmic reticulum and other intracellular membranes.

DiOC₆(3) (D273, Figure 22.3.1) has been the most widely used carbocyanine dye for membrane potential measurements,⁵ followed closely by DiOC₅(3) (D272, Figure 22.3.2); see Table 22.2 for selected references. In flow cytometry measurements, the detected intensity of carbocyanine

Figure 22.3.1 3,3'-dihexyloxacarbocyanine iodide (DiOC₆(3), D273).

fluorescence is dependent not only on the membrane potential, but also on cell size. In some cases, measurements of forward light scatter have been used to normalize the optical changes for cell size variability. A fluorescence ratio method (Figure 22.3.3) that exploits a potential-dependent red shift in the emission spectrum of DiOC₂(3) (D14730, Figure 22.3.4) has been developed for membrane potential measurements in bacteria^{6,7} (B34950). The 633 nm light-excitable indodicarbocyanine DiIC₁(5)⁸ (H14700, Figure 22.3.5) enables analysis of mitochondrial potential in apoptotic cells in combination with fluoresceinated annexin V⁹ (A13199, Section 15.5), a method we have utilized in two of our MitoProbe™ Assay Kits for flow cytometry (M34150, M34151; see below). Carbocyanine dyes, particularly thiacyanines such as DiSC₃(5) (D306, Figure 22.3.6), can inhibit respiration^{4,10} and may therefore be relatively cytotoxic.¹¹

JC-1 and JC-9

JC-1 (5,5',6,6'-tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarbocyanine iodide, T3168; Figure 22.3.7) exists as a green-fluorescent monomer at low concentrations or at low membrane potential. However, at higher concentrations (aqueous solutions above 0.1 μM) or higher potentials, JC-1 forms red-fluorescent “J-aggregates,” which exhibit a broad excitation spectrum and a very narrow emission spectrum (Figure 22.3.8). Because J-aggregate formation increases linearly with applied membrane potential over the range of 30–180 mV, this phenomenon can be exploited for potentiometric measurements^{12,13} (Table 22.2). JC-1 is more specific for mitochondrial versus plasma membrane potential and more consistent in its response to depolarization than some other cationic dyes such as DiOC₆(3) and rhodamine 123.¹⁴

Various types of ratio measurements are possible by combining signals from the green-fluorescent JC-1 monomer (absorption/emission maxima ~514/529 nm) and the red-fluorescent J-aggregate (Figure 22.3.9) (absorption/emission maxima ~585/590 nm), which can be effectively excited anywhere between 485 nm and its absorption maximum. Optical filters designed for fluorescein and tetramethylrhodamine can be used to separately visualize the monomer and J-aggregate forms, respectively. Alternatively, both forms can be observed simultaneously using a fluorescein longpass optical filter set. For flow cytometry, JC-1 can be excited at 488 nm and detected in bivariate mode using the green channel for the monomer and the red channel for the J-aggregate form^{15,16} (Figure 22.3.10).

JC-1 is widely used for detecting mitochondrial depolarization in apoptotic cells^{14,15,17–19} (MitoProbe™ JC-1 Assay Kit, M34152, described below) and for assaying multidrug-resistant cells²⁰ (Section 15.6). It is also frequently employed for mitochondrial function assessment in cell-based high-throughput assays.^{21,22} We have discovered another carbocyanine dye, JC-9 (3,3'-dimethyl- α -naphthoxycarbocyanine iodide, D22421; Figure 22.3.11), with potential-dependent spectroscopic properties (Figure 22.3.12) similar to those of JC-1 for detecting mitochondrial depolarization in apoptotic cells.^{23,24}

MitoProbe™ JC-1 Assay Kit for Flow Cytometry

The MitoProbe™ JC-1 Assay Kit (M34152) provides the cationic dye JC-1 and a mitochondrial membrane potential disrupter, CCCP (carbonyl cyanide 3-chlorophenylhydrazone), for the study of mitochondrial membrane potential. Use of JC-1 fluorescence ratio detection allows researchers to make comparative measurements of membrane potential and to determine the percentage of mitochondria within a population that respond to an applied stimulus (Figure 22.3.13). Subtle heterogeneity in cellular responses can be discerned in this way.^{13,15,18,25} For example, four distinct patterns of mitochondrial membrane potential change in response to glutamate receptor activation in neurons have been identified using confocal ratio imaging of JC-1 fluorescence.²⁶

Each MitoProbe™ JC-1 Assay Kit provides:

- JC-1
- Dimethylsulfoxide (DMSO)
- CCCP
- Concentrated phosphate-buffered saline (PBS)
- Detailed protocols

Sufficient reagents are provided for 100 assays, based on a labeling volume of 1 mL.

MitoProbe™ DiIC(5) and MitoProbe™ DiOC(3) Assay Kits for Flow Cytometry

The MitoProbe™ DiIC₁(5) and MitoProbe™ DiOC₂(3) Assay Kits (M34151, M34150) provide solutions of the far-red-fluorescent DiIC₁(5) (1,1',3,3,3',3'-hexamethylindodicarbocyanine

Figure 22.3.11 3,3'-dimethyl- α -naphthoxycarbocyanine iodide (JC-9; DiNOC₁(3), D22421).

Figure 22.3.8 Cultured human pre-adipocytes loaded with the ratiometric mitochondrial potential indicator JC-1 (T3168) at 5 μ M for 30 minutes at 37°C. In live cells, JC-1 exists either as a green-fluorescent monomer at depolarized membrane potentials or as an orange-fluorescent J-aggregate at hyperpolarized membrane potentials. Cells were then treated with 50 nM FCCP, a protonophore, to depolarize the mitochondrial membrane. Approximately 10 minutes after the addition of the uncoupler, the cells were illuminated at 488 nm and the emission was collected between 515–545 nm and 575–625 nm. Image contributed by Bob Terry, Biolmage A/S, Denmark.

Figure 22.3.9 Absorption and fluorescence emission (excited at 488 nm) spectra of JC-1 in pH 8.2 buffer containing 1% (v/v) DMSO.

Figure 22.3.12 A viable bovine pulmonary artery endothelial cell incubated with the ratiometric mitochondrial potential indicator, JC-9 (D22421). In live cells, JC-9 exists either as a green-fluorescent monomer at depolarized membrane potentials, or as a red-fluorescent J-aggregate at hyperpolarized membrane potentials.

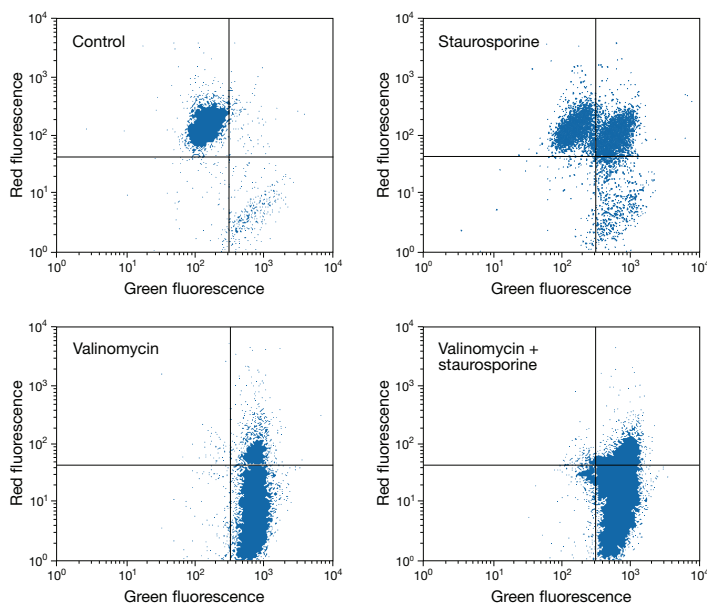

Figure 22.3.10 Bivariate JC-1 (T3168) analysis of mitochondrial membrane potential in HL60 cells by flow cytometry. The sensitivity of this technique is demonstrated by the response to depolarization using K⁺/valinomycin (V1644) (bottom two panels). Distinct populations of cells with different extents of mitochondrial depolarization are detectable following apoptosis-inducing treatment with 5 μ M staurosporine for 2 hours (top right panel). Figure courtesy of Andrea Cossarizza, University of Modena and Reggio Emilia, Italy.

Figure 22.3.13 Flow cytometric analysis of Jurkat cells using the MitoProbe™ JC-1 Assay Kit (M34152). Jurkat cells were stained with 2 μ M JC-1 for 15 minutes at 37°C, 5% CO₂, and then washed with phosphate-buffered saline (PBS) and analyzed on a flow cytometer using 488 nm excitation with 530 nm and 585 nm bandpass emission filters. Untreated cultured cells are shown in panel A. Panel B shows cells induced to apoptosis with 10 μ M camptothecin for 4 hours at 37°C.

Figure 22.3.14 Flow cytometric analysis of camptothecin-treated Jurkat cells stained with DiOC₂(3) (D14730, M34150) and allophycocyanin annexin V (A35110). Jurkat cells were incubated for 4 hours with camptothecin at 37°C, 5% CO₂, then stained with 50 nM DiOC₂(3) and allophycocyanin annexin V. Cells were analyzed on a flow cytometer using 488 nm and 633 nm excitations with 530 nm and 660 nm bandpass emission filters.

Figure 22.3.15 Response of *Staphylococcus aureus* to valinomycin and external potassium ions, as measured by flow cytometry using the BacLight™ Bacterial Membrane Potential Kit (B34950). Samples containing *S. aureus* were treated with 5 μM valinomycin in different concentrations of potassium buffer, and then stained using 30 μM DiOC₂(3) for 30 minutes, according to the kit protocol. Data are expressed either using a ratiometric parameter based on the formula provided in the kit protocol (Δ, right axis) or as the ratio of population mean red-fluorescence intensity/mean green-fluorescence intensity (●, left axis).

Figure 22.3.16 Detection of membrane potential in various bacteria with the BacLight™ Bacterial Membrane Potential Kit (B34950). Red/green fluorescence ratios were calculated using population mean fluorescence intensities for gram-positive (*Micrococcus luteus*, *Staphylococcus aureus*, *Bacillus cereus* and *Staphylococcus warnerii*) and gram-negative (*Escherichia coli* and *Salmonella choleraesuis*) bacteria incubated with 30 μM DiOC₂(3) for 30 minutes in either the presence or absence of 5 μM CCCP, according to the kit protocol.

iodide) and green-fluorescent DiOC₂(3) (3,3'-diethyloxacarbocyanine iodide) carbocyanine dyes, respectively, along with a mitochondrial membrane potential uncoupler, CCCP, for the study of mitochondrial membrane potential. These DiIC₁(5) and DiOC₂(3) carbocyanine dyes penetrate the cytosol of eukaryotic cells and, at concentrations below 100 nM, accumulate primarily in mitochondria with active membrane potentials. In the case of DiOC₂(3), this accumulation is accompanied by a shift from green to red emission due to dye stacking (Figure 22.3.3), allowing the use of a ratiometric parameter (red/green fluorescence ratio) that corrects for size differences when measuring membrane potential in bacteria.^{6,7} DiOC₂(3) can be paired with other reagents, such as the far-red-fluorescent allophycocyanin annexin V (A35110, Section 15.5) or TO-PRO™-3 nucleic acid stain (T3605, Section 8.1) for multiparameter study of vitality and apoptosis²⁷ (Figure 22.3.14).

The MitoProbe™ DiIC₁(5) and MitoProbe™ DiOC₂(3) Assay Kits provide:

- DiIC₁(5) (in Kit M34151) or DiOC₂(3) (in Kit M34150)
- CCCP
- Detailed protocols for labeling cells

Each kit provides sufficient reagents for 100 assays, based on a labeling volume of 1 mL.

BacLight™ Bacterial Membrane Potential Kit

The BacLight™ Bacterial Membrane Potential Kit (B34950) provides a fluorescent membrane-potential indicator dye, DiOC₂(3), along with a proton ionophore (CCCP) and premixed buffer. At low concentrations, DiOC₂(3) exhibits green fluorescence in all bacterial cells, but it becomes more concentrated in healthy cells that are maintaining a membrane potential, causing the dye to self-associate and the fluorescence emission to shift to red. The red- and green-fluorescent bacterial populations are easily distinguished using a flow cytometer (Figure 22.3.15). CCCP is included in the kit for use as a control because it eradicates the proton gradient, eliminating bacterial membrane potential.^{7,27}

The BacLight™ Bacterial Membrane Potential Kit contains:

- DiOC₂(3) in dimethylsulfoxide (DMSO)
- CCCP in DMSO
- Phosphate-buffered saline (PBS)
- Detailed protocols

Using the recommended reagent dilutions and volumes, this kit provides sufficient DiOC₂(3) to perform approximately 100 individual assays by flow cytometry; sufficient CCCP is provided for 30 depolarized control samples. The BacLight™ Bacterial Membrane Potential Kit is designed to assay bacterial concentrations between 10⁵ and 10⁷ organisms per mL. Note that DiOC₂(3) and CCCP are inhibitors of respiration, rendering the cells nonculturable beyond the brief time window required for staining and analysis.

Using the BacLight™ Bacterial Membrane Potential Kit, we have detected membrane potentials in all bacteria tested (including logarithmically growing cultures of *Micrococcus luteus*, *Staphylococcus aureus*, *Bacillus cereus*, *Staphylococcus warnerii*, *Escherichia coli* and *Salmonella choleraesuis*), although the magnitude varies with species (Figure 22.3.16).

Rhodamine 123, TMRM and TMRE

Rhodamine 123 (R302, R22420; Figure 22.3.17) is widely used as a structural marker for mitochondria (Section 12.2) and as an indicator of mitochondrial activity (Section 15.2, Figure 22.3.18). Highly selective, potential-dependent staining of mitochondria is obtained by setting the extracellular K^+ concentration close to intracellular values (~137 mM), thereby depolarizing the plasma membrane.²⁸

TMRM (T668, Figure 22.3.19) and TMRE (T669, Figure 22.3.20), the methyl and ethyl esters of tetramethylrhodamine, are closely related to rhodamine 123. They are primarily mitochondrial membrane potential sensors.^{29,30} As with rhodamine 123, accumulation of these cationic dyes in mitochondria results in diminished fluorescence due to self-quenching (Figure 22.3.18).³⁰ TMRM and TMRE cross the plasma membrane more rapidly than rhodamine 123, and their strong fluorescence allows the use of low probe concentrations, thus avoiding aggregation. Because their fluorescence is relatively insensitive to the environment, spatially resolved fluorescence of TMRM and TMRE presents an unbiased profile of their transmembrane distribution that can be directly related to the plasma membrane potential via the Nernst equation.^{30–34} TMRE has been successfully used in a high-throughput screening assay for drugs that affect mitochondrial membrane potential in live cells.³⁵ TMRM has been used in conjunction with X-rhod-1 AM, (X14210, Section 19.3) for simultaneous confocal imaging of mitochondrial membrane potential and calcium in rat cardiomyocytes.³⁶

Figure 22.3.20 Tetramethylrhodamine, ethyl ester, perchlorate (TMRE, T669).

Oxonols

Oxonol V and Oxonol VI

The anionic bis-isoxazolone oxonols (O266, Figure 22.3.21; O267, Figure 22.3.22) accumulate in the cytoplasm of depolarized cells by a Nernst equilibrium-dependent uptake from the extracellular solution.³⁷ Their voltage-dependent partitioning between water and membranes is often measured by absorption rather than fluorescence. Of the oxonols studied by Smith and Chance,³⁸ oxonol VI (O267) gave the largest spectral shifts, with an isobestic point at 603 nm. In addition, oxonol VI responds to changes in potential more rapidly than oxonol V and is therefore considered to be the better probe for measuring fast potential changes.³⁹

DiBAC (Bis-Oxonol) Dyes

The three bis-barbituric acid oxonols, often referred to as DiBAC dyes, form a family of spectrally distinct potentiometric probes with excitation maxima at approximately 490 nm (DiBAC₄(3); B438, B24570; Figure 22.3.23), 530 nm (DiSBAC₂(3), B413; Figure 22.3.24) and

Figure 22.3.21 Oxonol V (bis-(3-phenyl-5-oxoisoxazol-4-yl)pentamethine oxonol, O266).

Figure 22.3.22 Oxonol VI (bis-(3-propyl-5-oxoisoxazol-4-yl)pentamethine oxonol, O267).

Figure 22.3.18 Staining of rat cortical astrocytes by rhodamine 123 (R302, R22420). Potential-dependent accumulation of the cationic dye in mitochondria results in a relatively weak fluorescence signal due to self-quenching (left panel). Dissipation of the mitochondrial membrane potential by the uncoupler FCCP is marked by increasing fluorescence (middle panel) and subsequent redistribution of the dye throughout the cell (right panel). Figure 22.3.27 Detection of ATP-sensitive potassium (K_{ATP}) channel activation in isolated capillaries from guinea pig hearts using DiBAC₄(3) (B438, B24570), a slow potentiometric probe. Application of a K^+ channel opener (HOE 234) induced membrane hyperpolarization, resulting in a net efflux of intracellular DiBAC₄(3), which is registered as a decrease of fluorescence intensity. These effects were reversed by subsequent treatment with the channel blocker glibenclamide. Figure reproduced with permission from *J Physiol* (1997) 502:397.

590 nm (DiBAC₄(5), B436; Figure 22.3.25). Several papers have referred to these dyes simply as “bis-oxonol” and it is not always possible to determine which of the dyes was employed; however, DiBAC₄(3) (Figure 22.3.23) has been used in the majority of publications that cite a “bis-oxonol.”

These dyes enter depolarized cells where they bind to intracellular proteins or membranes and exhibit enhanced fluorescence and red spectral shifts.⁴⁰ Increased depolarization results in more influx of the anionic dye and thus an increase in fluorescence (Figure 22.3.26). Conversely, hyperpolarization is indicated by a decrease in fluorescence (Figure 22.3.27). In contrast to cationic carbocyanines, anionic bis-oxonols are largely excluded from mitochondria and are primarily sensitive to plasma membrane potential. Potential-dependent fluorescence changes generated by DiBAC₄(3) are typically ~1% per mV.^{41,42} Interactions between anionic oxonols and the cationic K^+ -valinomycin complex complicate the use of this ionophore when calibrating potentiometric responses.⁴³ Oxonol dyes have known pharmacological activity against various ion channels and receptors.^{44,45} It is therefore important to establish, as is the case in any experiment using fluorescent probes, that experimental observations with implied physiological significance are independent of the externally applied probe concentration.

Merocyanine 540

Although merocyanine 540 (M24571) was among the first fluorescent dyes to be used as a potentiometric probe,⁴⁶ its use for this application has declined with the advent of superior probes. A significant disadvantage of merocyanine 540 is its extreme phototoxicity; consequently, it is now more commonly used as a photosensitizer.^{47–56}

Merocyanine 540 exhibits a biphasic kinetic response to membrane polarization changes. It binds to the surface of polarized membranes in a perpendicular orientation, reorienting as the membrane depolarizes to form nonfluorescent dimers with altered absorption spectra.^{57,58} This fast (microseconds) reorientation is followed by a slower response caused by an increased dye uptake.

Merocyanine 540 is also a useful probe of lipid packing because it binds preferentially to membranes with highly disordered lipids.^{59,60} Fluorescence of merocyanine 540 is sensitive to heat-induced changes in the organization of membrane lipids.⁶¹

Figure 22.3.26 NIH 3T3 fibroblast undergoing progressive depolarization induced by the stepwise increase of KCl concentration from 5 mM (bottom panel) to 120 mM (top panel). The cell culture was loaded with DiSBAC₂(3) (B413) and examined under a confocal laser-scanning microscope after each appropriate medium change, keeping a constant plane of section (*Exp Cell Res* 231, 260 (1997)). The image was contributed by Rita Gatti, Institute of Histology and General Embryology, University of Parma, Parma, Italy.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Oxonols may require addition of a base to be soluble.
- Fluorescence of DiBAC₄(3) increases about 3-fold relative to H₂O on binding to proteins (Abs = 499 nm, Em = 519 nm). (Chem Phys Lipids (1994) 69:137)
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- QY for DiOC₂(3) in MeOH = 0.04. Abs = 478 nm, Em = 496 nm in H₂O. (Biochemistry (1974) 13:3315)
- JC-9 exhibits long-wavelength J-aggregate emission at ~635 nm in aqueous solutions and polarized mitochondria.
- DiIC₁(5) in H₂O; Abs = 636 nm, Em = 658 nm.
- JC-1 forms J-aggregates with Abs/Em = 585/590 nm at concentrations above 0.1 μM in aqueous solutions (pH 8.0). (Biochemistry (1991) 30:4480)

PRODUCT LIST 22.3 SLOW-RESPONSE PROBES

Cat. No.	Product	Quantity
B34950	BacLight™ Bacterial Membrane Potential Kit *for flow cytometry* *100 assays*	1 kit
B436	bis-(1,3-dibutylbarbituric acid)pentamethine oxonol (DiBAC ₄ (5))	25 mg
B438	bis-(1,3-dibutylbarbituric acid)trimethine oxonol (DiBAC ₄ (3))	25 mg
B24570	bis-(1,3-dibutylbarbituric acid)trimethine oxonol (DiBAC ₄ (3)) *FluoroPure™ grade*	5 mg
B413	bis-(1,3-diethylthiobarbituric acid)trimethine oxonol (DiSBAC ₂ (3))	100 mg
D273	3,3'-dihexyloxacarboyanine iodide (DiOC ₆ (3))	100 mg
D22421	3,3'-dimethyl- α -naphthoxacarboyanine iodide (JC-9; DiNOC ₁ (3))	5 mg
D272	3,3'-dipentyloxacarboyanine iodide (DiOC ₅ (3))	100 mg
D14730	DiOC ₂ (3) (3,3'-diethyloxacarboyanine iodide)	100 mg
D306	DiSC ₃ (5) (3,3'-dipropylthiadicarboyanine iodide)	100 mg
H14700	1,1',3,3',3'-hexamethylindodicarboyanine iodide (DiIC ₁ (5))	100 mg
M24571	merocyanine 540	25 mg
M34151	MitoProbe™ DiIC ₁ (5) Assay Kit *for flow cytometry* *100 assays*	1 kit
M34150	MitoProbe™ DiOC ₂ (3) Assay Kit *for flow cytometry* *100 assays*	1 kit
M34152	MitoProbe™ JC-1 Assay Kit *for flow cytometry* *100 assays*	1 kit
O266	oxonol V (bis-(3-phenyl-5-oxoisoxazol-4-yl)pentamethine oxonol)	100 mg
O267	oxonol VI (bis-(3-propyl-5-oxoisoxazol-4-yl)pentamethine oxonol)	100 mg
R302	rhodamine 123	25 mg
R22420	rhodamine 123 *FluoroPure™ grade*	25 mg
T3168	5,5',6,6'-tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarboyanine iodide (JC-1; CBIC ₂ (3))	5 mg
T669	tetramethylrhodamine, ethyl ester, perchlorate (TMRE)	25 mg
T668	tetramethylrhodamine, methyl ester, perchlorate (TMRM)	25 mg

CHAPTER 23

Antifades and Other Tools for Fluorescence

23.1 Fluorescence Microscopy Accessories and Reference Standards	941
Antifade Reagents and Mounting Media	941
ProLong® Gold Antifade Reagent	941
ProLong® Antifade Kit	943
SlowFade® Antifade Kit	946
SlowFade® Gold Antifade Reagent	946
Qmount® Qdot® Mounting Media	947
Image-iT® FX Signal Enhancer	947
FluoCells® Prepared Microscope Slides	947
FocalCheck™ Fluorescent Microspheres	948
FocalCheck™ Ring-Stained Fluorescent Microspheres	948
FocalCheck™ Thin-Ring Fluorescent Microspheres	950
FocalCheck™ Microspheres Pre-Mounted on Microscope Slides	950
FocalCheck™ Fluorescence Microscope Test Slides	950
FocalCheck™ Fluorescent Microspheres for Spectral Unmixing	950
MultiSpeck™, TetraSpeck™ and Constellation™ Fluorescent Microspheres	951
MultiSpeck™ Multispectral Fluorescence Microscopy Standards Kit	951
TetraSpeck™ Fluorescent Microspheres and Sampler Kits	951
Constellation™ Microspheres for Imaging	952
PS-Speck™ Microscope Point Source Kit	952
InSpeck™ Microscopy Image Intensity Calibration Kits	952
Fluorescence Reference Standards	953
Fluorescein NIST-Traceable Standard	953
Reference Dye Sampler Kit	954
Sample Chambers, Slides and Coverslips	954
CultureWell™ Cell Culture Systems	954
CultureWell™ Chambered Coverslips	955
CultureWell™ Chambered Coverglasses	955
CoverWell™ Imaging Chamber Gaskets	956
CoverWell™ Perfusion Chamber Gaskets	956
CoverWell™ Incubation Chamber Gaskets	957
Press-to-Seal Silicone Isolators and Secure-Seal™ Adhesive Spacers	957
HybriSlip™ Hybridization Covers	957
HybriWell™ Hybridization Sealing Systems	958
Secure-Seal™ Hybridization Chambers	958
ONCYTE® MultiWells with Slide and Matching Gasket	958
ProPlate™ Multi-Array System	958
Attofluor Cell Chamber	959
Coverslip Mini-Rack and Coverslip Maxi-Rack	959
Product List 23.1 Fluorescence Microscopy Accessories and Reference Standards	960

23.2 Flow Cytometry Reference Standards	962
AlignFlow™ and AlignFlow™ Plus Flow Cytometry Alignment Beads	962
LinearFlow™ Flow Cytometry Intensity Calibration Kits	962
PeakFlow™ Flow Cytometry Reference Beads	963
AbC™ and ArC™ Bead Kits for Flow Cytometry Compensation	964
AbC™ Anti-Mouse and AbC™ Anti-Rat/Hamster Bead Kits	964
ArC™ Amine-Reactive Compensation Bead Kit	964
Flow Cytometry Size Calibration Kit	964
CountBright™ Absolute Counting Beads	964
Product List 23.2 Flow Cytometry Reference Standards	965

23.1 Fluorescence Microscopy Accessories and Reference Standards

To obtain accurate and reproducible results from fluorescence imaging applications, it is essential to maximize the intensity and stability of the fluorescence signal in the experimental sample. We have developed several effective antifade reagents that minimize photobleaching of fluorescently labeled specimens. The Image-iT® FX signal enhancer (I36933) blocks nonspecific binding of dye-labeled antibodies, resulting in improved signal:background characteristics in images of immunolabeled cells and tissues. Our FluoCells® prepared microscope slides provide ready-to-use, multicolor-labeled cell or tissue preparations for educational and commercial fluorescence microscopy demonstrations. In collaboration with Grace Bio-Labs, we also offer a wide selection of microscopy accessories, including sample chambers, slides and coverslips.

Likewise, accurate and reproducible results depend on optimal performance of the optical system. The spectral compatibility of dyes and probes with excitation light sources (Table 23.1) and emission wavelength filters must be carefully evaluated. Downloadable reference spectra are available through our online Fluorescence SpectraViewer tool (www.invitrogen.com/handbook/spectraviewer, Using the Fluorescence SpectraViewer—Note 23.1), and guidance in choosing optical filters can be found in Selecting Optical Filters for Fluorescence Microscopy—Note 23.2. Careful calibration and instrumentation adjustment are also required for high-precision imaging of fluorescent probes, particularly in multicolor applications that involve multiple exposures, repetitive scans or three-dimensional sectioning. We offer a variety of microsphere reference standards designed to facilitate adjustment and calibration of both conventional fluorescence microscopes and confocal laser-scanning microscopes. In addition, the Reference Dye Sampler Kit (R14782) provides ready-made stock solutions of five extensively characterized fluorescence standards for use in spectrofluorometers and fluorescence microplate readers. We are also the source of the NIST-traceable fluorescein standard (F36915), which is directly traceable to the fluorescein standard adopted and maintained by the National Institute of Standards and Technology.

Antifade Reagents and Mounting Media

Loss of fluorescence through irreversible photobleaching processes can lead to a significant reduction in sensitivity, particularly when target molecules are of low abundance or when excitation light is of high intensity or long duration.¹⁻³ To minimize photobleaching of experimental samples, we have developed the ProLong®, ProLong® Gold, SlowFade® and SlowFade® Gold Antifade Kits and reagents, which have been shown to increase the photostability of many of our fluorophores in fixed cells, fixed tissues and cell-free preparations. The primary function of any antifade reagent is to sustain dye fluorescence, usually by inhibiting the generation and diffusion of reactive oxygen species. Other strategies for avoiding photobleaching include reducing the excitation light intensity by using high- NA numerical aperture objectives and low magnification as well as hardware control of the excitation light's spatial³ and temporal⁴ distribution. Loss of fluorescence signal due to attenuated excitation can be compensated to some extent by use of high-quality optical filters and high-efficiency photodetectors.

ProLong® Gold Antifade Reagent

ProLong® Gold antifade reagent is an improved version of the ProLong® antifade reagent, a component of the ProLong® Antifade Kit described below. The ProLong® Gold antifade reagent causes little or no quenching of the fluorescent signal while protecting the sample from

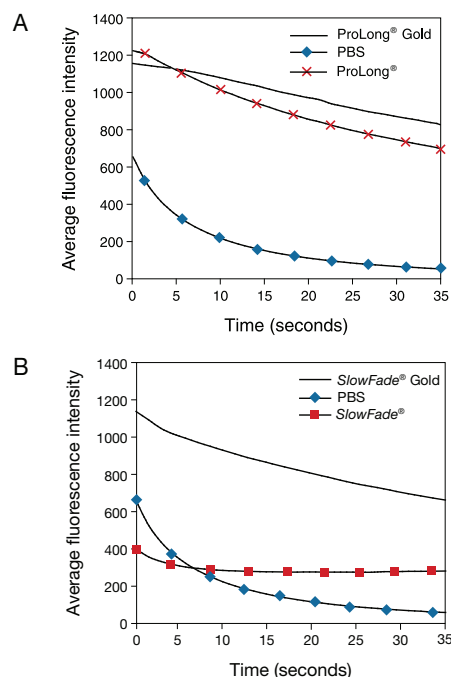

Figure 23.1.1 A comparison of the performance of Molecular Probes® antifade reagents. Bovine pulmonary arterial endothelial cells were labeled with fluorescein phalloidin and mounted using A) PBS, ProLong® Gold antifade reagent (P36930, P36934) or ProLong® Antifade Kit (P7481); B) PBS, SlowFade® Gold antifade reagent (S536936, S36937) or SlowFade® Antifade Kit (S2828). Samples were imaged using a 1.3 NA 40 \times oil immersion lens, Omega® XF100-2 filter set and frame-capture rate of 1 image/second. Images were acquired with a Hamamatsu Orca ER camera using the same exposure time for all samples. Y-axis values represent averages of the top 10% of the intensity-binned pixel values.

Table 23.1 Fluorescence excitation sources.

Source	Principal Lines (nm)
Mercury-arc lamp	366, 405, 436, 546, 578 *
Xenon-arc lamp	250–1000 *
Tungsten-halogen lamp	350–1000 *
Violet diode laser	405
Helium-cadmium laser	325, 442
Argon-ion laser	457, 488, 514
Nd:YAG laser	532 †
Helium-neon laser	543, 594, 633
Yellow diode laser	561
Krypton-ion laser	568, 647
Red diode laser	635

* Continuous white-light source. † Frequency-doubled principal line output.

NOTE 23.1

Using the Fluorescence SpectraViewer

The Fluorescence SpectraViewer (www.invitrogen.com/handbook/spectraviewer) is an online tool that allows researchers to assess the spectral compatibility of dyes and probes in the course of designing experiments that utilize fluorescence detection techniques. This note outlines the functionality of the SpectraViewer (Figure 1A) and examples of its utility in the experimental design process (Figure 1B, Figure 1C).

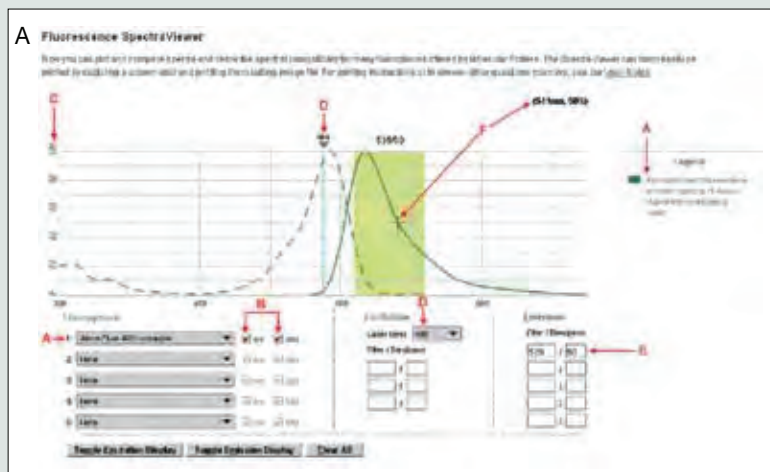

Figure 1A SpectraViewer features: **A.** Fluorophore selection menu. Up to 5 fluorophore data sets may be displayed simultaneously. Open the drop-down menu (▼) and select from the list of available excitation/emission data sets. The number of available data sets (as of July 2010) is 300, encompassing organic dyes, fluorescent proteins and Qdot® nanocrystals. Note that data sets may be added, deleted or modified at our editorial discretion and without notice, although in practice we aim to keep such changes to a minimum to maintain stability of the database. These data sets may be downloaded from our website as 4-column text files for importing into other plotting and calculation utilities. For each selected fluorophore data set, a legend containing sample context information is displayed on the panel to the right of the plot. **B.** For each fluorophore data set, excitation (ex) and emission (em) data may be displayed or hidden by checking or unchecking the respective boxes. **C.** Y-axis scaling for excitation and emission spectra is in terms of percentage of peak intensity value. For Qdot® nanocrystals, which exhibit quasi-continuous excitation profiles, the 100% intensity value has been arbitrarily defined as that at 300 nm. X-axis values on all plots are wavelengths in nanometers (nm). **D.** Excitation source spectral characteristics may be superimposed on the plot in the form of laser lines selected from a drop-down menu or filter characteristics input as numeric center wavelength (CWL) and bandpass (BP) values in nm in the boxes provided. In this example, laser excitation at 488 nm is indicated. **E.** Emission filter spectral characteristics may be superimposed on the plot in the form of numeric CWL and BP values in nm entered in the boxes provided. In this example, a typical FITC emission filter with CWL = 535 nm and BP = 50 nm is indicated. The transmission window of the filter is shown on the plot as a green-shaded rectangle. **F.** Mouse-controlled X,Y cursor. The crosshairs may be moved to any user-selected location within the plot window and are coupled to a numeric display of the corresponding (X,Y) values.

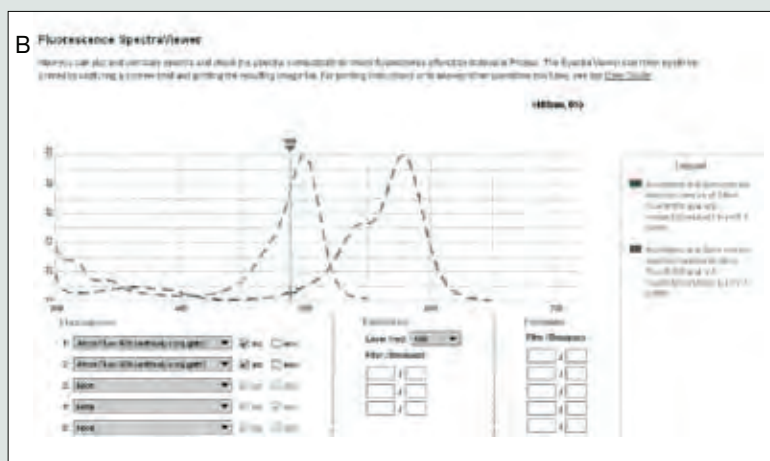

Figure 1B Evaluating fluorophores for multiplex detection experiments: Excitation spectra. This overlay of the fluorescence excitation spectra of Alexa Fluor® 488 and Alexa Fluor® 568 dyes provides a useful initial assessment of their suitability for use in a multiplex detection experiment. It also serves to highlight scaling factors that are critical determinants of the final detected signal levels but that are excluded from the SpectraViewer comparison. The plot indicates that excitation of Alexa Fluor® 568 at 488 nm is relatively inefficient (~5% of maximum indicated by the cursor). However, this consideration takes no account of the molar absorptivities (extinction coefficient, EC) of the fluorophores. The maximum EC values of Alexa Fluor® 488 and Alexa Fluor® 568 dyes are actually quite similar ($75,000 \text{ cm}^{-1} \text{ M}^{-1}$ and $93,000 \text{ cm}^{-1} \text{ M}^{-1}$, respectively, as listed in *The Molecular Probes® Handbook* data tables). An even more significant weighting factor is the relative abundances of the molecular targets of the fluorophores in the detector field of view; in general, cellular abundances of proteins vary over more orders of magnitude than the extinction coefficients of fluorophores. In the situation illustrated with excitation limited to 488 nm, the preferred course would be to use Alexa Fluor® 568 to detect the more abundant of the two molecular targets and Alexa Fluor® 488 to detect the less abundant target, thereby offsetting the absorptivity and target abundance factors.

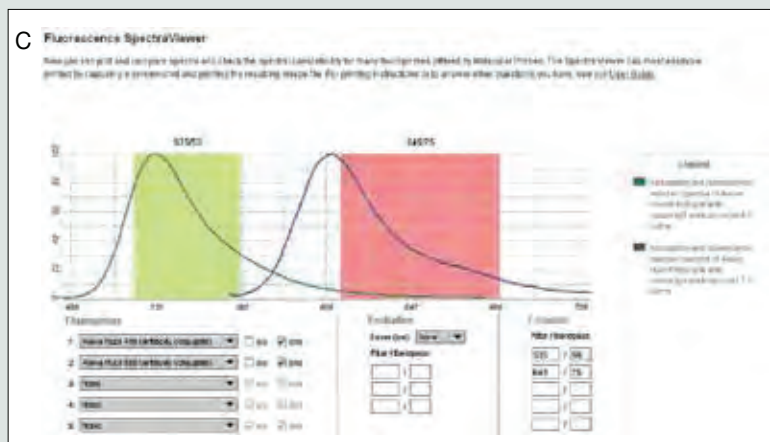

Figure 1C Evaluating fluorophores for multiplex detection experiments: Emission spectra. The fluorescence emission spectra of Alexa Fluor® 488 and Alexa Fluor® 568 dyes are shown with the spectral characteristics of typical emission filters superimposed. In this case, the main practical concern is the extent of overspill of Alexa Fluor® 488 fluorescence into the Alexa Fluor® 568 detection channel (CWL = 645 nm, BP = 75 nm), which can lead to false indications of molecular target colocalization in imaging applications. As in the excitation spectra comparison, this peak-normalized overlay provides an initial assessment of the suitability of fluorophore combinations for multiplex detection, but weighting of fluorescence signals by the relative abundances of molecular targets and other factors will heavily influence the final experimentally observed outcome.

photobleaching (Figure 23.1.1, Figure 23.1.2). Furthermore, unlike the reagents in the ProLong® Antifade Kit, the ProLong® Gold antifade reagent is premixed and ready to use—just add a drop to the preparation and mount. As with our original ProLong® antifade reagent, ProLong® Gold reagent cures within 24 hours and the sample can be saved for months after mounting. ProLong® Gold reagent offers excellent compatibility with a multitude of dyes and dye complexes, making it an especially valuable tool for multicolor applications⁵⁻⁷ (Figure 23.1.3). The ProLong® Gold antifade reagent is available in a single 10 mL bottle (P36930), as well as in a set of five 2 mL bottles (P36934).

As an added convenience, we also offer ProLong® Gold antifade reagent containing DAPI, the popular nuclear and chromosome stain that emits blue fluorescence upon binding to DNA. The addition of DAPI in the mounting media eliminates the need for a separate counterstaining step. ProLong® Gold antifade reagent with DAPI is available in a single 10 mL bottle (P36931), as well as in a set of five 2 mL bottles (P36935).

ProLong® Antifade Kit

The ProLong® Antifade Kit (P7481, Figure 23.1.4) contains our original ProLong® antifade reagent, which has proven to effectively enhance the resistance of many different fluorophores to photobleaching. Furthermore, specimens mounted using the ProLong® Antifade Kit exhibit little or no quenching of the fluorescent signal of most dyes.

Each ProLong® Antifade Kit contains:

- ProLong® antifade reagent powder
- ProLong® mounting medium
- Detailed protocols for mounting samples

Figure 23.1.2 A 20-second time series showing enhanced resistance to photobleaching afforded by ProLong® Gold antifade reagent. Fixed bovine pulmonary artery endothelial cells were labeled with anti- α -tubulin (A11126) and visualized with fluorescein goat anti-mouse IgG (F2761). The samples were mounted in ProLong® Gold antifade reagent (P36930; top) or phosphate-buffered saline (bottom). Images were acquired at 5-second intervals using a 40x/1.3 NA oil immersion objective with continuous illumination from a standard 100 watt mercury-arc lamp.

Figure 23.1.3 HeLa cell transfected with pShooter pCMV/myc/mito/GFP, then fixed and permeabilized. Green Fluorescent Protein (GFP) localized in the mitochondria was labeled with anti-GFP mouse IgG_{2a} (A11120) and detected with orange-fluorescent Alexa Fluor® 555 goat anti-mouse IgG (A21422), which colocalized with the dim GFP fluorescence. F-actin was labeled with green-fluorescent Alexa Fluor® 488 phalloidin (A12379), and the nucleus was stained with blue-fluorescent DAPI (D1306, D3571, D21490). The sample was mounted using ProLong® Gold antifade reagent (P36930). Some GFP fluorescence is retained in the mitochondria after fixation (left), but immunolabeling and detection greatly improve visualization (right).

Figure 23.1.4 The relative photobleaching rates of fluorescein and Texas Red® fluorophores with buffer alone (right series) or after treatment with the ProLong® antifade reagent (left series). Bovine pulmonary artery endothelial cells were fixed, permeabilized and labeled with Texas Red®-X phalloidin (T7471), which labels F-actin, and with a mouse monoclonal anti- β -tubulin antibody and fluorescein goat anti-mouse IgG antibody (F2761), which label microtubules. Images were acquired at appropriate wavelengths using a cooled CCD camera. The numbers on the left of each pair of frames represent the duration of continuous excitation in seconds.

NOTE 23.2**Selecting Optical Filters for Fluorescence Microscopy**

Sensitive and versatile fluorescence detection techniques are of ever-increasing importance and popularity in biological research microscopy. In the now-standard epi-illuminated microscope configuration, the optical filter set performs a critical function in separating the fluorescence emission photons that will form the final image from the more-intense excitation light field. For practical purposes, it is necessary to reduce the excitation light intensity in the detection path by a factor of 10^6 – 10^7 . This design objective has to be achieved in parallel with capturing as many of the available fluorescence photons as possible. High capture efficiency allows compensating reductions in overall excitation light levels, with accompanying reductions in dye photobleaching and cellular phototoxicity.

This technical note provides some basic fluorescence microscopy information, including discussions of:

- The Optical Filter Set
- The Trade-Off in Optical Filter Design
- Selecting an Optical Filter Set

The Fluorescence SpectraViewer (www.invitrogen.com/handbook/spectraviewer) is an online tool that allows researchers to assess the spectral compatibility of dyes, probes and optical filters in the course of designing experiments (Using the Fluorescence SpectraViewer—Note 23.1).

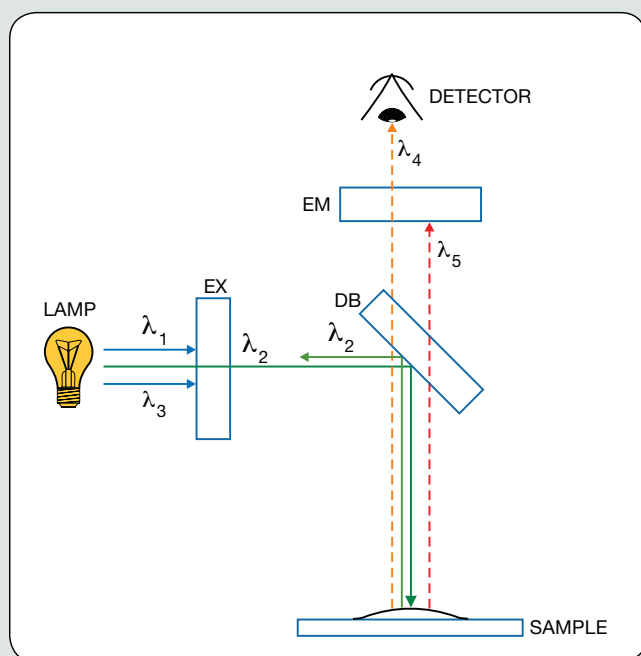

Figure 1 Functions of fluorescence microscope filter set components. The desired excitation wavelength (λ_2) is selected from the spectral output of the lamp by the excitation filter (EX) and directed to the sample via the dichroic beamsplitter (DB). The beamsplitter separates emitted fluorescence (---) from scattered excitation light (—). The emission filter (EM) selectively transmits a portion of the sample's fluorescence emission (λ_4) for detection and blocks other emission components (λ_5).

The Optical Filter Set

A set of optical filters for selective excitation and detection of fluorescence typically consists of a minimum of three components: an excitation filter, a dichroic beamsplitter (“dichroic mirror”) and an emission filter (“barrier filter”) (Figure 1). The excitation filter selectively transmits a portion of the spectral output from the light source (Table 23.1). The dichroic beamsplitter then reflects the selected light, directing it to the sample. Fluorescence emission photons traveling from the sample towards the detector are transmitted by the dichroic beamsplitter, while excitation light reflected back from the sample is diverted out of the detection light path. The emission filter blocks unwanted spectral components of the emitted fluorescence (e.g., sample autofluorescence) as well as any residual excitation light. An interactive Java tutorial demonstrating these functions is available online at the Molecular Expressions website of Florida State University (<http://micro.magnet.fsu.edu/primer/java/fluorescence/filtersetprofiles/index.html>).

The Trade-Off in Optical Filter Set Design

For optimal fluorescence detection when using a single dye, the excitation and emission filters should be centered on the dye's absorption and emission peaks. To maximize the signal, one can choose excitation and emission filters with wide bandwidths. However, this strategy may result in unacceptable overlap of the emission signal with the excitation signal, resulting in poor resolution. To minimize spectral overlap, one can instead choose excitation and emission filters that are narrow in bandwidth and are spectrally well separated to increase signal isolation. This approach will reduce optical noise but may also reduce the signal strength to unacceptable levels. When overlapping signals from multiple fluorophores in the same sample are being differentiated, both the spectra of the dyes and their expected intensities must be considered before choosing an

Figure 2 Potential-dependent staining of mitochondria in CCL64 fibroblasts by JC-1 (T3168). The mitochondria were visualized by epifluorescence microscopy using a 520 nm longpass optical filter. Regions of high mitochondrial polarization are indicated by red fluorescence due to J-aggregate formation by the concentrated dye. Depolarized regions are indicated by the green fluorescence of the JC-1 monomers. The image was contributed by Lan Bo Chen, Dana Farber Cancer Institute, Harvard Medical School.

optical filter. Complete spectral data for Molecular Probes® fluorophores can be found at www.invitrogen.com/handbook/spectraviewer using our interactive Fluorescence SpectraViewer utility (Using the Fluorescence SpectraViewer—Note 23.1). An interactive Java tutorial illustrating the trade-off among these parameters is available online at the Molecular Expressions website of Florida State University (<http://micro.magnet.fsu.edu/primer/java/fluorescence/fluorocubes/index.html>).

Selecting an Optical Filter Set

Filter set selection may involve a straightforward recommendation or a complex analysis of the spectral relationships of dyes and optical filters.¹ Emission filters are available with either longpass or bandpass wavelength transmission profiles. A typical longpass emission filter might transmit all wavelengths ≥ 530 nm, whereas a typical bandpass filter might transmit only wavelengths between 515 and 545 nm. Longpass filters should be used when the application requires maximum emission collection and when spectral discrimination is not desirable or necessary, which is generally the case for probes that generate a single emitting species in specimens with relatively low levels of background autofluorescence. Longpass filters are also useful for simultaneous detection of spectrally distinct dual emissions such as the monomer and J-aggregate forms of JC-1 (T3168, Section 12.2, Figure 2) and the monomer and excimer forms of BODIPY® FL C₅-ceramide (D3521, B22650; Section 12.4; Figure 3).

Bandpass filters are designed to maximize the signal-to-noise ratio for applications where discrimination of signal components is more important than overall image brightness. The spectral sensitivity of the detection system should also be considered in order to achieve optimum detector signal-to-noise or accurate color rendition. Some applications, such as confocal laser-scanning microscopy, may require the use of sensitive photomultiplier (PMT) detectors. Alternatively, an electron-multiplying charge-coupled device (EMCCD) may be employed for quantitative imaging or microspectrofluorometry. Dual-, triple- and quadruple-band filter sets enable microscopists to excite and detect two, three or four fluorophores simultaneously instead of performing sequential image acquisitions with intervening filter changes (Figure 4).

Figure 3 Selective staining of the Golgi apparatus using the green-fluorescent BODIPY® FL C₅-ceramide (D3521) (right panel). At high concentrations, the BODIPY® FL fluorophore forms excimers that can be visualized using a red longpass optical filter (left panel). The BODIPY® FL C₅-ceramide accumulation in the trans-Golgi is sufficient for excimer formation (J Cell Biol (1991) 113:1267). Images contributed by Richard Pagano, Mayo Foundation.

Selecting optimal filter sets for fluorescence microscopy applications requires matching optical filter specifications to the spectral characteristics of dyes. Comparisons should be made with care because some dyes have significantly different spectral properties in a particular application than those reported for the dye in solution. For example, the spectral characteristics of many nucleic acid stains depend on whether the dyes are in aqueous solution or bound to DNA or RNA. Similarly, styryl dyes such as FM® 1-43 (T3163, T35356; Section 14.4, Section 16.1) and di-4-ANEPPS (D1199, Section 22.2) have emission maxima that depend on whether they are dissolved in solvent or associated with membranes. To provide selection guidelines, we have compiled excitation and emission spectra for many of the most widely used probes in fluorescence microscopy in an online tool, the Fluorescence SpectraViewer (www.invitrogen.com/handbook/spectraviewer).

Technical Support

We invite customers to call our Technical Assistance Department for help in selecting the correct optical filter for a specific application. When calling, please be prepared to describe the dye(s), instrumentation and method of detection being used. A technical support scientist will then offer advice on the most effective filter configuration for the specified purposes. Alternatively, we recommend contacting Chroma Technology Corp., Omega Optical, Inc. or Semrock, Inc. or the microscope manufacturer for this information. Chroma Technology, Omega Optical and Semrock provide complete transmission curves and information on their specialty filters for ratio imaging, uncaging, multiphoton and other applications at their respective web sites (www.semrock.com, www.omegafilters.com, www.chroma.com).

1. Biophotonics Int (1999) 6:54.

Figure 4 Optical transmission characteristics of a triple-band filter set (XF63, Omega Optical Inc.) designed for simultaneous imaging of DAPI, fluorescein and Texas Red® dyes. Transmission curves for the individual filter set components are shown in blue (excitation filter), black (dichroic beamsplitter) and red (emission filter). Graphic supplied by and used with permission of Omega Optical Inc., Brattleboro, VT.

Bovine pulmonary arterial epithelial cells (BPAEC) labeled with fluorescein phalloidin (F432) photobleached to about 12% of the initial value in 30 seconds in PBS, while staying at the initial value under the same illumination conditions when mounted using the ProLong® Antifade Kit (Figure 23.1.5). As shown in Figure 23.1.6, the ProLong® Antifade Kit provides more fluorescence output than a popular *p*-phenylenediamine-containing antifade reagent⁸ when used to mount fluorescein-stained HEp-2 cells. The ProLong® antifade reagent also inhibits the fading of tetramethylrhodamine, as well as the fading of DNA-bound nucleic acid stains such as DAPI, propidium iodide and YOYO®-1 (Section 8.1), again without significantly quenching the fluorescence of these dyes.⁹ The compatibility of the ProLong® antifade reagent with a multitude of dyes and dye complexes makes it an especially valuable tool for multicolor analysis procedures such as multiplexed fluorescence *in situ* hybridization.¹⁰

Figure 23.1.5 Bovine pulmonary artery endothelial cells were labeled with fluorescein phalloidin (F432), which labels filamentous actin, and placed under constant illumination on the microscope with a FITC filter set using a 60× objective. Images were acquired at 1-second intervals for 30 seconds. Under these illumination conditions, fluorescein photobleached to about 12% of its initial value in 30 seconds in PBS (left), but stayed at the initial value under the same illumination conditions when mounted using the reagents in the ProLong® Antifade Kit (right, P7481).

SlowFade® Antifade Kit

Our original *SlowFade*® antifade formulation (S2828) was designed to reduce the fading rate of fluorescein to almost zero. Because it provides nearly constant emission intensity from fluorescein, this *SlowFade*® antifade reagent is especially useful for quantitative measurements and applications that employ confocal laser-scanning microscopy.¹¹ However, this original *SlowFade*® formulation substantially quenches the fluorescence of fluorescein and almost completely quenches that of the Alexa Fluor® 350, Alexa Fluor® 405 and Cascade Blue® fluorophores.

Each *SlowFade*® Antifade Kit contains:

- *SlowFade*® antifade reagent in 50% (v/v) glycerol, ready to use and sufficient for at least 200 coverslip-size experiments
- Concentrated *SlowFade*® antifade reagent solution, provided for those applications in which glycerol may not be compatible
- Equilibration buffer, which raises the pH of the sample, increasing the protection afforded by the *SlowFade*® antifade formulation
- Detailed protocols for mounting samples

SlowFade® Gold Antifade Reagent

To overcome the limitations of the original *SlowFade*® antifade reagent, especially with blue fluorophores, we have developed the *SlowFade*® Gold antifade reagent. The *SlowFade*® Gold antifade formulation slows fluorescein's fading rate by about fivefold without significantly reducing its initial fluorescence intensity, thereby dramatically increasing the signal-to-noise ratio in photomicroscopy. Moreover, quenching of the Alexa Fluor® 350, Alexa Fluor® 405, Cascade Blue®, tetramethylrhodamine and Texas Red® dyes is minimal. In fact, the *SlowFade*® Gold antifade reagent reduces the fading rate of the Cascade Blue® fluorophore to almost zero, while decreasing its emission intensity by only about 30%.

The *SlowFade*® Gold antifade reagent is available in a single 10 mL bottle (S36936), as well as in a set of five 2 mL bottles (S36937). As with the ProLong® Gold antifade reagents, we also offer *SlowFade*® Gold antifade reagent containing the blue-fluorescent nuclear counterstain DAPI. *SlowFade*® Gold antifade reagent with DAPI is available

Figure 23.1.7 Human carcinoma (HeLa) cell labeled with Qdot® nanocrystals and mounted with Qmount® media. Mitochondria were detected with anti-OxPhos complex V inhibitor protein IgG (A21355) and labeled with Qdot® 625 goat F(ab)₂ anti-mouse IgG antibody (A10195, red fluorescence); the Golgi apparatus was detected with rabbit anti-giantin antibody and labeled with Qdot® 585 goat F(ab)₂ anti-rabbit IgG antibody (Q11411MP, yellow fluorescence); tubulin was detected with rat anti-tubulin antibody and labeled with DSB-X™ biotin goat anti-rat IgG antibody (D20697) and Qdot® 525 streptavidin (Q10141MP, green fluorescence). The nucleus was labeled with Qnuclear™ Deep Red Stain (Q10363, purple fluorescence), and the slide was mounted with Qmount® Qdot® mounting media (Q10336).

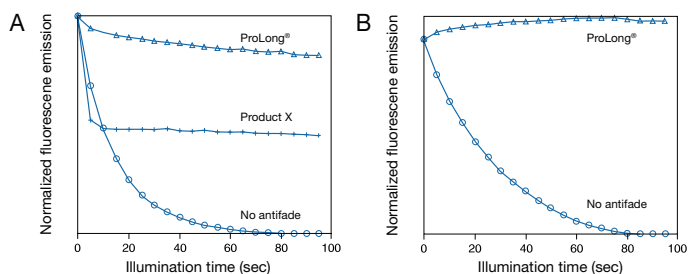

Figure 23.1.6 Bleaching profiles of A) fluorescein and B) Texas Red® dye conjugates in cell samples. In these photobleaching experiments, human epithelial (HEp-2) cells were probed with human anti-nuclear antibodies and then developed for visualization with fluorophore-labeled secondary reagents. Identical samples were mounted in ProLong® antifade reagent (Δ), Product X (+) or medium containing no antifade reagent (○). Although these data were normalized, we observed little or no quenching of samples mounted with the ProLong® mounting medium.

in a single 10 mL bottle (S36938), as well as in a set of five 2 mL bottles (S36939). These reagents permit simultaneous nuclear staining and protection of the stained sample from photobleaching.¹²

Unlike the ProLong® and ProLong® Gold antifade reagents, the *SlowFade®* and *SlowFade®* Gold antifade reagents do not cure over time so samples can be viewed immediately; however, *SlowFade®* Gold reagents are intended for short-term use (3–4 weeks) only and mounted samples may degrade over longer time periods. Secondary sealing of coverslips with wax or nail polish is recommended when working with high magnification objectives or preparing specimens for storage and subsequent imaging.

Qmount® Qdot® Mounting Media

The unique physical properties of Qdot® nanocrystals (Section 6.6) make them largely incompatible with ProLong® Gold, *SlowFade®* Gold and other mounting media designed primarily for use with organic dyes. Qmount® Qdot® mounting media (Q10336) is a specialized mountant that preserves the fluorescence signal of Qdot® nanocrystals with little to no quenching of the signal's initial intensity. The formulation cures within 12 hours and is provided in a convenient and easy-to-use dropper bottle. This mounting medium offers excellent compatibility with all eight Qdot® nanocrystal spectral types (Section 6.6) and their conjugates, as well as the nuclear counterstain Qnuclear™ Deep Red stain (Q10363, Section 12.5), making it an especially valuable tool for multicolor Qdot® nanocrystal imaging applications (Figure 23.1.7). Qmount® Qdot® mounting media is not recommended for use with Alexa Fluor® dyes or fluorescent proteins.

Figure 23.1.8 Reduced background staining afforded by Image-iT® FX signal enhancer. Mouse brain cryosections were permeabilized and antigen retrieval was carried out. The sections were then treated for 30 minutes with Image-iT® FX signal enhancer (I36933, left) or left untreated (right). Sections were labeled with the neural cell body selective antibody anti-Hu C/D (A21271) and visualized using TSA™ Kit #2 (T20912) with the HRP conjugate of goat anti-mouse IgG and Alexa Fluor® 488 tyramide. Sections were mounted using the reagents in the ProLong® Antifade Kit (P7481).

Figure 23.1.9 Increased label specificity and resolution provided by Image-iT® FX signal enhancer. Fixed and permeabilized bovine pulmonary artery endothelial cells were treated with Image-iT® FX signal enhancer (I36933, left) or left untreated (right) and then labeled with tetramethylrhodamine streptavidin (S870).

Image-iT® FX Signal Enhancer

By efficiently blocking nonspecific electrostatic interactions of anionic fluorescent dyes with cationic cell and tissue constituents, the Image-iT® FX signal enhancer (I36933) dramatically improves the signal-to-noise ratio of immunolabeled cells and tissues,^{13–15} allowing clear visualization of targets that would normally be indistinguishable due to background fluorescence (Figure 23.1.8, Figure 23.1.9, Figure 23.1.10). Background staining seen with fluorescent conjugates of streptavidin, goat anti-mouse IgG antibody or goat anti-rabbit IgG antibody is largely eliminated when Image-iT® FX signal enhancer is applied to fixed and permeabilized cells prior to staining.

FluoCells® Prepared Microscope Slides

Ideal for educators and instrument manufacturers, our popular FluoCells® prepared microscope slides contain multilabeled cell preparations for observation by epifluorescence or confocal laser-scanning microscopy. The multicolor staining in these cell and tissue preparations can deliver publication-quality images and lasts through repeated viewings. These slides are especially useful for setting up microscopes and camera systems and for assessing the capabilities of optical filter sets.^{16–18} When stored properly, these permanently mounted specimens will retain their bright and specific staining patterns for at least six months from the date of purchase. We currently offer five different FluoCells® prepared microscope slides:

Figure 23.1.10 Golgi complexes in fixed and permeabilized HeLa cells labeled with anti-golgin-97 antibody (A21270) and visualized with green-fluorescent Alexa Fluor® 488 goat anti-mouse IgG antibody (A11001). Actin was stained with red-fluorescent Alexa Fluor® 594 phalloidin (A12381); nuclei were stained with blue-fluorescent DAPI (D1306, D3571, D21490). Treatment with Image-iT® FX signal enhancer (I36933) largely eliminates nonspecific dye binding (bottom panel) as compared with untreated slide (top panel).

Figure 23.1.11 FluoCells[®] prepared slide #2 (F14781), which shows bovine pulmonary artery endothelial cells (BPAEC) that have been stained with an anti- β -tubulin mouse monoclonal antibody in conjunction with BODIPY[®] FL goat anti-mouse IgG (B2752) for labeling microtubules, Texas Red[®]-X phalloidin (T7471) for labeling F-actin and DAPI (D1306, D3571, D21490) for labeling nuclei. This multiple-exposure image was acquired using bandpass optical filter sets appropriate for DAPI, fluorescein and Texas Red[®] dye.

Figure 23.1.12 FluoCells[®] prepared slide #3 (F24630) contains a mouse kidney section stained with a combination of fluorescent dyes. Alexa Fluor[®] 488 wheat germ agglutinin (W11261) is a green-fluorescent lectin that was used to label elements of the glomeruli and convoluted tubules. The filamentous actin prevalent in glomeruli and the brush border were stained with red-orange-fluorescent Alexa Fluor[®] 568 phalloidin (A12380). Finally, the nuclei were stained with the blue-fluorescent DNA stain DAPI (D1306, D3571, D21490). This pseudocolored image was acquired on a Zeiss[®] confocal microscope located at the Institute of Neuroscience, University of Oregon.

- FluoCells[®] prepared slide #1 (F36924) shows bovine pulmonary artery endothelial cells (BPAEC) stained with MitoTracker[®] Red CMXRos for labeling mitochondria, Alexa Fluor[®] 488 phalloidin for labeling F-actin and DAPI for labeling the nucleus.
- FluoCells[®] prepared slide #2¹⁹ (F14781, Figure 23.1.11) again contains BPAEC, but this time stained with Texas Red[®]-X phalloidin for labeling F-actin, mouse monoclonal anti- α -tubulin antibody in conjunction with BODIPY[®] FL goat anti-mouse IgG antibody for labeling microtubules and DAPI for labeling the nucleus.
- FluoCells[®] prepared slide #3 (F24630; Figure 23.1.12, Figure 23.1.13, Figure 23.1.14) contains a 16 μ m cryostat section of a mouse kidney. Green-fluorescent Alexa Fluor[®] 488 wheat germ agglutinin stains the glomeruli and convoluted tubules; red-fluorescent Alexa Fluor[®] 568 phalloidin labels actin, which is especially prevalent in glomeruli and the brush border of proximal convoluted tubules; finally, DAPI stains the nuclei with blue fluorescence.
- FluoCells[®] prepared slide #4 (F24631, Figure 23.1.15) contains a 16 μ m cryostat section of a mouse intestine. Alexa Fluor[®] 350 wheat germ agglutinin labels the mucus of goblet cells with blue fluorescence; the red-fluorescent Alexa Fluor[®] 568 phalloidin labels actin filaments, which are especially prevalent in the brush border of the intestinal mucosa; and SYTOX[®] Green nucleic acid stain labels nuclei with green fluorescence.
- FluoCells[®] prepared slide #6 (F36925, Figure 23.1.16) contains muntjac skin fibroblast cells stained with a combination of fluorescent stains. Green-fluorescent Alexa Fluor[®] 488 phalloidin labels the prominent filamentous actin in these cells; a mouse monoclonal anti-OxPhos Complex V inhibitor protein antibody in conjunction with the orange-fluorescent Alexa Fluor[®] 555 goat anti-mouse IgG antibody labels mitochondria; far-red-fluorescent TO-PRO[®]-3 nucleic acid stain labels nuclei. Because it contains no blue-fluorescent dyes, this slide is ideal for use with confocal laser-scanning microscopes that rely on non-UV laser light sources.

FocalCheck[™] Fluorescent Microspheres

FocalCheck[™] Ring-Stained Fluorescent Microspheres

FocalCheck[™] fluorescent microspheres are specifically designed for examining the alignment, sensitivity and stability of confocal laser-scanning microscopes.^{17,20} They are particularly useful for confirming the optical sectioning thickness (Z-resolution) in three-dimensional imaging applications. These polystyrene beads—available in 6 μ m and 15 μ m diameters—have been treated using a proprietary method in which a fluorescent dye is allowed to penetrate to only a limited depth within the microsphere. The resulting beads have a well-defined dye layer that, when viewed in

Figure 23.1.13 FluoCells[®] prepared slide #3 (F24630) contains a section of mouse kidney stained with a combination of fluorescent dyes. Alexa Fluor[®] 488 wheat germ agglutinin (W11261), a green-fluorescent lectin, was used to label elements of the glomeruli and convoluted tubules. The filamentous actin prevalent in glomeruli and the brush border were stained with red-fluorescent Alexa Fluor[®] 568 phalloidin (A12380). Finally, the nuclei were counterstained with the blue-fluorescent DNA stain DAPI (D1306, D3571, D21490). This image is a composite of three micrographs acquired using filter sets appropriate for fluorescein, tetramethylrhodamine and DAPI.

Figure 23.1.14 FluoCells[®] prepared slide #3 (F24630) containing a 16 μ m cryostat section of mouse kidney stained with green-fluorescent Alexa Fluor[®] 488 wheat germ agglutinin (W11261), red-orange-fluorescent Alexa Fluor[®] 568 phalloidin (A12380) and blue-fluorescent DAPI (D1306, D3571, D21490). The image represents an optical section obtained by simultaneous two-photon excitation of all three dyes at 797 nm using a Bio-Rad[®] Radiance 2100 multiphoton microscope system. The image was acquired at the 2001 3D Microscopy of Living Cells Course, University of British Columbia, Vancouver, Canada, by John Jordan, Bio-Rad[®] Laboratories; and Iain Johnson, Life Technologies.

cross section in the confocal laser-scanning microscope, appears as a fluorescent ring of varying dimensions depending on the focal plane (Figure 23.1.17, Figure 23.1.18). We refer to this proprietary staining procedure as ring staining to differentiate it from routine staining throughout the bead.

FocalCheck™ microspheres are available in a variety of color configurations provided by five different fluorescent stains:

- Blue (365/430 nm)
- Green (505/515 nm)
- Orange (560/580 nm)
- Red (575/600 nm)
- Dark red (660/680 nm)

The excitation/emission maxima of the different stains are well matched to the laser sources and optical filters commonly used in confocal laser-scanning microscopy and are especially useful in testing and aligning confocal laser-scanning microscopes with multiple laser lines and detection channels (Figure 23.1.19). Moreover, because the dyes are localized *within* the bead and therefore protected from environmental factors, the FocalCheck™ microspheres are brighter and much more photostable than conventional surface-stained beads.

Figure 23.1.15 FluoCells® prepared slide #4 (F24631) contains a section of mouse intestine stained with a combination of fluorescent stains. Alexa Fluor® 350 wheat germ agglutinin (W11263) is a blue-fluorescent lectin that was used to stain the mucus of goblet cells. The filamentous actin prevalent in the brush border was stained with red-orange-fluorescent Alexa Fluor® 568 phalloidin (A12380). Finally, the nuclei were stained with SYTOX® Green nucleic acid stain (S7020). This image is a composite of three digitized images obtained with filter sets appropriate for fluorescein, DAPI and tetramethylrhodamine.

Figure 23.1.16 FluoCells® prepared slide #6 (F36925) showing a fixed, permeabilized and labeled muntjac skin fibroblast. Mitochondria were labeled with mouse anti-OxPhos Complex V inhibitor protein antibody and visualized using orange-fluorescent Alexa Fluor® 555 goat anti-mouse IgG antibody (A21422). F-actin was labeled with green-fluorescent Alexa Fluor® 488 phalloidin (A12379), and the nucleus was stained with TO-PRO®-3 iodide (T3605, pseudocolored magenta).

Figure 23.1.18 Images from confocal laser-scanning microscope optical cross-sectioning of our 15 µm FocalCheck™ microspheres that have a dark red-fluorescent ring stain with a green-fluorescent stain throughout the bead (F7239). The left panel provides a clear visual representation of poor instrument alignment. Correct image registration has been achieved in the right panel, where the dark red ring is aligned with the green disk. The image was contributed by Paulette Brunner, Keck Imaging Center, University of Washington, and Yu-Zhong Zhang, Life Technologies.

Figure 23.1.19 Normalized excitation spectra of the dyes contained in the FocalCheck™ microspheres. Emission lines of several commonly used laser excitation sources are superimposed on the dyes' excitation spectra to illustrate the wide range of usage of these beads as calibration references. Ar = Argon-ion laser. Kr-Ar = Krypton-argon laser. He-Ne = Helium-neon laser.

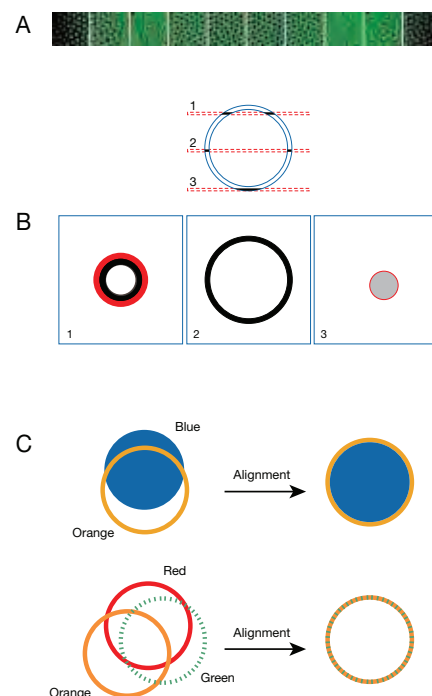

Figure 23.1.17 Confocal laser-scanning microscope optical cross-sectioning and alignment with FocalCheck™ microspheres. A) Serial optical sectioning from top to bottom along the z-axis of ring-stained microspheres reveals a continuous pattern of disc-to-ring-to-disc images. B) The diameter of the fluorescent ring (or disc) seen is dependent on the depth of the optical focal plane. C) In the confocal laser-scanning microscope, separate light paths exist for UV and visible wavelengths. Also, emitted fluorescence is detected by different photomultipliers. Proper optical alignment may be obtained with either of two types of FocalCheck™ microspheres. For example, the microspheres with an orange ring stain that are blue-fluorescent throughout the bead allow UV/visible wavelength alignment in three dimensions upon aligning the orange ring with the blue disc. Focal alignment is also possible simultaneously in three colors by aligning the green, orange and dark red rings of the FocalCheck™ microspheres containing fluorescent green/orange/dark red ring stains.

FocalCheck™ products are available in various different color configurations, including three suspensions that contain microspheres exhibiting ring stains of two or three different fluorescent colors:

- Blue-fluorescent and orange-fluorescent ring stains (15 μm, F7234)
- Green-fluorescent and dark red-fluorescent ring stains (15 μm, F7240)
- Green-fluorescent, orange-fluorescent and dark red-fluorescent ring stains (6 μm, F14806; 15 μm, F7235)

We also supply four suspensions that contain microspheres exhibiting a ring stain of one fluorescent color combined with a stain of a second fluorescent color throughout the bead:

- Green-fluorescent ring stain with blue-fluorescent stain throughout (6 μm, F14808; 15 μm, F7237)
- Green-fluorescent ring stain with dark red-fluorescent stain throughout (15 μm, F7238)
- Orange-fluorescent ring stain with blue-fluorescent stain throughout (15 μm, F7236)
- Dark red-fluorescent ring stain with green-fluorescent stain throughout (6 μm, F14807; 15 μm, F7239, Figure 23.1.18)

The sharp ring stains exhibited by the FocalCheck™ microspheres produce a striking visual representation of instrument misalignment or other aberrations, making them ideal as reference standards for confocal laser-scanning microscopy. Correct image registration is indicated when the multiple ring images of the ring-stained FocalCheck™ beads (or the ring and disk images of the combination ring-stained and stained-throughout FocalCheck™ beads) are perfectly coincident in all dimensions (Figure 23.1.17).

FocalCheck™ Thin-Ring Fluorescent Microspheres

Our FocalCheck™ Thin-Ring Fluorescent Microspheres Kit (F14791) contains smaller-diameter microspheres that have spectral and physical features similar to those of our 6 μm and 15 μm FocalCheck™ microspheres. Because we prepare these 1.0 μm beads using fluorescent stains that are restricted to the surface only, they exhibit sharper and thinner

Figure 23.1.20 A double-labeled microsphere from the FocalCheck™ DoubleGreen Fluorescent Microsphere Kit (F36905). The bead was imaged as a z-series using a Carl Zeiss® LSM 510 META system. The two green-fluorescent dyes were separated by spectral unmixing, and one of the dyes was pseudocolored red. In this composite image, the complete z-series is shown prior to software rendering. Rendering fills in the missing information between the slices by interpolation to create a solid object.

fluorescent ring patterns when viewed in cross section with a confocal laser-scanning microscope. The FocalCheck™ Thin-Ring Fluorescent Microspheres Kit contains three 200 μL suspensions of 1.0 μm beads. Each suspension contains beads with a different color configuration:

- Green-fluorescent (495/515 nm) and red-fluorescent (575/600 nm) ring stains
- Green-fluorescent (495/515 nm) ring stain with dark red-fluorescent (660/680 nm) stain throughout the bead
- Red-fluorescent (575/600 nm) ring stain with blue-fluorescent (365/430 nm) stain throughout the bead

FocalCheck™ Microspheres Pre-Mounted on Microscope Slides

In addition to the bead suspensions described above, we offer FocalCheck™ microspheres pre-mounted on microscope slides. The FocalCheck™ Fluorescent Microsphere Kits feature mounted samples of three different color configurations, in either the 6 μm (F24633) or the 15 μm (F24634) bead size:

- FocalCheck™ beads with green-fluorescent, orange-fluorescent and dark red-fluorescent ring stains
- FocalCheck™ beads with green-fluorescent ring stain and blue-fluorescent stain throughout the bead
- FocalCheck™ beads with dark red-fluorescent ring stain and green-fluorescent stain throughout the bead

FocalCheck™ Fluorescence Microscope Test Slides

FocalCheck™ fluorescence microscope test slides #1, #2 and #3 are specifically designed for calibrating fluorescence microscope systems and evaluating system and filter performance:

- FocalCheck™ fluorescence microscope test slide #1 (F36909) is ideal for routine checking and calibration of confocal and widefield fluorescence microscopes²¹
- FocalCheck™ fluorescence microscope test slide #2 (F36913) provides a robust, reproducible method of evaluating the performance of spectral imaging systems,²² as well as the ability to discriminate closely overlapping spectra. The slide consists of 6 μm-diameter microspheres labeled with a series of spectrally overlapping dyes
- FocalCheck™ fluorescence microscope test slide #3 (F36914) is useful for basic evaluation of filter performance and as a general practice slide for fluorescence microscopy and digital imaging

The slides each contain 10 sample areas arranged in two rows coated with proprietary fluorescent microspheres designed specifically for microscopy applications. The microspheres are mounted in optical cement (refractive index ~1.52) for maximal stability. The optical thickness of the mounted bead specimens may result in spherical aberration or inability to focus when using certain types of objectives. Users who encounter these problems are encouraged to contact our Technical Assistance Department.

FocalCheck™ Fluorescent Microspheres for Spectral Unmixing

We have prepared two FocalCheck™ Fluorescent Microspheres Kits for testing spectral separation on spectral imaging systems.²³ These microspheres are stained with two different fluorescent dyes that appear

similar in color by eye but are sufficiently different to be resolved by linear-unmixing techniques. When linear-unmixing data-processing algorithms are applied, the dyes are shown to be spectrally distinct and spatially separated—one appears only within the outer ring and the other appears throughout the microsphere (Figure 23.1.20). These 6 μm , dual-stained microspheres are provided mounted on a microscope slide in each of the following kits:

- FocalCheck™ DoubleGreen Fluorescent Microspheres Kit (F36905), with a green-fluorescent (500/512 nm) ring dye and a slightly longer-wavelength green-fluorescent (512/525 nm) core dye
- FocalCheck™ DoubleOrange Fluorescent Microspheres Kit (F36906), with an orange-fluorescent (532/552 nm) ring dye and a slightly longer-wavelength orange-fluorescent (545/565 nm) core dye

For generating reference spectra, these kits also contain two additional slides containing microspheres stained uniformly with each of the individual dyes. Downloadable reference spectra are also available through our online Fluorescence SpectraViewer tool (www.invitrogen.com/handbook/spectraviewer; Using the Fluorescence SpectraViewer—Note 23.1).

MultiSpeck™, TetraSpeck™ and Constellation™ Fluorescent Microspheres

Our MultiSpeck™ and TetraSpeck™ fluorescent microspheres greatly facilitate the adjustment and calibration of conventional fluorescence microscopes, confocal laser-scanning microscopes and associated image-processing equipment for multicolor applications. These uniform, multiply stained microspheres are useful for colocalizing and focusing different wavelengths of light in the same optical plane, as well as for checking multicolor image resolution, magnification and sensitivity.

MultiSpeck™ Multispectral Fluorescence Microscopy Standards Kit

The 4 μm MultiSpeck™ microspheres in our MultiSpeck™ Multispectral Fluorescence Microscopy Standards Kit (M7901) exhibit three relatively distinct emission bands—blue, green and red—throughout every particle (Figure 23.1.21). The spectral characteristics (excitation/emission peaks at 365/405 nm, 520/525 nm and 580/600 nm) are compatible with optical filter sets designed for commonly used blue, green and red fluorophores (e.g., DAPI, fluorescein and rhodamine or Texas Red® dyes or their Alexa Fluor® dye counterparts). The MultiSpeck™ beads can be used as external references for assessing image registration in two and three dimensions, allowing the researcher to accurately determine the spatial relationships of different labels in multiparameter experiments.

The MultiSpeck™ Multispectral Fluorescence Microscopy Standards Kit contains:

- Suspension of MultiSpeck™ multispectral microspheres
- Mixed suspension of separately stained blue-, green- and red-fluorescent microspheres, which exhibit the same three excitation/emission bands as the multispectral microspheres but in separate beads
- Mounting medium
- Slide-mounting protocol

Both suspensions are provided at a ready-to-use density and can be mounted on slides or incorporated into an experimental sample. Each kit supplies a sufficient amount of material for ~50 slide preparations using either of the two bead suspensions provided.

TetraSpeck™ Fluorescent Microspheres and Sampler Kits

Our TetraSpeck™ fluorescent microspheres^{17,19,20} expand the multispectral strategy introduced with the MultiSpeck™ beads in two important ways. First, the TetraSpeck™ beads have been stained throughout with a mixture of four different fluorescent dyes, yielding four well-separated excitation and emission peaks (Figure 23.1.22). The excitation/emission maxima of the dyes are

Figure 23.1.21 Multiple exposures of a prepared slide from our MultiSpeck™ Multispectral Fluorescence Microscopy Standards Kit (M7901). This kit provides fluorescent MultiSpeck™ microspheres that exhibit three relatively distinct excitation/emission bands—blue, green and red—all in the same particle. Thus, the same microsphere can appear a different color depending on the optical filter set used. This photograph was taken through bandpass optical filter sets appropriate for DAPI, fluorescein and Texas Red® dyes, with the field of view shifted slightly between exposures.

Figure 23.1.22 Four separate exposures of three TetraSpeck™ beads (T7283) photographed using optical filter sets appropriate for DAPI, fluorescein, tetramethylrhodamine and the Texas Red® dye. The stage was shifted after each exposure. Note that the same beads appear blue, green, orange or red, depending on the filters used.

Figure 23.1.23 Luminescent microsphere products provide an extensive range of sizes and fluorescent colors, illustrated by a sample of our Constellation™ microspheres for imaging (C14837).

Figure 23.1.24 Constellation™ microspheres (C14837) provide an assortment of sizes and colors for use in fluorescence microscopy demonstrations.

Figure 23.1.25 One PS-Speck™ green-fluorescent microsphere (P7220) used for point-spread function analysis. Shown are individual images, in pseudocolor, taken in x-y planes with 0.25 μm increments in the z-axis between planes. The image was contributed by Regina Armstrong, Uniformed Services University of the Health Sciences, Bethesda, Maryland.

365/430 nm (blue), 505/515 nm (green), 560/580 nm (orange) and 660/680 nm (dark red). Second, these microspheres are available in five nominal sizes (actual bead diameters are indicated on the product labels), spanning the range from subresolution to nearly cell-size particles:

- 0.1 μm (T7279)
- 0.2 μm (T7280)
- 0.5 μm (T7281)
- 1.0 μm (T7282)
- 4.0 μm (T7283)

Each of these products provides a 0.5 mL suspension sample of TetraSpeck™ microspheres that is sufficient for about 100 slides. We offer the TetraSpeck™ Fluorescent Microspheres Sampler Kit (T7284) and the TetraSpeck™ Fluorescent Microspheres Size Kit (T14792). The TetraSpeck™ Fluorescent Microspheres Sampler Kit consists of separate suspension samples of our 0.1 μm, 0.5 μm and 4.0 μm TetraSpeck™ beads, each sufficient for preparing about 20 slides. The TetraSpeck™ Fluorescent Microspheres Size Kit contains six microscope slides; five slides with a mounted sample of the 0.1 μm, 0.2 μm, 0.5 μm, 1.0 μm or 4.0 μm diameter TetraSpeck™ microspheres, and a sixth slide with a mixture of all five sizes. TetraSpeck™ microspheres have been used to calibrate the spatial distribution of illumination for high-content screening (HCS),^{24,25} and as reference markers for image alignment in high-resolution immunofluorescence colocalization analysis.^{24,26} In addition, various FluoSpheres® and TetraSpeck™ beads have been used as reference standards for two-photon excitation microscopy, and in particular for the *in situ* determination of the two-photon excitation point-spread function (PSF).^{27–29}

Constellation™ Microspheres for Imaging

Constellation™ microspheres for imaging (C14837; Figure 23.1.23, Figure 23.1.24) are 3 mL suspensions of assorted fluorescent microspheres with a variety of sizes and colors. Designed for use in laboratory tutorials and customer training sessions, they provide inexpensive and robust test samples for demonstrating filter switching, focus adjustment and other functional capabilities of fluorescence microscopes. The Constellation™ microspheres can be stored at room temperature, protected from light.

PS-Speck™ Microscope Point Source Kit

The fluorescent microspheres in the PS-Speck™ Microscope Point Source Kit (P7220) have a diameter of $0.175 \pm 0.005 \mu\text{m}$, making them ideal subresolution fluorescent sources for calibrating instrument optics. They are particularly useful for measuring the point-spread function (PSF) required for computational image deconvolution procedures^{17,30–32} (Figure 23.1.25, Figure 23.1.26). This kit's four ready-to-use suspensions contain bright monodisperse particles in the following fluorescent colors (and excitation/emission peaks):

- Blue (360/440 nm)
- Green (505/515 nm)
- Orange (540/560 nm)
- Deep red (633/660 nm)

The kit also includes mounting medium and a mounting protocol for the user's convenience. Each suspension provides sufficient material to mount about 100 slides. PS-Speck™ microspheres are too large to represent point source objects for microscopes equipped with high numerical aperture (e.g., NA 1.4) oil immersion objectives. In such cases, we recommend our 0.1 μm TetraSpeck™ fluorescent microspheres (T7279) or 0.1 μm and 0.04 μm FluoSpheres® carboxylate-modified microspheres (Section 6.5) for PSF determinations.

InSpeck™ Microscopy Image Intensity Calibration Kits

InSpeck™ Microscopy Image Intensity Calibration Kits provide microsphere standards that generate a series of well-defined fluorescence intensity levels (Figure 23.1.27) for constructing calibration curves and evaluating sample brightness.^{6,25,33} InSpeck™ microspheres have been used to estimate the global background and signal response for high-content screening (HCS).²⁵

Most of the kits are offered in a choice of two different microsphere sizes (2.5 μm or 6 μm) and five different fluorescent colors:

- InSpeck™ Blue (350/440 nm) Kit, (2.5 μm , I7221)
- InSpeck™ Green (505/515 nm) Kits (2.5 μm , I7219; 6 μm , I14785)
- InSpeck™ Orange (540/560 nm) Kits (2.5 μm , I7223; 6 μm , I14786)
- InSpeck™ Red (580/605 nm) Kits (2.5 μm , I7224; 6 μm , I14787)
- InSpeck™ Deep Red (633/660 nm) Kit (2.5 μm , I7225)

Each kit includes six separate suspensions of InSpeck™ fluorescent microspheres with relative fluorescence intensities of 100%, 30%, 10%, 3%, 1% and 0.3% (Figure 23.1.27), covering the range of intensities commonly encountered in microscopy applications. Unstained control beads and mounting medium are also supplied. The aqueous suspensions of microspheres may be applied directly to the sample for calibrating fluorescence intensities or mounted separately in an adjacent well or on another slide. Each suspension provides sufficient material to prepare about 100 slides.

Figure 23.1.26 An orthogonal (x-z) display representing a point-spread function. The microsphere used is a component of the PS-Speck™ Microscope Point Source Kit (P7220). This pseudocolored image was generated electronically from a series of microsphere images taken in x-y planes. The image was contributed by Jennifer Kramer, Scanalytics.

Fluorescence Reference Standards

Fluorescein NIST-Traceable Standard

The National Institute of Standards and Technology (NIST) chose high-grade Molecular Probes® fluorescein to create Standard Reference Material 1932 (SRM® 1932), a certified fluorescein solution. We now offer a NIST-traceable fluorescein standard (F36915) that not only meets the stringent criteria established by NIST, but is also directly traceable to SRM® 1932. We supply our NIST-traceable fluorescein standard as a calibrated 50 μM solution of fluorescein in 100 mM sodium borate buffer, pH 9.5; under these conditions, fluorescein is completely ionized³⁴ and is therefore in its most fluorescent form (Figure 23.1.28, Figure 23.1.29), exhibiting an extremely high quantum yield of 0.93.

Academic researchers and industry scientists alike can use our NIST-traceable fluorescein standard to assess day-to-day or experiment-to-experiment variation in fluorescence-based instrumentation, as well as to determine the Molecules of Equivalent Soluble Fluorophore (MESF) value for an experimental solution. The MESF value is defined not as the actual number of dye molecules present, but rather as the number of fluorophores that would yield a fluorescence intensity equivalent to that of the experimental solution when analyzed on the same instrument under the same conditions.^{35–38} Consequently, the MESF value is an important tool for characterizing the fluorescence intensity of a solution containing spectrally similar dye molecules attached to antibodies, nucleic acids, microspheres or other substrates that might enhance or diminish the fluorescence. When its pH is carefully matched with that of the experimental solution, our NIST-traceable fluorescein standard can be used for accurate MESF determinations of a wide range of green-fluorescent dye solutions and on an assortment of fluorescence-based instruments.

Figure 23.1.27 Flow cytometric analysis of the beads in the 6 μm InSpeck™ Green Microscope Image Intensity Calibration Kit (I14785). The microspheres have nominal relative fluorescence intensities of 100%, 30%, 10%, 3%, 1%, 0.3%. For each lot, actual relative intensities are determined by flow cytometry and printed on the product labels.

Figure 23.1.28 Ionization equilibria of fluorescein.

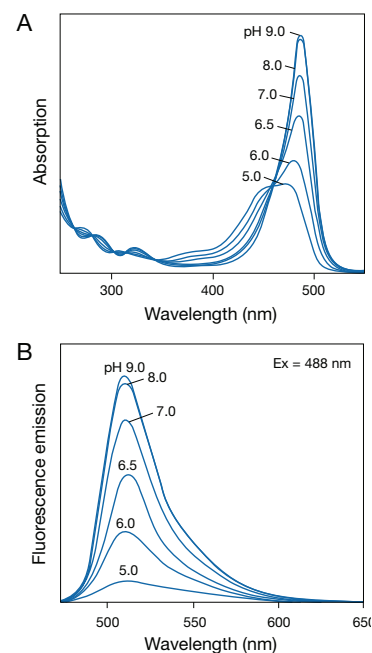

Figure 23.1.29 The pH-dependent spectra of fluorescein (F1300): A) absorption spectra, B) emission spectra.

Reference Dye Sampler Kit

Our Reference Dye Sampler Kit (R14782) provides samples of five extensively characterized fluorescence standards with emission spectra covering the entire visible wavelength range.³⁹ All five fluorescent standards are supplied as 1 mM stock solutions in 1 mL units, sufficient to prepare approximately 500 diluted working samples for spectrofluorometry. The compositions of the stock solutions are as follows:

- Quinine sulfate in 0.1 M sulfuric acid (H₂SO₄) (Figure 23.1.30)
- Fluorescein in dimethylsulfoxide (DMSO) (Figure 23.1.31)
- 5-Carboxytetramethylrhodamine in DMSO (Figure 23.1.32)
- Sulforhodamine 101 in DMSO (Figure 23.1.33)
- Nile blue perchlorate in DMSO (Figure 23.1.34)

Spectroscopic data for the five standards are summarized in Table 23.2. Reference spectra for all five fluorescent standard solutions are provided through our online Fluorescence SpectraViewer tool (www.invitrogen.com/handbook/spectraviewer).

Sample Chambers, Slides and Coverslips

In collaboration with Grace Bio-Labs, we offer a collection of accessories for imaging and microscopy. These accessories make slide preparation easy, facilitate sample perfusion and simplify sample manipulation during *in situ* hybridization and other procedures that involve multiple wash steps.

CultureWell™ Cell Culture Systems

The CultureWell™ cell culture systems provide an integrated set of tools for preparing cultured cells for staining and imaging. Each system uses medical-grade silicone gaskets preassembled with standard optical-quality coverslips into convenient inserts that fit into matching cell culture plates (Figure 23.1.35). The entire system is provided sterile and ready to use. Cell culture, treatment and staining are performed on the coverslip, which adheres securely to the culture plate via a silicone backing. The samples can then be imaged with or without the silicone gaskets. Two types of systems are available in several configurations to suit a variety of needs (Table 23.3).

The CultureWell™ multiwell cell culture systems use precut silicone gaskets to form convenient no-leak wells on 24 × 50 mm coverslips. The wells are spaced for compatibility with microfluidic handling robots. Low numbers of wells are ideal for titrating antibody dilutions or other staining conditions, whereas the higher numbers of wells facilitate high-throughput screening. Each insert includes four coverslips with gaskets, preassembled into a culture plate. Silicone dividers (C24770, Figure 23.1.36) are also available for separating portions of the coverslip into leak-proof wells, for different treatment and washing conditions.

The CultureWell™ multislip cell culture systems comprise multiple coverslips arrayed on a sheet of silicone and assembled into a convenient insert. The silicone backing adheres the coverslips to the tissue culture plate, preventing movement during plating, cell culture and washing steps. Each coverslip can be removed separately for individual

staining experiments. The CultureWell™ cell culture systems are provided in a set of 10 preassembled inserts in plates.

CultureWell™ Chambered Coverslips

The CultureWell™ chambered coverslips (Table 23.3, Figure 23.1.37) are the same gasketed coverslips provided in our CultureWell™ cell culture systems, but they are not preassembled into inserts. The chambered coverslip can be placed in CultureWell™ plates (C24769) or other cell culture dishes for cell culture and staining. The silicone gasket can be easily removed and the coverslip placed on a slide for microscopy. The CultureWell™ chambered coverslips provide maximum versatility for designing smaller scale cell culture applications. They are provided in sets of five sterile pouches, with four chambered coverslips per pouch.

CultureWell™ Chambered Coverglasses

The CultureWell™ chambered coverglass—provided sterile and ready to use—contains 16 wells that can each hold up to 250 μL , allowing cells to be cultured in a number of different conditions on a single slide (Figure 23.1.38). A silicone gasket forms a leakproof seal between the polystyrene upper structure and the coverglass. When the cells are ready to be imaged, coverglass removal is made easy by the use of a simple tool that separates the parts without the need for excessive force, eliminating the risk of coverglass breakage (Figure 23.1.39). Removal of the

Figure 23.1.41 CoverWell™ perfusion chamber gaskets.

Figure 23.1.42 CoverWell™ incubation chamber gaskets.

silicone gasket leaves no residue. The components of the chambered coverglass are manufactured and assembled with special orientation features to allow easy location of a specific specimen after the coverglass is mounted. Frosted microscope slides are also provided for mounting. The CultureWell™ removable chambered coverglass has several important features:

- Black silicone gasket reduces light scatter, enhancing fluorescence applications.
- Inert, non-cytotoxic silicone permits edge-to-edge growth of cells in the wells.
- Wells are spaced to allow the use of multichannel pipettes for fast and easy cell culturing.
- Silicone gasket remains attached to the coverglass after separation, allowing the wells to be used as reagent reservoirs.
- Gasket design is ideally suited for small-volume incubations, *in situ* hybridization and immunostaining.
- Chambered coverglass is provided sterile and ready to use.

We offer the CultureWell™ chambered coverglass in a package containing eight chambered coverglasses and the removal tool (C37000), as well as in a sample size containing a pair of chambered coverglasses (C37005).

CoverWell™ Imaging Chamber Gaskets

CoverWell™ imaging chamber gaskets (Table 23.4, Figure 23.1.40) incorporate a thin, optically clear plastic cover, making them ideal for light, epifluorescence and confocal laser-scanning microscopy.⁴⁰ By simply pressing an imaging chamber gasket to a microscope slide or coverslip, a sealed chamber is formed to contain mounting medium. The watertight chamber supports and stabilizes thick and free-floating specimens, permitting resolution of fine internal structures and analysis of markers without the compression or movement artifacts that affect observations made using an ordinary coverslip.

CoverWell™ Perfusion Chamber Gaskets

CoverWell™ perfusion chamber gaskets (Table 23.4, Figure 23.1.41) are designed for live-cell imaging and manipulation. With the same silicone gasket technology as the CoverWell™ imaging chamber gaskets, these gaskets form watertight “press-to-seal” chambers with dual-access ports for addition and removal of perfusing media. The access ports can be covered using

adhesive seal tabs (A18211), which are available separately. The heat-resistant gaskets can be sterilized and used for direct culturing of cells and tissues. CoverWell™ perfusion chamber gaskets are available in single- or multiwell configurations, allowing multiple experiments to be performed on a single microscope slide or coverslip.

CoverWell™ Incubation Chamber Gaskets

CoverWell™ incubation chamber gaskets (Table 23.4, Figure 23.1.42) are silicone gaskets with a clear plastic cover that are expressly designed for immunocytochemistry and *in situ* hybridization.^{41,42} The gasket is simply pressed onto a wet or dry microscope slide to form a watertight chamber that holds reactants in place and prevents evaporation. The chambers improve the uniformity and sensitivity of staining by enclosing a large sample area while minimizing the reagent volume required. The incubation chamber gaskets are easily removed and re-applied for multiple-step procedures. These chamber gaskets are heat resistant, autoclavable and nuclease free.

Press-to-Seal Silicone Isolators and Secure-Seal™ Adhesive Spacers

For the ultimate in utility and flexibility, Press-to-Seal silicone isolators (Table 23.5, Figure 23.1.43) are removable hydrophobic barriers that can be customized to meet specific experimental requirements. They may be used to isolate cells grown in culture dishes or to separate specimens on microscopy slides during staining procedures. The silicone material can be autoclaved and adheres to any smooth surface. Isolators without adhesive can be easily removed and reapplied for multiple incubation steps. Isolators are also available with adhesive on one side for added security or permanent mounting. In addition, we offer uncut silicone sheets that can easily be trimmed to prepare customized enclosures.

Similar to the Press-to-Seal silicone isolators, Secure-Seal™ adhesive spacers are ultra-thin gaskets with adhesive that can be stacked to any depth desired. For high-resolution microscopy, the spacer and specimen can be sandwiched between two No. 0 glass coverslips. The spacers are available in several configurations (Table 23.5).

HybriSlip™ Hybridization Covers

HybriSlip™ hybridization covers (Table 23.6, Figure 23.1.44) are nuclease free, ready-to-use and designed specifically for *in situ* hybridization.⁴³ These hydrophobic coverslips do not require lengthy preparation or blocking procedures to prevent probe trapping or binding. They are heat resistant and do not curl, even at high temperatures, making them ideal for denaturation steps or *in situ* PCR incubations. HybriSlip™ covers are available in three sizes.

Figure 23.1.45 HybriWell™ hybridization sealing systems.

Figure 23.1.46 Secure-Seal™ hybridization chambers.

Figure 23.1.47 ONCYTE® MultiWells.

Figure 23.1.48 ProPlate™ multi-array system (P37004). Individual modules (P37001), covered with seal strips (P37002), fit into a tray (P37003), producing a modular plate with a standard microplate footprint and well spacing.

HybriWell™ Hybridization Sealing Systems

HybriWell™ hybridization sealing systems (Table 23.6, Figure 23.1.45) are coverslip–seal combinations that attach to microscope slides to form microwells optimized for carrying out *in situ* hybridization procedures. These ready-to-use hybridization gaskets have a special adhesive that bonds to glass slides in seconds, creating a water-tight seal that is temperature resistant but can also be removed cleanly and easily after hybridization. Solutions are easily added or removed through dual-access ports without disrupting the specimen. The hydrophobic coverslips are nuclease free and will not trap or bind probes, allowing uniform distribution of the reagent over the specimen. The HybriWell™ sealing systems also include a quick-seal tool to secure the hydrophobic cover to the microscope slide, as well as nuclease-free adhesive seal tabs to cover the access ports. Adhesive seal tabs (A18211) are also available separately in sets of 400.

Secure-Seal™ Hybridization Chambers

Like the HybriWell™ hybridization sealing systems, Secure-Seal™ hybridization chambers (Table 23.6, Figure 23.1.46) are designed to isolate single or multiple specimens on a slide during *in situ* hybridization procedures. Access ports in the chamber surface allow for the addition or removal of solutions and are easily sealed using adhesive seal tabs (A18211), available separately. Because they are deeper than the HybriWell™ chambers, the Secure-Seal™ chambers provide optimum surface-to-volume fluid dynamics, which facilitate more uniform hybridization. However, the shallower chambers created by the HybriWell™ sealing systems hold a smaller reagent volume, minimizing the amount of probe required.

ONCYTE® MultiWells with Slide and Matching Gasket

The versatile ONCYTE® MultiWells (Figure 23.1.47) consist of a two-piece set that includes a slide printed with nitrocellulose circles and a matching removable gasket to enclose and isolate each sample. The nitrocellulose coating on the slide is specially formulated for fluorescence imaging. This ultra-thin microporous coating ensures uniform binding of tissue prints, cells or macromolecules and becomes transparent in a variety of mounting media. The matching press-to-seal silicone gaskets adhere easily to the surface of the slide to isolate specimens and reagents and prevent cross contamination. A coverslip can be added to create enclosed chambers for long incubations. Gaskets can be removed and cleaned simply by peeling them off. ONCYTE® MultiWells are available in two configurations: a set of 20 slides and gaskets, each with 12 wells, 5 mm in diameter (O24750), or a set of 20 slides and gaskets, each with a single well, 13 mm in diameter (O24751).

ProPlate™ Multi-Array System

The ProPlate™ multi-array system (P37004) from Grace Bio-Labs allows integration of microscope array technology with automated microplate processing (Figure 23.1.48). Individual modules (P37001), covered with seal strips (P37002), fit into a tray (P37003), producing a modular plate with a standard microplate footprint and well spacing. The modular design allows loading of 1–4 slides per tray for plate washing and reading. Individual ProPlate™ modules may also be processed by hand without the use of the tray. The large well volumes and isolation of 16 individual arrays (2 × 8) on a single microscope slide is particularly well suited for proteomics applications, including protein expression analysis, protein-protein interactions, antibody profiling and high-throughput automated analysis of multiple proteins. The ProPlate™ multi-array system can also be used to process cDNA or oligonucleotide arrays.⁴⁴

Attofluor Cell Chamber

The Attofluor cell chamber (A7816, Figure 23.1.49) is a durable and practical coverslip holder designed for viewing live-cell specimens on upright or inverted microscopes; spare O-rings for the Attofluor cell chamber are available in sets of 10 (O14804). Features of the Attofluor cell chamber include:

- Surgical stainless steel construction
- Autoclavable, allowing cells to be grown directly in the chamber
- O-ring seal design that prevents sample contamination by oil and leakage of media from the coverslip
- Accepts 25 mm–diameter round coverslips and mounts in a standard 35 mm–diameter stage holder
- Thin 0.5 mm base, allowing clearance for the objective when focusing

Figure 23.1.49 Attofluor cell chamber (A7816).

Coverslip Mini-Rack and Coverslip Maxi-Rack

Our unique coverslip mini-rack (C14784, Figure 23.1.50) is a miniature support designed to vertically hold eight standard round or square coverslips. The mini-rack fits easily into a standard 50 mL beaker and can accommodate a small stir bar beneath the rack. Use of the mini-rack eliminates the necessity for repeatedly moving coverslips between solutions with forceps. Because it is constructed of Teflon®, the mini-rack does not adsorb biopolymers, withstands strong acids and bases, is not damaged by heat and may be sterilized by a variety of methods such as autoclaving, organic solvent treatment or ethylene oxide exposure. The mini-rack is easily disassembled for cleaning and storage. The mini-rack is particularly useful in immunocytochemical and *in situ* hybridization procedures involving sequential wash steps where thorough and consistent removal staining, fixation, permeabilization or blocking reagents from the coverslips is critical. The coverslip maxi-rack (C24784, Figure 23.1.51) provides efficient support for the simultaneous staining and washing of up to 50 samples on 18 mm square or circular coverslips in a self-contained covered container. The maxi-rack includes a convenient handle to remove the rack from the staining solution.

Figure 23.1.50 Coverslip mini-rack (C14784).

Figure 23.1.51 Coverslip maxi-rack (C24784).

PRODUCT LIST 23.1 FLUORESCENCE MICROSCOPY ACCESSORIES AND REFERENCE STANDARDS

Cat. No.	Product	Quantity
A18211	Adhesive seal-tab, for HybriWell™ hybridization sealing system *set of 400*	1 set
A7816	Attofluor cell chamber *for microscopy*	each
C14837	Constellation™ microspheres for imaging *mixture of assorted sizes and colors*	3 mL
C24784	coverslip maxi-rack *for 50 coverslips*	each
C14784	coverslip mini-rack *for 8 coverslips*	each
C18160	CoverWell™ imaging chamber gasket, one chamber, 20 mm diameter, 0.5 mm deep *set of 40*	1 set
C18161	CoverWell™ imaging chamber gasket, one chamber, 20 mm diameter, 1.0 mm deep *set of 40*	1 set
C24726	CoverWell™ imaging chamber gasket with adhesive, one chamber, 20 mm diameter, 0.5 mm deep *set of 40*	1 set
C24727	CoverWell™ imaging chamber gasket with adhesive, one chamber, 20 mm diameter, 1.0 mm deep *set of 40*	1 set
C18155	CoverWell™ incubation chamber gasket, one chamber, 13 mm diameter, 0.2 mm deep *set of 25*	1 set
C18156	CoverWell™ incubation chamber gasket, one chamber, 13 mm diameter, 0.5 mm deep *set of 50*	1 set
C18150	CoverWell™ incubation chamber gasket, one chamber, 40 mm x 22 mm, 0.2 mm deep *set of 25*	1 set
C18151	CoverWell™ incubation chamber gasket, one chamber, 40 mm x 22 mm, 0.5 mm deep *set of 50*	1 set
C18139	CoverWell™ perfusion chamber gasket, eight chambers, 9 mm diameter, 0.5 mm deep *set of 20*	1 set
C18140	CoverWell™ perfusion chamber gasket, eight chambers, 9 mm diameter, 1.0 mm deep *set of 20*	1 set
C18141	CoverWell™ perfusion chamber gasket, eight chambers, 9 mm diameter, 2.0 mm deep *set of 20*	1 set
C18142	CoverWell™ perfusion chamber gasket, eight chambers, 9 mm diameter, 2.5 mm deep *set of 20*	1 set
C18128	CoverWell™ perfusion chamber gasket, four chambers, 19 mm x 6 mm, 0.5 mm deep *set of 40*	1 set
C18136	CoverWell™ perfusion chamber gasket, one chamber, 20 mm diameter, 1.0 mm deep *set of 40*	1 set
C18120	CoverWell™ perfusion chamber gasket, one chamber, 32 mm x 19 mm, 0.5 mm deep *set of 40*	1 set
C18121	CoverWell™ perfusion chamber gasket, one chamber, 32 mm x 19 mm, 1.0 mm deep *set of 40*	1 set
C24769	CultureWell™ cell culture plate *set of 10*	1 set
C37005	CultureWell™ chambered coverglass for cell culture *sixteen wells per coverglass* *set of 2*	1 pack
C37000	CultureWell™ chambered coverglass for cell culture *sixteen wells per coverglass* *set of 8*	1 set
C24770	CultureWell™ coverslip divider *set of 4*	1 set
C24760	CultureWell™ multislip cell culture system MSI-12 *plate and insert, fifteen 12 mm coverslips per insert* *set of 10*	1 set
C24761	CultureWell™ multislip cell culture system MSI-18 *plate and insert, eight 18 mm coverslips per insert* *set of 10*	1 set
C24762	CultureWell™ multiwell cell culture system CWI 2R-1.0 *plate and insert, four 24 mm x 50 mm coverslips per insert, two 1 mm-deep wells per coverslip* *set of 10*	1 set
C24763	CultureWell™ multiwell cell culture system CWI 2R-2.0 *plate and insert, four 24 mm x 50 mm coverslips per insert, two 2 mm-deep wells per coverslip* *set of 10*	1 set
C24764	CultureWell™ multiwell cell culture system CWI 3S-1.0 *plate and insert, four 24 mm x 50 mm coverslips per insert, three 1 mm-deep wells per coverslip* *set of 10*	1 set
C24765	CultureWell™ multiwell cell culture system CWI 4R-1.0 *plate and insert, four 24 mm x 50 mm coverslips per insert, four 1 mm-deep wells per coverslip* *set of 10*	1 set
C24766	CultureWell™ multiwell cell culture system CWI 8R-1.0 *plate and insert, four 24 mm x 50 mm coverslips per insert, eight 1 mm-deep wells per coverslip* *set of 10*	1 set
C24767	CultureWell™ multiwell cell culture system CWI 8R-1.0 TS *plate and insert, four 24 mm x 50 mm coverslips per insert, eight 1 mm-deep wells per coverslip* *set of 2*	1 set
C24768	CultureWell™ multiwell cell culture system CWI 50R-1.0 *plate and insert, four 24 mm x 50 mm coverslips per insert, fifty 1 mm-deep wells per coverslip* *set of 10*	1 set
C24775	CultureWell™ multiwell chambered coverslip CWCS 2R-1.0 *24 mm x 50 mm coverslips, two 1 mm-deep wells per coverslip* *set of 20*	1 set
C24776	CultureWell™ multiwell chambered coverslip CWCS 2R-2.0 *24 mm x 50 mm coverslips, two 2 mm-deep wells per coverslip* *set of 20*	1 set
C24777	CultureWell™ multiwell chambered coverslip CWCS 3S-1.0 *24 mm x 50 mm coverslips, three 1 mm-deep wells per coverslip* *set of 20*	1 set
C24778	CultureWell™ multiwell chambered coverslip CWCS 4R-1.0 *24 mm x 50 mm coverslips, four 1 mm-deep wells per coverslip* *set of 20*	1 set
C24779	CultureWell™ multiwell chambered coverslip CWCS 8R-1.0 *24 mm x 50 mm coverslips, eight 1 mm-deep wells per coverslip* *set of 20*	1 set
C24780	CultureWell™ multiwell chambered coverslip CWCS 50R-1.0 *24 mm x 50 mm coverslips, fifty 1 mm-deep wells per coverslip* *set of 20*	1 set
F36924	FluoCells® prepared slide #1 *BPAE cells with MitoTracker® Red CMXRos, Alexa Fluor® 488 phalloidin, DAPI*	each
F14781	FluoCells® prepared slide #2 *BPAE cells with mouse anti- α -tubulin, BODIPY® FL goat anti-mouse IgG, Texas Red®-X phalloidin, DAPI*	each
F24630	FluoCells® prepared slide #3 *mouse kidney section with Alexa Fluor® 488 WGA, Alexa Fluor® 568 phalloidin, DAPI*	each
F24631	FluoCells® prepared slide #4 *mouse intestine section with Alexa Fluor® 350 WGA, Alexa Fluor® 568 phalloidin, SYTOX® Green*	each
F36925	FluoCells® prepared slide #6 *muntjac cells with mouse anti-OxPhos Complex V inhibitor protein, Alexa Fluor® 555 goat anti-mouse IgG, Alexa Fluor® 488 phalloidin, TO-PRO®-3*	each
F36915	fluorescein *NIST-traceable standard* *nominal concentration 50 μ M* *special packaging*	5 x 1 mL
F36905	FocalCheck™ DoubleGreen Fluorescent Microspheres Kit, 6 μ m *mounted on slides*	1 kit
F36906	FocalCheck™ DoubleOrange Fluorescent Microspheres Kit, 6 μ m *mounted on slides*	1 kit
F36909	FocalCheck™ fluorescence microscope test slide #1 *for alignment, intensity, and calibration*	each
F36913	FocalCheck™ fluorescence microscope test slide #2 *for spectral imaging systems*	each
F36914	FocalCheck™ fluorescence microscope test slide #3 *5 colors, high and low intensities*	each
F24633	FocalCheck™ Fluorescent Microspheres Kit, 6 μ m *mounted on slides*	1 kit
F24634	FocalCheck™ Fluorescent Microspheres Kit, 15 μ m *mounted on slides*	1 kit
F14807	FocalCheck™ microspheres, 6 μ m, fluorescent dark-red ring stain/green throughout	0.5 mL
F14808	FocalCheck™ microspheres, 6 μ m, fluorescent green ring stain/blue throughout	0.5 mL
F14806	FocalCheck™ microspheres, 6 μ m, fluorescent green/orange/dark-red ring stains	0.5 mL
F7234	FocalCheck™ microspheres, 15 μ m, fluorescent blue/orange ring stains	0.5 mL
F7239	FocalCheck™ microspheres, 15 μ m, fluorescent dark-red ring stain/green throughout	0.5 mL

PRODUCT LIST 23.1 FLUORESCENCE MICROSCOPY ACCESSORIES AND REFERENCE STANDARDS—*continued*

Cat. No.	Product	Quantity
F7237	FocalCheck™ microspheres, 15 µm, fluorescent green ring stain/blue throughout	0.5 mL
F7238	FocalCheck™ microspheres, 15 µm, fluorescent green ring stain/dark red throughout	0.5 mL
F7240	FocalCheck™ microspheres, 15 µm, fluorescent green/dark-red ring stains	0.5 mL
F7235	FocalCheck™ microspheres, 15 µm, fluorescent green/orange/dark-red ring stains	0.5 mL
F7236	FocalCheck™ microspheres, 15 µm, fluorescent orange ring stain/blue throughout	0.5 mL
F14791	FocalCheck™ Thin-Ring Fluorescent Microspheres Kit, 1.0 µm *three suspensions*	1 kit
H18200	HybriSlip™ hybridization cover, 22 mm x 22 mm *RNase free* *set of 500*	1 set
H18201	HybriSlip™ hybridization cover, 40 mm x 22 mm *RNase free* *set of 500*	1 set
H18202	HybriSlip™ hybridization cover, 60 mm x 22 mm *RNase free* *set of 500*	1 set
H24720	HybriWell™ hybridization sealing system, 13 mm diameter chamber, 0.25 mm deep *set of 100*	1 set
H24721	HybriWell™ hybridization sealing system, 20 mm diameter chamber, 0.15 mm deep *set of 100*	1 set
H24723	HybriWell™ hybridization sealing system, 22 mm x 22 mm chamber, 0.15 mm deep *set of 100*	1 set
H18210	HybriWell™ hybridization sealing system, 40 mm x 21 mm chamber, 0.15 mm deep *set of 100*	1 set
H24722	HybriWell™ hybridization sealing system, 40 mm x 22 mm chamber, 0.25 mm deep *set of 100*	1 set
I36933	Image-iT® FX signal enhancer	10 mL
I7221	InSpeck™ Blue (350/440) Microscope Image Intensity Calibration Kit, 2.5 µm	1 kit
I7225	InSpeck™ Deep Red (633/660) Microscope Image Intensity Calibration Kit, 2.5 µm	1 kit
I7219	InSpeck™ Green (505/515) Microscope Image Intensity Calibration Kit, 2.5 µm	1 kit
I14785	InSpeck™ Green (505/515) Microscope Image Intensity Calibration Kit, 6 µm	1 kit
I7223	InSpeck™ Orange (540/560) Microscope Image Intensity Calibration Kit, 2.5 µm	1 kit
I14786	InSpeck™ Orange (540/560) Microscope Image Intensity Calibration Kit, 6 µm	1 kit
I7224	InSpeck™ Red (580/605) Microscope Image Intensity Calibration Kit, 2.5 µm	1 kit
I14787	InSpeck™ Red (580/605) Microscope Image Intensity Calibration Kit, 6 µm	1 kit
M7901	MultiSpeck™ Multispectral Fluorescence Microscopy Standards Kit *in suspension*	1 kit
O24751	ONCYTE® MultiWells, one well, 13 mm diameter, with slide and matching gasket *set of 20*	1 set
O24750	ONCYTE® MultiWells, 12 wells, 5 mm diameter, with slide and matching gasket *set of 20*	1 set
O14804	O-rings for Attofluor cell chamber, set of 10	each
P18174	Press-to-Seal silicone isolator, one well, 20 mm diameter, 0.5 mm deep *set of 50*	1 set
P18175	Press-to-Seal silicone isolator, one well, 20 mm diameter, 1.0 mm deep *set of 50*	1 set
P24743	Press-to-Seal silicone isolator with adhesive, eight wells, 9 mm diameter, 0.5 mm deep *set of 25*	1 set
P24744	Press-to-Seal silicone isolator with adhesive, eight wells, 9 mm diameter, 1.0 mm deep *set of 25*	1 set
P24740	Press-to-Seal silicone isolator with adhesive, one well, 20 mm diameter, 0.5 mm deep *set of 50*	1 set
P24741	Press-to-Seal silicone isolator with adhesive, one well, 20 mm diameter, 1.0 mm deep *set of 50*	1 set
P24742	Press-to-Seal silicone isolator with adhesive, 24 wells, 2.5 mm diameter, 2.0 mm deep *set of 25*	1 set
P24745	Press-to-Seal silicone sheet with adhesive, 13 cm x 18 cm, 0.5 mm thick *set of 5*	1 set
P18178	Press-to-Seal silicone sheet, 13 cm x 18 cm, 0.5 mm thick *set of 5*	1 set
P18179	Press-to-Seal silicone sheet, 13 cm x 18 cm, 1.0 mm thick *set of 5*	1 set
P7481	ProLong® Antifade Kit	1 kit
P36930	ProLong® Gold antifade reagent	10 mL
P36934	ProLong® Gold antifade reagent *special packaging*	5 x 2 mL
P36931	ProLong® Gold antifade reagent with DAPI	10 mL
P36935	ProLong® Gold antifade reagent with DAPI *special packaging*	5 x 2 mL
P37002	ProPlate™ adhesive seal-strips *set of 50 seal-strips and one applicator*	1 set
P37001	ProPlate™ multi-array slide module *set of 2*	1 set
P37004	ProPlate™ multi-array system *includes four 16-well slide modules, one tray and cover, ten seal-strips and one applicator*	1 set
P37003	ProPlate™ tray and cover *includes one tray and cover*	1 set
P7220	PS-Speck™ Microscope Point Source Kit *blue, green, orange and deep red fluorescent beads*	1 kit
Q10336	Qmount® Qdot® mounting media	3 x 2 mL
R14782	Reference Dye Sampler Kit *five 1 mM solutions, 1 mL each*	1 kit
S24732	Secure-Seal™ hybridization chamber gasket, eight chambers, 9 mm diameter, 0.8 mm deep *set of 20*	1 set
S24733	Secure-Seal™ hybridization chamber gasket, eight chambers, 9 mm diameter, 1.3 mm deep *set of 20*	1 set
S24730	Secure-Seal™ hybridization chamber gasket, one chamber, 20 mm diameter, 0.8 mm deep *set of 40*	1 set
S24731	Secure-Seal™ hybridization chamber gasket, one chamber, 20 mm diameter, 1.3 mm deep *set of 40*	1 set
S24734	Secure-Seal™ hybridization chamber gasket, one chamber, 22 mm x 22 mm, 0.8 mm deep *set of 50*	1 set
S24737	Secure-Seal™ spacer, eight wells, 9 mm diameter, 0.12 mm deep *set of 100*	1 set

23.2 Flow Cytometry Reference Standards

Flow cytometers are designed to perform quantitative measurements on individual cells and other particles with speed, accuracy and precision. As with all high-performance instrumentation, flow cytometers must be calibrated frequently to ensure accuracy and reliability. The stability, uniformity and reproducibility of our fluorescent microsphere products make them ideal reference standards for flow cytometry. However, because of the high variability in quantum yields of bound dyes and the heterogeneity of protein labeling, as well as problems with stoichiometry and accessibility in binding to targets, bead standards containing a known number of fluorophores per bead do not necessarily provide accurate information about the number of ligands bound to a cell.¹⁻⁴

AlignFlow™ and AlignFlow™ Plus Flow Cytometry Alignment Beads

In order to ensure accurate and reproducible quantitative results, flow cytometers should be checked at least daily for proper performance. AlignFlow™ and AlignFlow™ Plus flow cytometry alignment beads permit the calibration of a flow cytometer's laser(s), optics and stream flow without wasting valuable and sensitive experimental material.⁵⁻⁷ These fluorescently stained polystyrene microspheres are highly uniform with respect to both size and fluorescence intensity, and they are designed to approximately replicate the size, emission wavelength and intensity of biological samples. Because the dyes are contained inside the microsphere's matrix instead of on the surface, AlignFlow™ beads have excellent photochemical and physical stability, providing reliable reference signals for aligning, focusing and calibrating flow cytometers. The fluorescent dyes have been carefully selected for optimal excitation by laser sources commonly used in flow cytometry.

The 2.5 µm AlignFlow™ flow cytometry alignment beads are available in four versions: for UV (350–370 nm) excitation (A7304), for 488 nm excitation (A7302), for 633 nm excitation (A7312) and for 630–660 nm excitation (A14835); the 6 µm AlignFlow™ Plus beads are available for the same four excitation-wavelength ranges: for UV (350–370 nm) excitation (A7305), for 488 nm excitation (A7303), for 633 nm excitation (A7313)

Figure 23.2.1 AlignFlow™ Plus (A7303) flow cytometry alignment beads excited at 488 nm by an argon-ion laser and monitored in three emission channels. The broad fluorescence emission is detected in all three channels. Note the exceptionally small variation of fluorescence intensity of the beads. Contributed by Carleton Stewart, Roswell Park Cancer Institute.

and for 630–660 nm excitation (A14836). The UV light-excitable beads emit from 400 nm to 470 nm, the 488 nm light-excitable beads emit broadly from 515 nm to 660 nm (Figure 23.2.1), the 633 nm light-excitable beads emit from 645 nm to 680 nm, and the 630–660 nm light-excitable beads emit from 670 nm to 720 nm. The AlignFlow™ and AlignFlow™ Plus flow cytometry alignment beads are supplied as suspensions packaged in dropper vials for convenient dispensation.

LinearFlow™ Flow Cytometry Intensity Calibration Kits

LinearFlow™ Flow Cytometry Intensity Calibration Kits provide flow cytometer operators with intensity references for generating calibration curves, establishing photomultiplier settings and evaluating sample brightness.⁸⁻¹⁰ Each kit contains fluorescent microspheres in which the degree of staining has been carefully controlled to provide precisely determined intensity levels when excited in a flow cytometer (Figure 23.2.2). The microspheres are supplied as suspensions packaged in dropper vials for convenient dispensation. The LinearFlow™ Flow Cytometry Intensity Calibration Kits are available in two different bead sizes (2.5 µm or 6 µm) and five different fluorescent colors covering the spectral ranges commonly encountered in flow cytometry:

- Blue (for UV excitation/430 nm emission). Available in 2.5 µm (L14812) and 6 µm (L14813) sizes; both kits contain microspheres stained at 100%, 20%, 4.0% and 0.8% relative fluorescence intensity levels.
- Green (for 488 nm excitation/515 emission). Available in 2.5 µm (L14821) and 6 µm (L14822) sizes; both kits contain microspheres stained at 100%, 10%, 2.0%, 0.4%, 0.1% and 0.02% relative fluorescence intensity levels. The LinearFlow™ Green Flow Cytometry Low-Intensity Calibration Kits contain 2.5 µm (L14823) or 6 µm (L14824) diameter beads stained at 0.1%, 0.02%, 0.004% and 0.001% relative fluorescence intensity levels. The fluorescence from the beads with the lowest intensity level is approximately half that of the autofluorescence typically observed from unstained cells.
- Orange (for 488 nm excitation/575 nm emission). Available in 2.5 µm (L14814) and 6 µm (L14815) sizes; both kits contain microspheres stained at 100%, 10%, 2.0%, 0.4%, 0.1% and 0.02% relative fluorescence intensity levels.
- Carmine (for 488 nm excitation/620 nm emission). Available in 2.5 µm (L14816) and 6 µm (L14817) sizes; both kits contain microspheres stained at 100%, 10%, 2.0%, 0.4%, 0.1% and 0.02% relative fluorescence intensity levels.
- Deep Red (for 633 nm excitation/660 nm emission). Available in 2.5 µm (L14818) and 6 µm (L14819, Figure 23.2.2) sizes; both kits contain microspheres stained at 100%, 20%, 4.0%, 0.8%, 0.2% and 0.04% relative fluorescence intensity levels.

The 365/430 nm fluorescence excitation/emission maxima of the microspheres in the LinearFlow™ Blue Kits provide a close spectral match to samples stained with DAPI, Hoechst 33258 or Hoechst 33342 nucleic acid stains. These kits are ideal for intensity calibration of flow cytometers equipped with UV laser excitation. The microspheres in the

LinearFlow™ Green Kits are designed for calibrating the green (FL1) detection channel. Although the microspheres actually have an excitation maximum of ~505 nm, they are effectively excited by the 488 nm spectral line of the argon-ion laser. Their emission maximum of ~515 nm closely matches that of samples labeled with fluorescein, Oregon Green® 488 or Alexa Fluor® 488 dyes or with SYTOX® Green nucleic acid stain. Microspheres in the LinearFlow™ Orange Kit are spectrally similar to phycoerythrin and tetramethylrhodamine conjugates, making this kit useful for calibrating the orange (FL2) channel. Although these microspheres actually have an excitation maximum of ~570 nm, they are effectively excited by the 488 nm spectral line of the argon-ion laser. Microspheres in the LinearFlow™ Carmine Kit exhibit excitation and emission spectra similar to the spectra of the propidium iodide complex with DNA or the spectra of Texas Red® or Alexa Fluor® 594 dyes and are suitable for calibrating the red (FL3) channel. The microspheres in the LinearFlow™ Carmine Kit have an excitation maximum of ~580 nm, but they can also be excited by the 488 nm spectral line of the argon-ion laser. The microspheres in the LinearFlow™ Deep Red Kit have maximal emission at ~660 nm, closely matching that of Alexa Fluor® 647 dye, Cy®5 dye and allophycocyanin, and they are useful for calibrating flow cytometers equipped with 633 nm He-Ne laser excitation. Although primarily intended for 633 nm excitation, the LinearFlow™ Deep Red microspheres can be adequately excited at 488 nm and will provide accurate relative intensity readings with this excitation.

Figure 23.2 Fluorescence intensity histogram of the six different 6 µm polystyrene bead samples supplied in the LinearFlow™ Deep Red Flow Cytometry Intensity Calibration Kit (L14819). Fluorescence measurements were performed with a flow cytometer using excitation at 633 nm. This histogram is a composite of two graphs; the same mixture of microspheres was sampled and analyzed using two distinct PMT voltage settings in order to cover the full intensity range.

PeakFlow™ Flow Cytometry Reference Beads

PeakFlow™ flow cytometry reference beads are stained with fluorescent dyes that have been carefully selected to produce emission peaks coincident with labeled cells used in typical flow cytometry applications. The emission profiles for these standards are intentionally narrow in comparison to fluorescein-labeled cells (Figure 23.2.3). Consequently, PeakFlow™ beads serve as reference sources with emissions centered upon the expected fluorescence of the experimental sample. Because PeakFlow™ beads are highly uniform with respect to both size and fluorescence intensity, and because they approximate the size, emission wavelength and intensity of many biological samples, they can be used to calibrate a flow cytometer's laser source, optics, stream flow and cell sorting system without wasting valuable and sensitive experimental material. Furthermore, due to their narrow emission profiles, PeakFlow™ beads of two different fluorescent colors exhibit minimal spectral overlap, and little or no color compensation is needed when setting up for multicolor experiments.

As with all of our flow cytometry standard microspheres, PeakFlow™ beads are stained internally rather than on the surface. The dyes are therefore insulated from environmental interactions that could cause variable fluorescence output, resulting in excellent signal stability. These fluorescent polystyrene microspheres are supplied as suspensions packaged in dropper vials for convenient dispensation, with a choice of seven fluorescent colors and, for most products, two different sizes (Table 23.7).

Figure 23.3 Normalized emission spectra of PeakFlow™ Green flow cytometry reference beads (P14827, solid line) and fluorescein-labeled cells (dashed line). The narrow emission spectrum of PeakFlow™ beads is approximately centered on the broader emission spectrum of fluorescein.

Table 23.7 Spectral characteristics of PeakFlow™ flow cytometry reference beads.

Cat. No.	Size (µm)	Nominal Color	Abs* (nm)	Em* (nm)	Emission Matches Cells Stained with:

* Approximate absorption and emission maxima for beads in suspension. † Suitable for excitation by the UV (351–364 nm) spectral line of argon-ion lasers. ‡ Suitable for excitation by the 488 nm spectral line of argon-ion lasers. § Suitable for excitation by the 633 nm spectral line of He-Ne lasers.

AbC™ and ArC™ Bead Kits for Flow Cytometry Compensation

AbC™ Anti-Mouse and AbC™ Anti-Rat/Hamster Bead Kits

The AbC™ Anti-Mouse Bead Kit (A10344) provides a consistent, accurate and simple-to-use technique for the setting of flow cytometry compensation when using fluorophore-conjugated mouse antibodies. The kit contains two types of specially modified polystyrene microspheres, the AbC™ capture beads, that bind all isotypes of mouse immunoglobulin, and the negative beads that have no antibody binding capacity. After incubation with a fluorophore-conjugated mouse antibody, the two bead components provide distinct positive and negative populations of beads that can be used to set compensation (Figure 23.2.4). Because of the consistent nature of bead scatter and high surface antibody-binding capacity, more consistent and accurate compensation settings for any combination of fluorophore-labeled mouse antibodies can be achieved. The AbC™ Anti-Rat/Hamster Bead Kit (A10389) provides parallel functionality for protocols using fluorophore-labeled rat or hamster antibodies. The AbC™ capture beads and negative beads have a diameter of approximately 6 μm (actual size for each lot is listed on the component vial). The bead suspensions are supplied in dropper vials for convenient sample application.

ArC™ Amine-Reactive Compensation Bead Kit

The ArC™ Amine-Reactive Compensation Bead Kit (A10346) provides a consistent, accurate and simple-to-use technique for the setting of flow cytometry compensation when using any of the LIVE/DEAD® fixable dead cell stains. The LIVE/DEAD® Fixable Dead Cell Stain Kits (Section 15.3) use an amine-reactive dye labeling method to evaluate the viability of mammalian cells by flow cytometry.¹¹ The ArC™ Amine-Reactive Compensation Bead Kit includes two types of specially modified polystyrene microspheres to allow easy compensation of the LIVE/DEAD® fixable stains: the ArC™ reactive beads (Component A), which bind any of the amine-reactive dyes, and the ArC™ negative beads (Component B), which have no reactivity. After incubation with any amine-reactive dye, the two kit components provide distinct positive and negative populations of beads that can be used to set compensation.

Flow Cytometry Size Calibration Kit

The Flow Cytometry Size Calibration Kit (F13838) provides non-fluorescent particle-size calibration standards for use in forward light scattering measurements of cell size by flow cytometry.^{12,13} This kit contains suspensions of six different nonfluorescent microspheres packaged in convenient dropper vials. The individual standards contain highly uniform polystyrene microspheres with nominal diameters of 1.0 μm , 2.0 μm , 4.0 μm , 6 μm , 10 μm and 15 μm .

CountBright™ Absolute Counting Beads

Flow cytometry provides a rapid method for quantitating cell characteristics; however, most flow cytometers cannot directly provide the cell concentration or absolute count of cells in a sample. Absolute cell counts have been widely used in quantitating cell populations and disease progression^{14–18} and are generally obtained either by combining a separate cell concentration determination from a hematology analyzer with flow cytometry population data (multiple-platform testing) or by adding an internal microsphere counting standard to the flow cytometry sample (single-platform testing). The single-platform method is preferred as it is technically less complicated and more accurate than multiple-platform testing.¹⁹ To facilitate this single-platform method, we offer CountBright™ absolute counting beads (C36950), a calibrated suspension of microspheres that are brightly fluorescent across a wide range of excitation and emission wavelengths and contain a known concentration of microspheres. For absolute counts, a specific volume of the CountBright™ microsphere suspension is added to a specific volume of sample, such that the ratio of sample volume to microsphere volume is known.²⁰ The volume of sample analyzed can be calculated from the number of microsphere events and then used with cell events to determine cell concentration. In general, at least 1000 bead events should be acquired to assure a statistically significant determination of sample volume. Sufficient reagents are provided for 100 flow cytometry assays, each using 50 μL of counting beads per test.

CountBright™ absolute counting beads are broadly fluorescent and can be used with either a fluorescence or scatter threshold. Fluorescence can be excited by wavelengths from UV to 635 nm; fluorescence

Figure 23.2.4 Compensation using the AbC™ Anti-Mouse Bead Kit (A10344). (A) R-Phycoerythrin (R-PE)-conjugated mouse anti-human CD56 antibodies (MHCD56044) label the AbC™ capture beads for a positive signal, and negative beads provide a negative signal. (B) FITC-conjugated mouse anti-human CD3 antibodies (MHCD03014) label the AbC™ capture beads for a positive signal, and negative beads provide a negative signal. (C) Dual-parameter plot showing gated human lymphocytes labeled with R-PE-conjugated mouse anti-human CD56 and FITC-conjugated mouse anti-human CD3 antibodies using compensation settings obtained with the AbC™ Anti-Mouse Bead Kit.

emission can be read between 385 nm and 800 nm. The fluorescence intensity of the microspheres has been adjusted to be about 5–50 times brighter than the anticipated intensities of typically stained cells. When using a scatter threshold, the microsphere signal should be above the threshold. The microspheres can be gated by a single parameter, but a combination of parameters can be used to resolve microspheres from cells and other events.

CountBright™ absolute counting beads can be used with any sample type, including no-wash/lysed whole blood. The microspheres in the reagents are approximately 7 µm in diameter and have sedimentation properties similar to lymphocytes. The accuracy of cell counts based on CountBright™ absolute counting beads depends on sample handling and the precise delivery of the volume of beads. The CountBright™ absolute counting beads must be mixed well to assure a uniform suspension of microspheres. After vortexing for 30 seconds, the microsphere suspension can be pipetted by standard techniques; however, more viscous solutions such as blood require reverse pipetting for accurate volume delivery. Cell suspensions may be diluted but should be assayed without wash steps. Other sample preparation steps that can lead to cell or microsphere loss should also be avoided. For antibody protocols, CountBright™ absolute counting beads should be used with reagents titrated for no-wash staining.
