Introduction to Fluorescence Techniques

Fluorescent probes enable researchers to detect particular components of complex biomolecular assemblies, such as live cells, with exquisite sensitivity and selectivity. The purpose of this introduction is to briefly outline fluorescence principles and techniques for newcomers to the field.

The Fluorescence Process

Fluorescence is the result of a three-stage process that occurs in certain molecules (generally polyaromatic hydrocarbons or heterocycles) called fluorophores or fluorescent dyes. A fluorescent probe is a fluorophore designed to respond to a specific stimulus or to localize within a specific region of a biological specimen. The process responsible for the fluorescence of fluorescent probes and other fluorophores is illustrated by the simple electronic-state diagram (Jablonski diagram) shown in Figure 1.

Stage 1: Excitation

A photon of energy $h\nu_{EX}$ is supplied by an external source such as an incandescent lamp or a laser and absorbed by the fluorophore, creating an excited electronic singlet state (S_1'). This process distinguishes fluorescence from chemiluminescence, in which the excited state is populated by a chemical reaction.

Stage 2: Excited-State Lifetime

The excited state exists for a finite time (typically 1–10 nanoseconds). During this time, the fluorophore undergoes conformational changes and is also subject to a multitude of possible interactions with its molecular environment. These processes have two important consequences. First, the energy of S_1' is partially dissipated, yielding a relaxed singlet excited state (S_1) from which fluorescence emission originates. Second, not all the molecules initially excited by absorption (Stage 1) return to the ground state (S_0) by fluorescence emission. Other processes such as collisional quenching, fluorescence resonance energy transfer (FRET) (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2) and intersystem crossing may also depopulate S_1 . The fluorescence

quantum yield, which is the ratio of the number of fluorescence photons emitted (Stage 3) to the number of photons absorbed (Stage 1), is a measure of the relative extent to which these processes occur.

Stage 3: Fluorescence Emission

A photon of energy $h\nu_{EM}$ is emitted, returning the fluorophore to its ground state S_0 . Due to energy dissipation during the excited-state lifetime, the energy of this photon is lower, and therefore of longer wavelength, than the excitation photon $h\nu_{EX}$. The difference in energy or wavelength represented by $(h\nu_{EX} - h\nu_{EM})$ is called the Stokes shift. The Stokes shift is fundamental to the sensitivity of fluorescence techniques because it allows emission photons to be detected against a low background, isolated from excitation photons. In contrast, absorption spectrophotometry requires measurement of transmitted light relative to high incident light levels at the same wavelength.

Fluorescence Spectra

The entire fluorescence process is cyclical. Unless the fluorophore is irreversibly destroyed in the excited state (an important phenomenon known as photobleaching), the same fluorophore can be repeatedly excited and detected. The fact that a single fluorophore can generate many thousands of detectable photons is fundamental to the high sensitivity of fluorescence detection techniques. For polyatomic molecules in solution, the discrete electronic transitions represented by $h\nu_{EX}$ and $h\nu_{EM}$ in Figure 1 are replaced by rather broad energy spectra called the fluorescence excitation spectrum and fluorescence emission spectrum, respectively (Table 1). The bandwidths of these spectra are parameters of particular importance for applications in which two or more different fluorophores are simultaneously detected. The fluorescence excitation spectrum of a single fluorophore species in dilute solution is usually identical to its absorption spectrum. The absorption spectrum can therefore be used as a surrogate excitation spectrum data set. Under the same conditions, the fluorescence emission spectrum is independent of the excitation wavelength, due to the partial dissipation of excitation energy during the excited-state lifetime, as illustrated in Figure 1. The emission intensity is proportional to the amplitude of the fluorescence excitation spectrum at the excitation wavelength (Figure 2).

Figure 1 Jablonski diagram illustrating the processes involved in the creation of an excited electronic singlet state by optical absorption and subsequent emission of fluorescence. The labeled stages 1, 2 and 3 are explained in the adjoining text.

Figure 2 Excitation of a fluorophore at three different wavelengths (EX 1, EX 2, EX 3) does not change the emission profile but does produce variations in fluorescence emission intensity (EM 1, EM 2, EM 3) that correspond to the amplitude of the excitation spectrum.

Fluorescence Detection

Fluorescence Instrumentation

Four essential elements of fluorescence detection systems can be identified from the preceding discussion: 1) an excitation source, 2) a fluorophore, 3) wavelength filters to isolate emission photons from excitation photons, 4) a detector that registers emission photons and produces a recordable output, usually as an electrical signal. Regardless of the application, compatibility of these four elements is essential for optimizing fluorescence detection.

Fluorescence instruments are primarily of four types, each providing distinctly different information:

- Spectrofluorometers and microplate readers measure the *average* properties of bulk (μL to mL) samples.
- Fluorescence microscopes resolve fluorescence as a function of spatial coordinates in two or three dimensions for microscopic objects (less than ~ 0.1 mm diameter).
- Fluorescence scanners, including microarray readers, resolve fluorescence as a function of spatial coordinates in two dimensions for macroscopic objects such as electrophoresis gels, blots and chromatograms.
- Flow cytometers measure fluorescence per cell in a flowing stream, allowing subpopulations within a large sample to be identified and quantitated.

Other types of instrumentation that use fluorescence detection include capillary electrophoresis apparatus, DNA sequencers¹ and microfluidic devices.^{2,3} Each type of instrument produces different

measurement artifacts and makes different demands on the fluorescent probe. For example, although photobleaching is often a significant problem in fluorescence microscopy, it is not a major impediment in flow cytometry because the dwell time of individual cells in the excitation beam is short.

Fluorescence Signals

Fluorescence intensity is quantitatively dependent on the same parameters as absorbance—defined by the Beer–Lambert law as the product of the molar extinction coefficient, optical path length and solute concentration—as well as on the fluorescence quantum yield of the dye and the excitation source intensity and fluorescence collection efficiency of the instrument (Table 1). In dilute solutions or suspensions, fluorescence intensity is linearly proportional to these parameters. When sample absorbance exceeds about 0.05 in a 1 cm pathlength, the relationship becomes nonlinear and measurements may be distorted by artifacts such as self-absorption and the inner-filter effect.^{4,5}

Because fluorescence quantitation is dependent on the instrument, fluorescent reference standards are essential for calibrating measurements made at different times or using different instrument configurations.^{6–8} To meet these requirements, we offer high-precision fluorescent microsphere reference standards for fluorescence microscopy and flow cytometry and a set of ready-made fluorescent standard solutions for spectrofluorometry (Section 23.1, Section 23.2).

A spectrofluorometer is extremely flexible, providing continuous ranges of excitation and emission wavelengths. Laser-scanning microscopes and flow cytometers, however, require probes that are excitable at a single fixed wavelength. In contemporary instruments, the excitation source is usually the 488 nm spectral line of the argon-ion laser. As

Table 1 Spectroscopic properties of fluorescent dyes.

Property	Definition	Significance
Fluorescence excitation spectrum*	An X,Y plot of excitation wavelength versus number of fluorescence photons generated by a fluorophore.	Optimum instrument setup should deliver excitation light as close to the peak of the excitation spectrum of the fluorophore as possible.
Absorption spectrum	An X,Y plot of wavelength versus absorbance of a chromophore or fluorophore.	To a first approximation, the absorption spectrum of a fluorophore is equivalent to the fluorescence excitation spectrum.† To the extent that this approximation holds, the absorption spectrum can be used as a surrogate for the fluorescence excitation spectrum.
Fluorescence emission spectrum*	An X,Y plot of emission wavelength versus number of fluorescence photons generated by a fluorophore.	Fluorescence emission spectral discrimination is the most straightforward basis for multiplex detection‡ and for resolving probe fluorescence from background autofluorescence.
Extinction coefficient (EC)	Capacity for light absorption at a specific wavelength.§	Fluorescence output per fluorophore (“brightness”) is proportional to the product of the extinction coefficient (at the relevant excitation wavelength) and the fluorescence quantum yield.
Fluorescence quantum yield (QY)	Number of fluorescence photons emitted per excitation photon absorbed.	See “Extinction coefficient.”
Quenching	Loss of fluorescence signal due to short-range interactions between the fluorophore and the local molecular environment, including other fluorophores (self-quenching).	Loss of fluorescence is reversible to the extent that the causative molecular interactions can be controlled.**
Photobleaching	Destruction of the excited fluorophore due to photosensitized generation of reactive oxygen species (ROS), particularly singlet oxygen ($^1\text{O}_2$).	Loss of fluorescence signal is irreversible if the bleached fluorophore population is not replenished (e.g., via diffusion). Extent of photobleaching is dependent on the duration and intensity of exposure to excitation light.

* Our online Fluorescence SpectraViewer (www.invitrogen.com/handbook/spectraviewer) provides an interactive utility for plotting and comparing fluorescence excitation and emission spectra for over 250 fluorophores (Using the Fluorescence SpectraViewer—Note 23.1).

† Generally true for single fluorophore species in homogeneous solutions but not in more complex heterogeneous samples.

‡ Multiplex detection refers to the process of simultaneously labeling a specimen with two or more fluorescent probes to allow correlation of multiple structural or functional features. As well as specific association with their targets, the probes must have distinctive spectroscopic properties that can be discriminated by the detection instrument.

§ EC (units: $\text{cm}^{-1} \text{M}^{-1}$) is defined by the Beer-Lambert law $A = \text{EC} \cdot c \cdot l$, where A = absorbance, c = molar concentration, l = optical pathlength. EC values at the absorption maximum wavelength are listed in the Section Data Tables throughout *The Molecular Probes® Handbook*.

** In the case of self-quenching, this can be accomplished by disruption of fluorophore compartmentalization, denaturation or fragmentation of biopolymer conjugates, or functionalization of the fluorophore to produce increased electrostatic repulsion and water solubility.

shown in Figure 3, separation of the fluorescence emission signal (S1) from Rayleigh-scattered excitation light (EX) is facilitated by a large fluorescence Stokes shift (i.e., separation of A1 and E1). Biological samples labeled with fluorescent probes typically contain more than one fluorescent species, making signal-isolation issues more complex. Additional optical signals, represented in Figure 3 as S2, may be due to background fluorescence or to a second fluorescent probe.

Background Fluorescence

Fluorescence detection sensitivity is severely compromised by background signals, which may originate from endogenous sample constituents (referred to as autofluorescence) or from unbound or nonspecifically bound probes (referred to as reagent background). Detection of autofluorescence can be minimized either by selecting filters that reduce the transmission of E2 relative to E1 or by selecting probes that absorb and emit at longer wavelengths. Although narrowing the fluorescence detection bandwidth increases the resolution of E1 and E2, it also compromises the overall fluorescence intensity detected. Signal distortion caused by autofluorescence of cells, tissues and biological fluids is most readily minimized by using probes that can be excited at >500 nm. Furthermore, at longer wavelengths, light scattering by dense media such as tissues is much reduced, resulting in greater penetration of the excitation light.⁹

Multicolor Labeling Experiments

A multicolor labeling experiment entails the deliberate introduction of two or more probes to simultaneously monitor different biochemical functions. This technique has major applications in flow cytometry,^{10–12} DNA sequencing,¹ fluorescence *in situ* hybridization^{13,14} and fluorescence microscopy.^{15–17} Signal isolation and data analysis are facilitated by maximizing the spectral separation of the multiple emissions (E1 and E2 in Figure 3). Consequently, fluorophores with narrow emission spectral bandwidths, such as BODIPY® dyes (Section 1.4) and Qdot® nanocrystals (Section 6.6), are particularly useful in multicolor applications. An ideal combination of dyes for multicolor labeling would exhibit strong absorption at a coincident excitation wavelength and well-separated emission spectra (Figure 3). Unfortunately, it is not easy to find single dyes with the requisite combination of a large extinction coefficient for absorption and a large Stokes shift. Qdot® nanocrystals (Section 6.6) and phycobiliprotein tandem conjugates (Section 6.4)

Figure 3 Fluorescence detection of mixed species. Excitation (EX) in overlapping absorption bands A1 and A2 produces two fluorescent species with spectra E1 and E2. Optical filters isolate quantitative emission signals S1 and S2.

have been developed to meet these requirements and have proven effective in multicolor labeling experiments.^{11,18,19}

Ratiometric Measurements

In some cases—for example the Ca^{2+} indicators fura-2 and indo-1 (Section 19.2) and the pH indicators BCECF and SNARF® (Section 20.2)—the free and ion-bound forms of fluorescent ion indicators have different emission or excitation spectra. With this type of indicator, the ratio of the optical signals (S1 and S2 in Figure 3) can be used to monitor the association equilibrium and to calculate ion concentrations. Ratiometric measurements eliminate distortions of data caused by photobleaching and variations in probe loading and retention, as well as by instrumental factors such as illumination stability.^{20,21} (Loading and Calibration of Intracellular Ion Indicators—Note 19.1).

Fluorescence Output of Fluorophores

Comparing Different Dyes

Fluorophores currently used as fluorescent probes offer sufficient permutations of wavelength range, Stokes shift and spectral bandwidth to meet requirements imposed by instrumentation (e.g., 488 nm excitation), while allowing flexibility in the design of multicolor labeling experiments. Our online Fluorescence SpectraViewer (www.invitrogen.com/handbook/spectraviewer) provides an interactive utility for evaluating these factors during the experimental design process (Using the Fluorescence SpectraViewer—Note 23.1). The fluorescence output of a given dye depends on the efficiency with which it absorbs and emits photons, and its ability to undergo repeated excitation/emission cycles. Absorption and emission efficiencies are most usefully quantified in terms of the molar extinction coefficient (EC) for absorption and the quantum yield (QY) for fluorescence. Both are constants under specific environmental conditions. The value of EC is specified at a single wavelength (usually the absorption maximum), whereas QY is a measure of the total photon emission over the entire fluorescence spectral profile. Fluorescence intensity per dye molecule is proportional to the product of EC and QY (Table 1). The range of these parameters among organic dye and autofluorescent protein fluorophores is approximately 5000 to 200,000 $\text{cm}^{-1}\text{M}^{-1}$ for EC and 0.05 to 1.0 for QY. Phycobiliproteins such as R-phycoerythrin (Section 6.4) have multiple fluorophores on each protein and consequently have much larger extinction coefficients (on the order of $2 \times 10^6 \text{ cm}^{-1}\text{M}^{-1}$) than low molecular weight fluorophores. Qdot® nanocrystals have even larger extinction coefficients ($>2 \times 10^6 \text{ cm}^{-1}\text{M}^{-1}$), particularly in the blue visible and ultraviolet wavelength regions (Section 6.6).

Photobleaching

Under high-intensity illumination conditions, the irreversible destruction or photobleaching of the excited fluorophore becomes the primary factor limiting fluorescence detectability. The multiple photochemical reaction pathways responsible for photobleaching have been investigated and described in considerable detail.^{22–24} Some pathways include reactions between adjacent dye molecules, making the process considerably more complex in labeled biological specimens than in dilute solutions of free dye. In all cases, photobleaching originates from the triplet excited state, which is created from the singlet state (S₁, Figure 1) via an excited-state process called intersystem crossing.²⁵

The most effective remedy for photobleaching is to maximize detection sensitivity, which allows the excitation intensity to be

Figure 4 Comparison of photostability of green-fluorescent antibody conjugates. The following fluorescent goat anti-mouse IgG antibody conjugates were used to detect mouse anti-human IgG antibody labeling of human anti-nuclear antibodies in HEp-2 cells on prefixed test slides (INOVA Diagnostics Corp.): Alexa Fluor® 488 (A11001, ○), Oregon Green® 514 (O6383, ■), BODIPY® FL (B2752, △), Oregon Green® 488 (O6380, □) or fluorescein (F2761, ●). Samples were continuously illuminated and viewed on a fluorescence microscope using a fluorescein longpass filter set. Images were acquired every 5 seconds. For each conjugate, three data sets, representing different fields of view, were averaged and then normalized to the same initial fluorescence intensity value to facilitate comparison.

Figure 5 Photobleaching resistance of the green-fluorescent Alexa Fluor® 488, Oregon Green® 488 and fluorescein dyes, as determined by laser-scanning cytometry. EL4 cells were labeled with biotin-conjugated anti-CD44 antibody and detected by Alexa Fluor® 488 (S11223; S32354), Oregon Green® 488 (S6368) or fluorescein (S869) streptavidin. The cells were then fixed in 1% formaldehyde, washed and wet-mounted. After mounting, cells were scanned 10 times on a laser-scanning cytometer; laser power levels were 25 mW for the 488 nm spectral line of the argon-ion laser. Scan durations were approximately 5 minutes, and each repetition was started immediately after completion of the previous scan. Data are expressed as percentages derived from the mean fluorescence intensity (MFI) of each scan divided by the MFI of the first scan. Data contributed by Bill Telford, Experimental Transplantation and Immunology Branch, National Cancer Institute.

reduced. Detection sensitivity is enhanced by low-light detection devices such as CCD cameras, as well as by high-numerical aperture objectives and the widest bandpass emission filters compatible with satisfactory signal isolation. Alternatively, a less photolabile fluorophore may be substituted in the experiment.²⁶ Alexa Fluor® 488 dye is an important fluorescein substitute that provides significantly greater photostability than fluorescein (Figure 4, Figure 5, Figure 6), yet is compatible with standard fluorescein optical filters. Antifade reagents such as *SlowFade*® and *ProLong*® reagents (Section 23.1) can also be applied to reduce photobleaching; however, they are usually incompatible with live cells. In general, it is difficult to predict the necessity for and effectiveness of such countermeasures because photobleaching rates are dependent to some extent on the fluorophore's environment.^{27–29}

Signal Amplification

The most straightforward way to enhance fluorescence signals is to increase the number of fluorophores available for detection.³⁰ Fluorescent signals can be amplified using 1) avidin–biotin or antibody–hapten secondary detection techniques, 2) enzyme-labeled secondary detection reagents in conjunction with fluorogenic substrates^{31–33} or 3) probes that contain multiple fluorophores such as phycobiliproteins or FluoSpheres® fluorescent microspheres. Our most sensitive reagents and methods for signal amplification are discussed in Chapter 6.

Simply increasing the probe concentration can be counterproductive and often produces marked changes in the probe's chemical and optical characteristics. It is important to note that the effective intracellular concentration of probes loaded by bulk permeabilization methods (Loading and Calibration of Intracellular Ion Indicators—Note 19.1) is usually much higher (>10-fold) than the extracellular incubation concentration. Also, increased labeling of proteins or membranes ultimately leads to precipitation of the protein or gross changes in membrane permeability. Antibodies labeled with more than four to six fluorophores per protein may exhibit reduced specificity and reduced binding affinity. Furthermore, at high degrees of substitution, the extra fluorescence obtained per added fluorophore typically decreases due to self-quenching (Figure 7).

Environmental Sensitivity of Fluorescence

Fluorescence spectra and quantum yields are generally more dependent on the environment than absorption spectra and extinction coefficients. For example, coupling a single fluorescein label to a protein typically reduces fluorescein's QY ~60% but only decreases its EC by ~10%. Interactions either between two adjacent fluorophores or between a fluorophore and other species in the surrounding environment can produce environment-sensitive fluorescence.

Figure 6 Comparison of the photobleaching rates of the Alexa Fluor® 488 and Alexa Fluor® 546 dyes and the well-known fluorescein and Cy®3 fluorophores. The cytoskeleton of bovine pulmonary artery endothelial cells (BPAEC) was labeled with (top series) Alexa Fluor® 488 phalloidin (A12379) and mouse monoclonal anti- α -tubulin antibody (A11126) in combination with Alexa Fluor® 546 goat anti-mouse IgG antibody (A11003) or (bottom series) fluorescein phalloidin (F432) and the anti- α -tubulin antibody in combination with a commercially available Cy®3 goat anti-mouse IgG antibody. The pseudocolored images were taken at 30-second intervals (0, 30, 90 and 210 seconds of exposure from left to right). The images were acquired with bandpass filter sets appropriate for fluorescein and rhodamine.

Fluorophore–Fluorophore Interactions

Fluorescence quenching can be defined as a bimolecular process that reduces the fluorescence quantum yield without changing the fluorescence emission spectrum (Table 1); it can result from transient excited-state interactions (collisional quenching) or from formation of nonfluorescent ground-state species. Self-quenching is the quenching of one fluorophore by another;³⁴ it therefore tends to occur when high loading concentrations or labeling densities are used (Figure 7, Figure 8). DQ™ substrates (Section 10.4) are heavily labeled and therefore highly quenched biopolymers that exhibit dramatic fluorescence enhancement upon enzymatic cleavage³⁵ (Figure 9).

Fluorescence resonance energy transfer (FRET) (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2) is a strongly distance-dependent excited-state interaction in which emission of one fluorophore is coupled to the excitation of another. Some excited fluorophores interact to form excimers, which are excited-state dimers that exhibit altered emission spectra. Excimer formation by the polyaromatic hydrocarbon pyrene is described in Section 13.2 (Figure 10).

Because they all depend on the interaction of adjacent fluorophores, self-quenching, FRET and excimer formation can be exploited for monitoring a wide array of molecular assembly or fragmentation processes such as membrane fusion (Assays of Volume Change, Membrane Fusion and Membrane Permeability—Note 14.3), nucleic acid hybridization, ligand–receptor binding and polypeptide hydrolysis.

Other Environmental Factors

Many other environmental factors exert influences on fluorescence properties. The three most common are:

- Solvent polarity (solvent in this context includes interior regions of cells, proteins, membranes and other biomolecular structures)
- Proximity and concentrations of quenching species
- pH of the aqueous medium

Fluorescence spectra may be strongly dependent on solvent. This characteristic is most often observed with fluorophores that have large excited-state dipole moments, resulting in fluorescence spectral shifts to longer wavelengths in polar solvents. Representative fluorophores include the aminonaphthalenes such as prodan, badan (Figure 11) and dansyl, which are effective probes of environmental polarity in, for example, a protein's interior.³⁶

Binding of a probe to its target can dramatically affect its fluorescence quantum yield (Monitoring Protein-Folding Processes with Environment-Sensitive Dyes—Note 9.1). Probes

Figure 7 Comparison of relative fluorescence as a function of the number of fluorophores attached per protein for goat anti-mouse IgG antibody conjugates prepared using Oregon Green® 514 carboxylic acid succinimidyl ester (O6139, ■), Oregon Green® 488 carboxylic acid succinimidyl ester (O6147, ●), fluorescein-5-EX succinimidyl ester (F6130, ○) and fluorescein isothiocyanate (FITC; F143, F1906, F1907; □). Conjugate fluorescence is determined by measuring the fluorescence quantum yield of the conjugated dye relative to that of the free dye and multiplying by the number of fluorophores per protein.

Figure 8 Comparison of the relative fluorescence of goat anti-mouse IgG antibody conjugates of Rhodamine Red™-X succinimidyl ester (R6160, ●) and Lissamine rhodamine B sulfonyl chloride (L20, L1908; ○). Conjugate fluorescence is determined by measuring the fluorescence quantum yield of the conjugated dye relative to that of the free dye and multiplying by the number of fluorophores per protein. Higher numbers of fluorophores attached per protein are attainable with Rhodamine Red™-X dye due to the lesser tendency of this dye to induce protein precipitation.

Figure 9 Principle of enzyme detection via the disruption of intramolecular self-quenching. Enzyme-catalyzed hydrolysis of the heavily labeled and almost totally quenched substrates provided in the EnzChek® Assay Kits relieves the intramolecular self-quenching, yielding brightly fluorescent reaction products.

Figure 10 Excimer formation by pyrene in ethanol. Spectra are normalized to the 371.5 nm peak of the monomer. All spectra are essentially identical below 400 nm after normalization. Spectra are as follows: 1) 2 mM pyrene, purged with argon to remove oxygen; 2) 2 mM pyrene, air-equilibrated; 3) 0.5 mM pyrene (argon-purged); and 4) 2 μM pyrene (argon-purged). The monomer-to-excimer ratio (371.5/470 nm) is dependent on both pyrene concentration and the excited-state lifetime, which is variable because of quenching by oxygen.

Figure 11 Fluorescence emission spectra of the 2-mercaptoethanol adduct of badan (B6057) in: 1) toluene, 2) chloroform, 3) acetonitrile, 4) ethanol, 5) methanol and 6) water. Each solution contains the same concentration of the adduct. Excitation of all samples is at 380 nm.

that have a high fluorescence quantum yield when bound to a particular target but are otherwise effectively nonfluorescent yield extremely low reagent background signals. The ultrasensitive SYBR[®], SYTO[®], PicoGreen[®], RiboGreen[®] and OliGreen[®] nucleic acid stains (Chapter 8) are prime examples of this strategy. Similarly, fluorogenic enzyme substrates, which are nonfluorescent or have only short-wavelength emission until they are converted to fluorescent products by enzymatic cleavage, allow sensitive detection of enzymatic activity (Chapter 10).

Extrinsic quenchers, the most ubiquitous of which are paramagnetic species such as O₂ and heavy atoms such as iodide, reduce fluorescence quantum yields in a concentration-dependent manner. If quenching is caused by collisional interactions, as is usually the case, information on the proximity of the fluorophore and quencher and their mutual diffusion rate can be derived. This quenching effect has been used productively to measure chloride-ion flux in cells (Section 21.2). Many fluorophores are also quenched by proteins. Examples are NBD, fluorescein and BODIPY[®] dyes, in which the effect is apparently due to charge-transfer interactions with aromatic amino acid residues.^{37,38} Consequently, antibodies raised against these fluorophores are effective and highly specific fluorescence quenchers³⁸ (Section 7.4).

Fluorophores such as BCECF and carboxy SNARF[®]-1 that have strongly pH-dependent absorption and fluorescence characteristics can be used as physiological pH indicators. Fluorescein and hydroxycoumarins (umbelliferones) are further examples of this type of fluorophore. Structurally, pH sensitivity is due to a reconfiguration of the fluorophore's π -electron system that occurs upon protonation. BODIPY[®] FL and Alexa Fluor[®] 488 fluorophores, both of which lack protolytically ionizable substituents, provide spectrally equivalent alternatives to fluorescein for applications requiring a pH-insensitive probe (Section 1.3, Section 1.4).

CHAPTER 1

Fluorophores and Their Amine-Reactive Derivatives

1.1 Introduction to Amine Modification	15
Common Applications for Amine-Reactive Probes	15
Labeling Biomolecules	15
Preparing the Optimal Bioconjugate	15
Derivatizing Low Molecular Weight Molecules	15
Reactivity of Amino Groups	19
Isothiocyanates	19
Active Esters and Carboxylic Acids	20
Succinimidyl Esters	20
Carboxylic Esters and Their Conversion into Sulfosuccinimidyl Esters and STP Esters	20
Tetrafluorophenyl (TFP) Esters	21
Sulfodichlorophenol (SDP) Esters	21
Carbonyl Azides	21
Sulfonyl Chlorides	21
Other Amine-Reactive Reagents	21
1.2 Kits for Labeling Proteins and Nucleic Acids	22
Kits for Labeling Proteins with a Fluorescent Dye	22
APEX® Antibody Labeling Kits	22
Alexa Fluor® Microscale Protein Labeling Kits	22
Monoclonal Antibody Labeling Kits	24
SAIVI™ Antibody Labeling Kits	26
Easy-to-Use Protein Labeling Kits	27
FluoReporter® Protein Labeling Kits	27
Zenon® Antibody Labeling Kits	28
Kits for Labeling Proteins with Biotin or Dinitrophenyl (DNP)	28
Biotin-XX Microscale Protein Labeling Kits	28
FluoReporter® Mini-Biotin-XX Protein Labeling Kit	28
FluoReporter® Biotin-XX Protein Labeling Kit	28
FluoReporter® Biotin/DNP Protein Labeling Kit	29
DSB-X™ Biotin Protein Labeling Kit	29
Kits for Labeling Nucleic Acids with a Fluorescent Dye	29
ULYSIS® Nucleic Acid Labeling Kits	29
ARES™ DNA Labeling Kits	30
Alexa Fluor® Oligonucleotide Amine Labeling Kits	30
Biotin Quantitation Assay Kits	31
FluoReporter® Biotin Quantitation Assay Kit for Biotinylated Proteins	31
FluoReporter® Biotin Quantitation Assay Kit for Biotinylated Nucleic Acids	31

Product List 1.8 Reagents for Analysis of Low Molecular Weight Amines	96

1.1 Introduction to Amine Modification

The Molecular Probes® Handbook describes a full spectrum of fluorophores and haptens for covalent derivatization of biopolymers and low molecular weight molecules. Chapters 1–5 describe the chemical and spectroscopic properties of the reactive reagents we offer, whereas the remainder of this book is primarily devoted to our diverse collection of fluorescent probes and their applications in cell biology, neurobiology, immunology, molecular biology and biophysics.

Common Applications for Amine-Reactive Probes

Labeling Biomolecules

Amine-reactive probes are widely used to modify proteins, peptides, ligands, synthetic oligonucleotides and other biomolecules. In contrast to our thiol-reactive reagents (Chapter 2), which frequently serve as probes of protein structure and function, amine-reactive dyes are most often used to prepare bioconjugates for immunochemistry, fluorescence *in situ* hybridization (FISH), cell tracing, receptor labeling and fluorescent analog cytochemistry. In these applications, the stability of the chemical bond between the dye and biomolecule is critical. The bioconjugate will typically be applied to a biochemically complex (and sometimes active) specimen. Furthermore, it will often be subjected to a series of post-processing steps such as washing, permeabilization, fixation and mounting. The integrity of the bioconjugate must be maintained throughout these processes if the fluorescence signal generated by the dye is to have any useful relationship to the abundance or localization of the bioconjugate's molecular target.

Our selection of amine-reactive fluorophores for modifying biomolecules covers the entire visible and near-infrared spectrum (Table 1.1, Table 1.2). Up-to-date bibliographies are available for most of our amine-reactive probes at www.invitrogen.com. Also available are other product-specific bibliographies, as well as keyword searches of the over 60,000 literature references in our product application bibliography database.

Chapter 1 discusses the properties of Molecular Probes® fluorophores, including:

- Alexa Fluor® dyes (Section 1.3)
- BODIPY® dyes (Section 1.4)
- Oregon Green® and Rhodamine Green™ dyes (Section 1.5)
- Rhodamine Red™-X and Texas Red® dyes (Section 1.6)
- UV light–excitable Cascade Blue®, Cascade Yellow™, Marina Blue®, Pacific Blue™ and AMCA-X fluorophores (Section 1.7)

Our essentially nonfluorescent QSY® dyes (Section 1.6, Section 1.8) have strong visible absorption, making them excellent acceptors for fluorescence resonance energy transfer (FRET) applications (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2).

Preparing the Optimal Bioconjugate

The preferred bioconjugate usually has a high fluorescence output (or, in the case of a haptenylated conjugate, a suitable degree of labeling) yet retains the critical functional properties of the unlabeled biomolecule, such as solubility, selective binding to a receptor or nucleic acid,

activation or inhibition of a particular enzyme or the ability to incorporate into a biological membrane.¹ Frequently, however, conjugates with the highest degree of labeling precipitate out of solution or bind non-specifically.² Thus there is usually a trade-off between degree of labeling and functional properties that must be resolved through experimental optimization. Lysine residues, the primary targets for amine modification of proteins, are relatively abundant. In mammalian proteins, lysine has the fifth highest occurrence frequency of the 20 naturally occurring amino acids. A typical IgG antibody molecule has about 90 lysine residues, of which about 30 at most can be modified under forcing conditions of high acylating reagent concentration and prolonged incubation. However, maintenance of functional properties (more specifically, antigen binding affinity) typically requires a degree of labeling of <10 dyes per IgG, representing a low fractional modification of available targets. A further consequence of low fractional modification is that, with the exception of small peptides or rare proteins with few lysine residues, bioconjugates prepared by amine modification are poly-disperse mixtures containing a range of dye:protein stoichiometries.^{3,4}

For the most critical assays, we recommend that researchers consider preparing and optimizing their own conjugates. Our amine-reactive dyes are supplied with a detailed protocol that describes how to use them for labeling biomolecules. This procedure is straightforward and requires no special equipment. Following conjugation, it is very important to remove as much unconjugated labeling reagent as possible, usually by gel filtration, dialysis, bioconjugate precipitation and resolubilization, HPLC or a combination of these techniques. The presence of free dye, particularly if it remains chemically reactive, can greatly complicate subsequent experiments with the bioconjugate. The entire process of labeling reaction and conjugate purification can be completed in little more than two hours, and the main prerequisite is a sufficient amount of purified protein or amine-modified nucleic acid.

With the exception of the phycobiliproteins (Section 6.4, Table 6.2), fluorescent microspheres (Section 6.5, Table 6.7), Qdot® nanocrystals (Section 6.6), Zenon® Antibody Labeling Kits (Section 7.3, Table 7.7) and ULYSIS® Nucleic Acid Labeling Kits (Section 8.2, Table 8.6), virtually all reagents used to prepare Molecular Probes® fluorescent bioconjugates are amine-reactive organic fluorophores, and almost all are described in this chapter.

We have also developed convenient kit formats for labeling proteins and nucleic acids with our most important fluorophores, or alternatively with biotin. Section 1.2 and Table 1.3 include a complete description of these kits. Alternatively, we prepare custom fluorescent conjugates for research use; contact Invitrogen Custom Services for more information. Conjugations with phycobiliproteins, fluorescent polystyrene microspheres and Qdot® nanocrystals require specialized procedures that are described in Section 6.4, Section 6.5 and Section 6.6, respectively.

Derivatizing Low Molecular Weight Molecules

Some amine-reactive probes described in this chapter are also important reagents for various bioanalytical applications, including amine quantitation, protein and nucleic acid sequencing and chromatographic and electrophoretic analysis of low molecular weight molecules. Reagents that are particularly useful for derivatizing low molecular weight amines—including fluorescamine, *o*-phthaldialdehyde, ATTO-TAG™ reagents, NBD chloride and dansyl chloride—are

Table 1.1 Molecular Probes® amine-reactive dyes.

Fluorophore	COOH *	SE *	Other *	Abs (nm)	Em (nm)	Notes
Methoxycoumarin	M1420MP	M1410		340	405	• pH-insensitive alternative to 7-hydroxycoumarins
Dansyl		D6104 (X)	D21 (SC)	340	520 ‡	• Environment-sensitive fluorescence • Large Stokes shift
Pyrene		P130 P6114	P24 (SC)	345	378	• Long excited-state lifetime • Spectral shifts due to excimer emission
Alexa Fluor® 350		A10168		346	442	• Higher fluorescence output than AMCA • Optimally detected with DAPI optical filter sets
AMCA		A6118 (X)		349	448	• Widely used blue-fluorescent labeling dye • Compact structure
Marina Blue® dye		M10165		365	460	• Strongly fluorescent at neutral pH • Optimally detected with DAPI optical filter sets
Dapoxyl® dye		D10161	D10160 (SC)	373	551 ‡	• Environment-sensitive fluorescence • Large Stokes shift
Dialkylaminocoumarin	D126 D1421	D374 D1412		375 430	470 § 475 **	• Longer-wavelength alternatives to AMCA
Bimane	B30250			380	458	• Blue-fluorescent dye • Small size
Hydroxycoumarin	H185 H1428	H1193		385	445 ††	• pH-sensitive fluorescence • Compact structure
Cascade Blue® dye			C2284 (AA)	400	420	• Resistant to quenching upon protein conjugation • Water soluble
Pacific Orange™ dye		P30253		400	551	• Excited with the 405 nm violet diode laser • Compatible with the Pacific Blue™ dye for two-color analysis using the violet diode laser
Alexa Fluor® 405		A30000 A30100		402	421	• Cascade Blue® derivative containing a spacer between the fluorophore and the reactive SE • Near-perfect match to the 405 nm violet diode laser
Cascade Yellow™ dye		C10164		402	545	• Large Stokes shift • High molar absorptivity
Pacific Blue™ dye		P10163		410	455	• Recommended for 405 nm violet diode laser excitation
PyMPO		S6110		415	570	• Large Stokes shift
Alexa Fluor® 430		A10169		434	539	• Large Stokes shift
NBD		S1167 (X)	F486 (AH)	465	535	• Environment-sensitive fluorescence • Compact structure
QSY® 35		Q20133		475	none	• Nonfluorescent quencher • An efficient energy transfer acceptor from blue and green fluorophores
Fluorescein	C1359 C1360 C1904 †	C2210 C6164 C1311 † F6106 (X) F2181 (X) † F6129 (X) † F6130 (EX) C20050 (PA)	D16 (DTA) F143 (ITC) F1906 (ITC) F1907 (ITC)	494	518	• Most widely used green-fluorescent labeling dye • Absorption overlaps the 488 nm spectral line of the argon-ion laser • Prone to photobleaching • pH-sensitive fluorescence between pH 5–8 • Fluorescein-5-EX succinimidyl ester (F6130) is the preferred reactive fluorescein for protein conjugation
Alexa Fluor® 488		A20000 † A20100 †	A30005 (TFP) A30052 (SDP)	495	519	• Bright and photostable fluorescein substitute • Fluorescence output unmatched by any other spectrally similar dye • pH-insensitive fluorescence between pH 4 and 10 • Ideal for excitation by the 488 nm spectral line of the argon-ion laser • As compared with the SE, the TFP ester is less susceptible to spontaneous hydrolysis during conjugation reactions
Oregon Green® 488	O6146	O6147 O6149	O6080 (ITC) †	496	524	• Photostable fluorescein substitute • pH-insensitive fluorescence at pH >6
BODIPY® 493/503		D2191		500	506	• pH-insensitive fluorescence • Narrow spectral bandwidth • Higher 488 nm absorptivity than the BODIPY® FL fluorophore
Rhodamine Green dye		R6107 † R6113 (X) †		502	527	• Photostable fluorescein substitute • pH-insensitive fluorescence

The absorption (Abs) and fluorescence emission (Em) maxima listed in this table are for the goat anti-mouse IgG antibody or dextran conjugates in aqueous buffer. discussed in Section 1.8. However, many of the reactive dyes described in Sections 1.2 to 1.7 can also be used as derivatization reagents; likewise, most of the derivatization reagents in Section 1.8 can be utilized for biomolecule conjugation.

Reactivity of Amino Groups

The amine-reactive organic fluorophores described in this chapter are mostly acylating reagents that form carboxamides, sulfonamides or thioureas upon reaction with amines. The kinetics of the reaction depend on the reactivity and concentration of both the acylating reagent and the amine.⁵ Of course, buffers that contain free amines such as Tris and glycine must be avoided when using *any* amine-reactive probe. Ammonium sulfate used for protein precipitation must also be removed before performing dye conjugations. In addition, high concentrations of nucleophilic thiols should be avoided because they may react with the amine-reactive reagent to form an unstable intermediate that could consume the dye. Reagents for reductive alkylation of amines are described in Chapter 2 and Chapter 3.

The most significant factors affecting an amine's reactivity are its class (aliphatic or aromatic) and its basicity. Virtually all proteins have lysine residues, and most have a free amine at the N-terminus. Aliphatic amines such as lysine's ϵ -amino group are moderately basic and reactive with most acylating reagents. However, the concentration of the free base form of aliphatic amines below pH 8 is very low; thus, the kinetics of amine acylation by isothiocyanates, succinimidyl esters or other reagents are strongly pH dependent. A pH of 8.5 to 9.5 is usually optimal for modifying lysine residues. In contrast, the α -amino group at a protein's N-terminus usually has a pK_a of ~ 7 , so it can sometimes be selectively modified by reaction at near neutral pH. Furthermore, although amine acylation should usually be carried out above pH 8.5, the acylation reagents tend to degrade in the presence of water, with the rate increasing as the pH increases.⁵ Protein modification by succinimidyl esters can typically be done at pH 8.3, whereas isothiocyanates usually require a pH >9 for optimal conjugations; this high pH may be a factor when working with base-sensitive proteins. DNA and most polysaccharides can be modified at a relatively basic pH if necessary.

Aromatic amines, which are uncommon in biomolecules, are very weak bases and thus unprotonated at pH 7. Modification of aromatic amines requires a highly reactive reagent, such as an isocyanate, isothiocyanate, sulfonyl chloride or acid halide, but can be done at any pH above ~ 4 . A tyrosine residue can be selectively modified to form an *o*-aminotyrosine aromatic amine, which can then be reacted at a relatively low pH with certain amine-reactive probes⁶ (Figure 1.1.1).

In aqueous solution, acylating reagents are virtually unreactive with the amide group of peptide bonds and the side-chain amides of glutamine and asparagine residues, the guanidinium group of arginine, the imidazolium group of histidine and the nonbasic amines, such as adenine or guanosine, found in nucleotides and nucleic acids.

Figure 1.1.1 Nitration of tyrosine by reaction with tetranitromethane, followed by reduction with sodium dithionite, to yield an *o*-aminotyrosine.

Isothiocyanates

Because they are very susceptible to deterioration during storage, we do not sell any isocyanates. Some acyl azides (Section 3.2), however, are readily converted to isocyanates (Figure 1.1.2), which then react with amines to form ureas. As an alternative to the unstable isocyanates, we

Figure 1.1.2 Derivatization of an alcohol using the diacetate of fluorescein-5-carbonyl azide (F6218). This process consists of three steps: 1) rearrangement of the acyl azide to an isocyanate, 2) reaction of the isocyanate with an alcohol to form a urethane and 3) deprotection of the nonfluorescent urethane derivative using hydroxylamine.

Figure 1.1.3 Reaction of a primary amine with an isothiocyanate.

Figure 1.1.4 Reaction of a primary amine with a succinimidyl ester or a tetrafluorophenyl (TFP) ester.

Figure 1.1.6 Reaction of a primary amine with an STP ester.

offer a large selection of isothiocyanates, which are moderately reactive but quite stable in water and most solvents. Isothiocyanates form thioureas upon reaction with amines (Figure 1.1.3). Although the thiourea product is reasonably stable, it has been reported that antibody conjugates prepared from fluorescent isothiocyanates deteriorate over time,⁷ prompting us to use fluorescent succinimidyl esters and sulfonyl halides almost exclusively for synthesizing bioconjugates. The thiourea formed by the reaction of fluorescein isothiocyanate with amines is also susceptible to conversion to a guanidine by concentrated ammonia.⁸ Despite the growing number of choices in amine-reactive fluorophores, fluorescein isothiocyanate (FITC) and tetramethylrhodamine isothiocyanate (TRITC) are still widely used reactive fluorescent dyes for preparing fluorescent bioconjugates.

Active Esters and Carboxylic Acids

Succinimidyl Esters

Succinimidyl esters are reliable reagents for amine modification because the amide bonds they form (Figure 1.1.4) are as stable as peptide bonds. We provide over 100 succinimidyl esters of fluorescent dyes and nonfluorescent molecules, most of which have been developed within our own laboratories (Table 1.1, Table 1.2). These reagents are generally stable during storage if well desiccated, and they show good reactivity with aliphatic amines and very low reactivity with aromatic amines, alcohols, phenols (including tyrosine) and histidine. Side-reactions of succinimidyl esters with alcohols are generally only observed in applications such as derivatization for mass spectrometry, in which much larger molar excesses of succinimidyl ester reagents and longer reaction times are used than is typically the case in protein labeling for fluorescence detection applications.^{9,10} Succinimidyl esters will also react with thiols in organic solvents to form thioesters. If formed in a protein, a thioester may transfer the acyl moiety to a nearby amine. Succinimidyl ester hydrolysis (generating the unreactive carboxylic acid) competes with conjugation, but this side reaction is usually slow below pH 9.

Carboxylic Esters and Their Conversion into Sulfosuccinimidyl Esters and STP Esters

Some succinimidyl esters may not be compatible with a specific application because they can be quite insoluble in aqueous solution. To overcome this limitation, we offer carboxylic acid derivatives of many fluorophores, which can be converted into sulfosuccinimidyl esters or 4-sulfotetrafluorophenyl (STP) esters. These sulfonated esters have higher water solubility than simple succinimidyl esters and sometimes eliminate the need for organic solvents in the conjugation reaction. They are, however, also more polar than succinimidyl esters, which makes them less likely to react with buried amines in proteins or to penetrate cell

Figure 1.1.5 Stabilization of an unstable O-acylisourea intermediate by *N*-hydroxysulfosuccinimide (NHSS, H2249) in a carbodiimide-mediated (EDAC, E2247) modification of a carboxylic acid with a primary amine.

membranes. Because of their combination of reactivity and polarity, sulfosuccinimidyl esters are not easily purified by chromatographic means and thus only a few are currently available. Sulfosuccinimidyl esters can generally be prepared *in situ* simply by dissolving the carboxylic acid dye in an amine-free buffer that contains *N*-hydroxysulfosuccinimide and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (NHSS, H2249; EDAC, E2247; Section 3.4). Addition of NHSS to the buffer has been shown to enhance the yield of carbodiimide-mediated conjugations¹¹ (Figure 1.1.5). STP esters (Figure 1.1.6) are prepared in the same way from 4-sulfo-2,3,5,6-tetrafluorophenol¹² (S10490, Section 3.4), and we find them to be more readily purified by chromatography than their sulfosuccinimidyl ester counterparts. The carboxylic acid derivatives may also be useful for preparing acid chlorides and anhydrides, which, unlike succinimidyl esters, can be used to modify aromatic amines and alcohols.

Tetrafluorophenyl (TFP) Esters

2,4,5,6-Tetrafluorophenyl (TFP) esters (Figure 1.1.4) are more resistant to nonspecific hydrolysis than either succinimidyl esters (Figure 1.1.7) or sulfosuccinimidyl esters, yet they exhibit equal or superior reactivity with amines.¹³ At this time, Alexa Fluor® 488 carboxylic acid is the only fluorescent TFP ester we offer (A30005, Section 1.3).

Sulfodichlorophenol (SDP) Esters

The sulfodichlorophenol (SDP) ester is currently the most hydrolytically stable amine-reactive moiety that we offer. As with TFP esters, Alexa Fluor® 488 carboxylic acid is the only fluorescent SDP ester available (A30052, Section 1.3). Conjugates produced with the Alexa Fluor® 488 5-SDP ester produce the same strong amide bond between the dye and the compound of interest as succinimidyl and tetrafluorophenyl (TFP) esters. Because of its improved stability in water and buffers, however, the SDP ester can potentially offer increased control and consistency in reactions as compared with its succinimidyl ester and TFP ester counterparts.

Carbonyl Azides

Section 3.2 describes coumarin, fluorescein and tetramethylrhodamine carbonyl azides (D1446, M1445, F6218, T6219). Like succinimidyl esters, carbonyl azides are active esters that can react with amines to yield amides; however, a more common application of carbonyl azides is thermal rearrangement to a labile isocyanate (which can then react with both aliphatic and aromatic amines to form ureas) for derivatizing alcohols and phenols (Section 3.2, Figure 1.1.2).

Figure 1.1.7 Stability of the tetrafluorophenyl (TFP) and succinimidyl (NHS) esters at basic pH (8.0–9.0).

Sulfonyl Chlorides

Sulfonyl chlorides, including the dansyl, pyrene, Lissamine rhodamine B and Texas Red® derivatives, are highly reactive but also quite unstable in water, especially at the higher pH required for reaction with aliphatic amines. For example, we have determined that dilute Texas Red® sulfonyl chloride is totally hydrolyzed within 2–3 minutes in pH 8.3 aqueous solution at room temperature.¹⁴ Protein modification by this reagent is therefore best done at low temperature. Once conjugated, however, the sulfonamides that are formed (Figure 1.1.8) are extremely stable; they even survive complete protein hydrolysis (for example, dansyl end-group analysis¹⁵).

Sulfonyl chlorides can also react with phenols (including tyrosine), aliphatic alcohols (including polysaccharides), thiols (such as cysteine) and imidazoles (such as histidine), but these reactions are not common in proteins or in aqueous solution. Sulfonyl chloride conjugates of thiols and imidazoles are generally unstable, and conjugates of aliphatic alcohols are subject to nucleophilic displacement.¹⁶ Note that sulfonyl chlorides are unstable in dimethylsulfoxide (DMSO) and should never be used in that solvent.¹⁷

Other Amine-Reactive Reagents

Aldehydes react with amines to form Schiff bases. Notable aldehyde-containing reagents described in Section 1.8 include *o*-phthalaldehyde (OPA) and naphthalenedicarboxaldehyde (NDA), as well as the 3-acylquinolinecarboxaldehyde (ATTO-TAG™) reagents CBQCA and FQ devised by Novotny and collaborators.^{18–20} All of these reagents are useful for the sensitive quantitation of amines in solution, by HPLC and by capillary electrophoresis. In addition, certain arylating reagents such as NBD chloride, NBD fluoride and dichlorotriazines react with both amines and thiols, forming bonds with amines that are particularly stable.

1.2 Kits for Labeling Proteins and Nucleic Acids

We provide a vast number of stand-alone reagents for preparing bioconjugates, most of which are described in detail in other sections of this chapter. This section describes the many specialized kits that we have developed for covalently labeling proteins and nucleic acids with our organic dyes and haptens (Table 1.2, Table 1.3).

As an alternative to direct conjugation of primary antibodies with our reactive dyes and haptens, we recommend using Zenon® technology (Section 7.3) to form labeled antibody complexes. Zenon® labeling can typically be completed in minutes with quantitative yield starting with submicrogram quantities of antibody, and the labeling stoichiometry can be easily adjusted to deliver optimum fluorescence output. Although they do not provide covalent labeling, the Zenon® Antibody Labeling Kits are listed in Table 1.2, as well as in Table 7.7.

Kits for Labeling Proteins with a Fluorescent Dye

APEX® Antibody Labeling Kits

APEX® Antibody Labeling Kits (Table 1.2, Table 1.3) provide a convenient method for covalently labeling small amounts (10–20 µg) of IgG antibody with Alexa Fluor® dyes, Oregon Green® 488 dye or Pacific Blue™ dye. A primary antibody directly labeled with a fluorophore often produces lower background fluorescence and less nonspecific binding than secondary antibodies. Furthermore, multiple primary antibodies of the same isotype or derived from the same species can be used in the same immunostaining experiment if they are directly labeled with compatible fluorophores. Many IgG antibodies, however, are often

only available in small quantities and may be mixed with stabilizing proteins, such as BSA, that can react nonproductively with the amine-reactive labeling reagents.

APEX® Antibody Labeling Kits are specifically designed to allow labeling of small amounts of IgG antibody, even in the presence of contaminants. These kits utilize a solid-phase labeling technique that captures the IgG antibody on resin inside an APEX® antibody labeling tip (Figure 1.2.1). Any contaminants, including stabilizing proteins or amine-containing buffers, are eluted through the tip before labeling. After applying the amine-reactive fluorophore to the IgG antibody trapped on the resin, a fluorescent IgG conjugate is formed and subsequently eluted from the resin using elution buffer. The fluorescent IgG conjugate is ready to use in an imaging or flow cytometry assay in as little as 2.5 hours with minimal hands-on time. The typical yield of labeled antibody using this method is between 40 and 80%.

Each APEX® Antibody Labeling Kit provides all reagents required to perform five separate labeling reactions of 10–20 µg IgG antibody, including:

- Five vials of amine-reactive fluorescent dye
- Five APEX® antibody labeling tips
- Wash, labeling, neutralization and elution buffers
- Dimethylsulfoxide (DMSO)
- Labeling protocol

For labeling larger amounts of protein, we recommend the Alexa Fluor® Microscale Protein Labeling Kits, which are optimized for 20–100 µg samples of proteins between 10,000 and 150,000 daltons; the Alexa Fluor® Monoclonal Antibody Labeling Kits, which are optimized for 100 µg samples of mono- or polyclonal antibodies; or the Alexa Fluor® Protein Labeling Kits, which are optimized for 1 mg samples of >30,000-dalton proteins.

Alexa Fluor® Microscale Protein Labeling Kits

Alexa Fluor® Microscale Protein Labeling Kits (Table 1.2, Table 1.3) provide a convenient means for labeling small amounts (20–100 µg) of purified protein with the highly fluorescent Alexa Fluor® dyes. Spin columns are used to purify the labeled protein, with yields between 60 and 90% depending primarily on the molecular weight of the starting material. Labeling and purification can be completed in as little as 30 minutes.

These kits have been optimized for labeling proteins with molecular weights between 12,000 and 150,000 daltons and contain everything needed to perform three labeling reactions and to separate the resulting conjugates from excess dye. Each Alexa Fluor® Microscale Protein Labeling Kit provides:

- Three vials of amine-reactive fluorescent dye (succinimidyl ester or tetrafluorophenyl ester)
- Sodium bicarbonate
- Reaction tubes
- Purification resin and spin filters
- Detailed protocols for conjugation, purification and determination of the degree of labeling

Figure 1.2.1 Illustration of the use of the APEX® antibody labeling tip, provided in APEX® Antibody Labeling Kits. **A**) Applying solutions to the resin in the tip. **B**) Pushing solutions onto the resin in the tip by attaching the APEX® antibody labeling tip to a pipette.

Figure 1.2.2 Illustration of the three simple steps in the protocol for the Monoclonal Antibody Labeling Kits, which provide a convenient method for covalently labeling small amounts of IgG antibodies.

Monoclonal Antibody Labeling Kits

Monoclonal Antibody Labeling Kits (Table 1.2, Table 1.3) provide researchers with a simple yet efficient means of labeling small amounts of IgG antibodies with Alexa Fluor® dyes (Figure 1.2.2). Unlike polyclonal antibodies and most other commercially available proteins, monoclonal antibodies are typically only available in small quantities. These kits contain everything needed to perform five separate labeling reactions containing ~100 µg each of carrier-free monoclonal IgG samples (although other proteins can be labeled).

Each Monoclonal Antibody Labeling Kit provides:

- Five vials of amine-reactive fluorescent dye (succinimidyl ester or tetrafluorophenyl ester)
- Sodium bicarbonate
- Spin columns and collection tubes
- Detailed protocols for conjugation, purification and determination of the degree of labeling

Table 1.3 Molecular Probes® kits for protein and nucleic acid labeling.

Kit Name	# Labelings	Kit Components	Features
Kits for Labeling Proteins with Fluorescent Dyes			
APEX® Antibody Labeling Kit	5 labelings of 10–20 µg each of IgG antibody	<ul style="list-style-type: none"> 5 vials of amine-reactive fluorescent label Five APEX® antibody labeling tips Wash, labeling, neutralization and elution buffers Dimethylsulfoxide (DMSO) Labeling protocol 	APEX® Antibody Labeling Kits utilize a solid-phase labeling technique that captures the IgG antibody on the resin inside the APEX® antibody labeling tip. Any contaminants, including stabilizing proteins, are eluted through the tip prior to labeling with the amine-reactive fluorescent dye. The fluorescent IgG conjugate is ready to use in 2.5 hours, with ~15 minutes hands-on time.
Alexa Fluor® Microscale Protein Labeling Kit	Three 20–100 µg protein samples of a 12,000- to 150,000-dalton protein	<ul style="list-style-type: none"> 3 vials of the succinimidyl ester (or tetrafluorophenyl ester) of the fluorescent dye Sodium bicarbonate Reaction tubes Purification resin and spin filters Detailed protocols for conjugation, purification and determination of the degree of labeling 	Alexa Fluor® Microscale Protein Labeling Kits provide a convenient means for labeling small amounts (20–100 µg) of purified protein with our superior Alexa Fluor® dyes and purifying the resulting conjugate. Convenient spin columns are used to purify the labeled protein, with yields between 60 and 90% depending primarily on the molecular weight of the starting material. Labeling and purification can be completed in as little as 30 minutes. Microscale Protein Labeling Kits are also available for biotinylating proteins.
Monoclonal Antibody Labeling Kit	5 labelings of ~100 µg each of carrier-free monoclonal IgG samples	<ul style="list-style-type: none"> 5 vials of the succinimidyl ester (or tetrafluorophenyl ester) of the fluorescent dye Sodium bicarbonate Spin columns and collection tubes Detailed protocols for conjugation, purification and determination of the degree of labeling 	A buffered solution of the protein is added to one of the five vials of amine-reactive dye. The reactive dye has a succinimidyl ester (or tetrafluorophenyl ester) moiety that reacts efficiently with primary amines of proteins to form stable dye–protein conjugates. The conjugate can be purified on the included size-exclusion spin columns. Labeling and purification can be completed in less than 2 hours.
SAIVI™ Rapid Antibody Labeling Kit	3 labelings of 0.5–3 mg each of carrier-free antibody solution	<ul style="list-style-type: none"> 3 vials of amine-reactive Alexa Fluor® dye Sodium bicarbonate Regulator solution Purification resin and purification columns Phosphate-buffered saline (PBS) Syringes, syringe filters, column-loading pipettes and catch tubes Detailed protocols for conjugation, purification and determination of the degree of labeling 	SAIVI™ Antibody Labeling Kits provide a convenient means to label antibodies with an optimal degree of labeling for <i>in vivo</i> imaging applications over a 6-fold antibody concentration range with no adjustments in reaction volume, dye concentration or antibody concentration necessary. Purification of the dye-labeled antibody is achieved with a simple protocol that can be completed in less than 10 minutes. These optimally labeled antibodies are ready for applications that require azide-free reagents, such as live-cell imaging or direct injection into animals.
Easy-to-Use Protein Labeling Kit	Three ~1 mg protein samples of a 150,000-dalton protein, such as an IgG	<ul style="list-style-type: none"> 3 vials of the succinimidyl ester (or tetrafluorophenyl ester) of the fluorescent dye, each containing a magnetic stir bar Sodium bicarbonate Gravity-feed columns, a size-exclusion resin and concentrated elution buffer Column funnels, foam column holders, disposable pipettes and collection tubes Detailed protocols for conjugation, purification and determination of the degree of labeling 	A buffered solution of the protein is added to one of the three vials of the amine-reactive dye. The reactive dye has a succinimidyl ester (or tetrafluorophenyl ester) moiety that reacts efficiently with primary amines of proteins to form stable dye–protein conjugates. Purification of the conjugate can be accomplished on the included gravity-feed size-exclusion columns.
FluoReporter® Protein Labeling Kit	5 to 10 protein samples of 0.2–2 mg each in 200 µL volumes	<ul style="list-style-type: none"> 5 vials of the amine-reactive dye Anhydrous DMSO Reaction tubes, each containing a stir bar Spin columns and collection tubes Detailed protocols for conjugation, purification and determination of the degree of labeling 	The amount of dye necessary for the desired protein sample is calculated using the guidelines outlined in the kit protocol. The reactive dye has a succinimidyl ester moiety that reacts efficiently with primary amines of proteins to form stable dye–protein conjugates. Purification of the conjugate can be easily accomplished using the included spin columns.
Qdot® Antibody Conjugation Kit—see Section 6.6			
Zenon® Antibody Labeling Kit—see Section 7.3			
Kits for Labeling Proteins with Biotin or Dinitrophenyl (DNP)			
Biotin-XX Microscale Protein Labeling Kit	Three 20–100 µg protein samples of a 12,000- to 150,000-dalton protein	<ul style="list-style-type: none"> 3 vials of biotin-XX sulfosuccinimidyl ester Sodium bicarbonate Reaction tubes Purification resin and spin filters Detailed protocols for conjugation and purification 	The Biotin-XX Microscale Protein Labeling Kit provides a convenient means for biotinylating small amounts (20–100 µg) of purified protein. Convenient spin columns are used to purify the labeled protein with yields between 60 and 90%, depending primarily on the molecular weight of the starting material. Labeling and purification can be completed in as little as 30 minutes. For determining the degree of labeling, the FluoReporter® Biotin Quantitation Assay Kit for proteins is available separately or in combination with the Biotin-XX Microscale Protein Labeling Kit.
FluoReporter® Mini-Biotin-XX Protein Labeling Kit	5 biotinylation reactions of 0.1–3 mg each	<ul style="list-style-type: none"> 5 vials of biotin-XX sulfosuccinimidyl ester Reaction tubes, each containing a stir bar Purification resin, spin columns and collection tubes Dialysis tubing Detailed protocols for conjugation and purification 	The biotin-XX sulfosuccinimidyl ester (SSE) is water soluble and reacts with primary amines of proteins or other biomolecules to form stable biotin conjugates. The biotin-XX SSE has a 14-atom spacer that enhances the binding of biotin derivatives to avidin's relatively deep binding sites. Ready-to-use spin columns are included for purification of the biotinylated protein from excess reagents.

continued on next page

Simply dissolve the carrier-free monoclonal antibody at ~1 mg/mL in the provided buffer, then add it to one of the five vials of amine-reactive dye; no organic solvents are required. Purification of the fluorescent conjugate is accomplished on a size-exclusion spin column optimized for proteins with molecular weight greater than 30,000 daltons. Labeling and purification can typically be completed in less than 2 hours.

Mouse monoclonal antibodies in serum, in ascites fluid or diluted with carrier proteins should not be labeled with these kits; however, such antibody preparations can be efficiently labeled with the APEX® Antibody Labeling Kits described above or with the Zenon® Mouse IgG Labeling Kits (Section 7.3, Table 7.7) described below.

SAIVI™ Antibody Labeling Kits

The optimal fluorescent antibody conjugate for *in vitro* detection assays produces an intense fluorescent signal yet retains the binding affinity and specificity of the unlabeled antibody. When preparing a fluorescent antibody conjugate for *in vivo* animal imaging, however, the pharmacokinetics of the labeled probe must also be considered.¹ These additional constraints have led to the development of the SAIVI™ Antibody Labeling Kits for small animal *in vivo* imaging applications (Table 1.2, Table 1.3).

SAIVI™ Antibody Labeling Kits feature reactive far-red and near-infrared Alexa Fluor® dyes, along with a labeling protocol specifically designed to produce a suitable degree of labeling (DOL) for *in vivo*

Table 1.3 Molecular Probes® kits for protein and nucleic acid labeling—*continued*.

Kit Name	# Labelings	Kit Components	Features
FluoReporter® Biotin-XX Protein Labeling Kit	5 biotinylation reactions, each with 5–20 mg of protein	<ul style="list-style-type: none"> Biotin-XX succinimidyl ester DMSO Gel filtration column Avidin–HABA complex Biotinylated goat IgG Detailed protocols for conjugation, purification and determination of the degree of labeling 	The biotin-XX succinimidyl ester (SE) reacts with primary amines of proteins or other biomolecules to form stable biotin conjugates. The biotin-XX SE has a 14-atom spacer that enhances the binding of biotin derivatives to avidin's relatively deep binding sites. A gel filtration column is provided for purifying the labeled proteins from excess biotin reagent. After purification, the degree of biotinylation can be estimated using the included avidin–biotin displacement assay.
FluoReporter® Biotin/DNP Protein Labeling Kit	5 to 10 labeling reactions of 0.2–2 mg of protein each	<ul style="list-style-type: none"> 5 vials of DNP-X–biotin-X succinimidyl ester DMSO Reaction tubes Spin columns and collection tubes Detailed protocols for conjugation, purification and determination of the degree of labeling 	The FluoReporter® Biotin/DNP Protein Labeling Kit is similar to other FluoReporter® Protein Labeling Kits, except that it contains DNP-X–biotin-X succinimidyl ester as the reactive label. When proteins are labeled with this chromophoric biotin derivative, the degree of biotinylation can be readily assessed from the extinction coefficient of DNP ($EC_{360} = 15,000 \text{ cm}^{-1}\text{M}^{-1}$). An additional feature of the conjugates labeled with DNP-X–biotin-X succinimidyl ester is that they can be recognized by avidin derivatives (or anti-biotin antibodies) and by anti-DNP antibodies, enabling researchers to choose among several detection techniques suitable for fluorescence and electron microscopy.
DSB-X™ Protein Labeling Kit	5 protein conjugations of 0.5–3 mg each	<ul style="list-style-type: none"> 5 vials of DSB-X™ biotin succinimidyl ester DMSO Reaction tubes Purification resin, spin columns and collection tubes Dialysis tubing for larger-scale separations Detailed protocols for conjugation and purification 	DSB-X™ biotin succinimidyl ester, a derivative of desthiobiotin with an additional seven-atom spacer, reacts with amine groups of biomolecules to form stable amides. The DSB-X™ biotin conjugate can be detected with avidin or streptavidin derivatives. Binding is almost totally reversed by addition of free biotin at neutral pH and normal ionic strength. Materials are included for both small- and large-scale preparations.
Kits for Labeling Nucleic Acids with Fluorescent Dyes			
ULYSIS® Nucleic Acid Labeling Kit	20 labelings of 1 µg DNA	<ul style="list-style-type: none"> ULS® labeling reagent and appropriate solvent Labeling buffer Deoxyribonuclease I (DNase I), for digesting DNA longer than 1000 base pairs prior to labeling DNase I storage and reaction buffers Control DNA from calf thymus Nuclease-free H₂O Labeling protocol 	The ULS® reagent reacts with the N-7 position of guanine residues to provide a stable coordination complex between the nucleic acid and the fluorophore label. Separation of the labeled nucleic acids from the unreacted ULS® complex can be accomplished through a simple procedure using a spin column (not provided).
ARES™ DNA Labeling Kit	10 labelings of 1–5 µg DNA	<ul style="list-style-type: none"> 5-(3-Aminoallyl)-dUTP Amine-reactive fluorescent dye and appropriate solvent Sodium bicarbonate Nuclease-free H₂O Detailed protocol for labeling DNA using reverse transcriptase or nick translation 	In the first step, an amine-modified nucleotide, 5-(3-aminoallyl)-dUTP, is incorporated into DNA using conventional enzymatic labeling methods. In the second step, the amine-modified DNA is chemically labeled using an amine-reactive fluorescent dye. The amine-modified DNA can be purified using the PureLink™ PCR Purification Kit (K3100-01).
FISH Tag™ DNA Kit—see Section 8.2			
FISH Tag™ RNA Kit—see Section 8.2			
Oligonucleotide Amine Labeling Kit	3 labelings of 50 µg each of an amine-modified oligonucleotide	<ul style="list-style-type: none"> 3 vials of the amine-reactive dye DMSO Labeling buffer Labeling protocol 	The reactive dye used in the labeling has an amine-reactive succinimidyl ester moiety that reacts efficiently with an amine-modified oligonucleotide. Following the labeling reaction, the conjugate can be purified from the reaction mixture by preparative gel electrophoresis or reverse-phase HPLC.

imaging applications. When optimally labeled, a fluorescent antibody conjugate produces an intense, targeted fluorescent signal that persists throughout the *in vivo* study, without significant redistribution or clearance of the probe.

The conjugation protocol in the SAIVI™ Rapid Antibody Labeling Kits produces an optimal DOL (~2 fluorophores per antibody) over a 6 fold antibody concentration range with no adjustments in reaction volume, dye concentration or antibody concentration necessary. Purification of the dye-labeled antibody is achieved using a simple protocol that can typically be completed in less than 10 minutes. With these kits, optimally labeled antibodies are ready for applications that require azide-free reagents, such as live-cell imaging or direct injections into animals. SAIVI™ Rapid Antibody Labeling Kits containing either Alexa Fluor® 680 or Alexa Fluor® 750 dye (S30045, S30046) provide sufficient reagents for three labeling reactions of 0.5–3 mg of protein each, including:

- Three vials of amine-reactive Alexa Fluor® 680 or Alexa Fluor® 750 dye
- Sodium bicarbonate
- Regulator solution
- Purification resin and purification columns
- Phosphate-buffered saline (PBS)
- Syringes, syringe filters, column-loading pipettes and catch tubes
- Detailed protocols for conjugation, purification and determination of the degree of labeling

To control the DOL of the antibody conjugate, the SAIVI™ Alexa Fluor® 647 Antibody/Protein Labeling Kit (S30044) includes a DOL modulating reagent and instructions for decreasing the DOL from its intrinsic highest value by adding specific amounts of this reagent to the labeling reaction. With this method, antibody preparations with varying ratios of dye to protein can be quickly and reproducibly obtained without significant alteration of labeling or purification conditions, allowing more efficient optimization for *in vivo* imaging applications. Each kit provides sufficient reagents for three labeling reactions of 1 mg protein each, including:

- Three vials of amine-reactive Alexa Fluor® 647 dye
- Sodium bicarbonate
- DOL modulating reagent
- Purification resin and purification columns
- Wash buffer
- Column funnels, column holders, disposable pipettes and collection tubes
- Detailed protocols for conjugation, purification and determination of the degree of labeling

Easy-to-Use Protein Labeling Kits

Our Easy-to-Use Protein Labeling Kits (Table 1.2, Table 1.3) provide a nearly effortless way to label proteins, especially IgG antibodies, with a fluorescent dye (Figure 1.2.3). Simply add ~1 mg of protein (in a volume of ~500 µL and free of amine-containing buffers such as Tris) to one of the three included vials, which contain a premeasured quantity of amine-reactive dye and a magnetic stir bar. Because the reactive dyes used in these kits are water soluble, no organic solvents are required. Purification is accomplished on a gravity-feed size-exclusion

column, which is supplied with the kit. Labeling and purification can typically be completed in about 2 hours, with very little hands-on time.

Each Protein Labeling Kit provides sufficient reagents for labeling three ~1 mg protein samples of a 150,000-dalton protein (such as an IgG), including:

- Three vials of the amine-reactive fluorescent dye (succinimidyl ester or tetrafluorophenyl ester), each containing a magnetic stir bar
- Sodium bicarbonate
- Gravity-feed columns, a size-exclusion resin and concentrated elution buffer
- Column funnels, foam column holders, disposable pipettes and collection tubes
- Detailed protocols for conjugation, purification and determination of the degree of labeling

Researchers have modified α -synuclein using either the Oregon Green® 488 Protein Labeling Kit (O10241) or the Alexa Fluor® 594 Protein Labeling Kit (A10239).² They intentionally produced fluorescent conjugates with a low degree of labeling (DOL) so as not to perturb oligomerization. When comparing Oregon Green® 488 synuclein with Alexa Fluor® 594 synuclein, they observed essentially the same results in terms of fibril formation as analyzed by fluorescence polarization. They also detected the Oregon Green® 488 synuclein conjugate with mouse monoclonal anti-fluorescein/Oregon Green® antibody (monoclonal 4-4-20, A6421; Section 7.4) and gold-labeled anti-mouse IgG antibody using electron microscopy.

FluoReporter® Protein Labeling Kits

The FluoReporter® Protein Labeling Kits (Table 1.2, Table 1.3) facilitate research-scale preparation of protein conjugates labeled with some of our brightest fluorescent dyes. Typically, labeling and purifying conjugates with the FluoReporter® Protein Labeling Kits can typically be completed in under 3 hours, with very little hands-on time. First, the amount of dye necessary for the desired protein sample is calculated using the guidelines outlined in the kit protocol. After dissolving the dye in dimethylsulfoxide (DMSO), the calculated amount of dye is added to the protein and the reaction is incubated for 1–1.5 hours. Purification

Figure 1.2.3 Illustration of the three simple steps in the protocol for the Easy-to-Use Protein Labeling Kits, which provide a convenient method for covalently labeling most proteins.

is easily accomplished using convenient spin columns designed for use with proteins of molecular weight greater than 30,000 daltons.

Each FluoReporter® Protein Labeling Kits provides sufficient reagents to label 5 to 10 protein samples of 0.2–2 mg each in 200 µL volumes:

- Five vials of the amine-reactive dye
- Dimethylsulfoxide (DMSO)
- Reaction tubes, each containing a stir bar
- Spin columns and collection tubes
- Detailed protocols for conjugation, purification and determination of the degree of labeling

Zenon® Antibody Labeling Kits

The Zenon® Antibody Labeling Kits (Table 1.2, Table 7.7) are useful for the rapid and quantitative labeling of antibodies with dyes (including phycobiliproteins and their tandem conjugates), biotin or enzymes³ (Figure 1.2.4). Zenon® Antibody Labeling Kits are designed to label intact antibodies in amounts from less than 1 µg to as much as 50 µg, starting with a purified antibody fraction or with a crude antibody preparation such as serum, ascites fluid or a hybridoma supernatant. The Zenon® antibody labeling technology is discussed further in Section 7.3.

Kits for Labeling Proteins with Biotin or Dinitrophenyl (DNP)

Biotin-XX Microscale Protein Labeling Kits

The Biotin-XX Microscale Protein Labeling Kit (B30010; Table 1.2, Table 1.3) provides a convenient means for biotinylating small amounts (20–100 µg) of purified protein. The water-soluble biotin-XX sulfosuccinimidyl ester has a 14-atom spacer (Figure 1.2.5) that enhances the binding of biotin derivatives to avidin's relatively deep binding sites. Spin columns are used to purify the labeled protein, with yields between 60 and 90% depending primarily on the molecular weight of the starting material. Labeling and purification can be completed in as little as 30 minutes.

This kit, which has been optimized for labeling proteins with molecular weights between 12,000 and 150,000 daltons, contains everything needed to perform three labeling reactions and to separate the resulting conjugates from excess reactive biotin. Each Biotin-XX Microscale Protein Labeling Kit provides:

- Three vials of amine-reactive biotin-XX sulfosuccinimidyl ester
- Sodium bicarbonate
- Reaction tubes

- Purification resin and spin filters
- Detailed protocols for conjugation and purification

For determining the degree of labeling, the FluoReporter® Biotin Quantitation Assay Kit for proteins is available separately (F30751) or in combination with the Biotin-XX Microscale Protein Labeling Kit (B30756). When biotinylating larger amounts of protein, we recommend the FluoReporter® Biotin-XX Protein Labeling Kit, which is optimized for 5–20 mg samples, or the FluoReporter® Mini-Biotin-XX Protein Labeling Kit, which is optimized for 0.1–3 mg samples of >30,000-dalton proteins.

FluoReporter® Mini-Biotin-XX Protein Labeling Kit

The FluoReporter® Mini-Biotin-XX Protein Labeling Kit (F6347; Table 1.2, Table 1.3) permits efficient biotinylation of small amounts of antibodies or other proteins. The water-soluble biotin-XX sulfosuccinimidyl ester has a 14-atom spacer (Figure 1.2.5) that enhances the binding of biotin derivatives to avidin's relatively deep binding sites. The ready-to-use spin columns provide a convenient method of purifying the biotinylated protein from excess reagents.

Each FluoReporter® Mini-Biotin-XX Protein Labeling Kit provides sufficient reagents for five labeling reactions of 0.1–3 mg protein each, including:

- Five vials of amine-reactive biotin-XX sulfosuccinimidyl ester
- Reaction tubes, each containing a stir bar
- Purification resin, spin columns and collection tubes
- Dialysis tubing
- Detailed protocols for conjugation and purification

FluoReporter® Biotin-XX Protein Labeling Kit

The FluoReporter® Biotin-XX Protein Labeling Kit (F2610; Table 1.2, Table 1.3) is designed to provide five biotinylation reactions, each containing 5–20 mg of protein. A gel filtration column is used to purify the labeled proteins from excess biotin reagent. Once purified, the degree of biotinylation can be determined using the included avidin–HABA displacement assay; biotinylated goat IgG is provided as a standard.

Each FluoReporter® Biotin-XX Protein Labeling Kit provides sufficient reagents for five labeling reactions of 5–20 mg protein each, including:

- Amine-reactive biotin-XX succinimidyl ester
- Dimethylsulfoxide (DMSO)
- Gel filtration column
- Avidin–HABA complex

Figure 1.2.4 Labeling scheme utilized in the Zenon® Antibody Labeling Kits. **A)** An unlabeled IgG antibody is incubated with the Zenon® labeling reagent, which contains a fluorophore-labeled, Fc-specific anti-IgG Fab fragment. **B)** This labeled Fab fragment binds to the Fc portion of the IgG antibody. **C)** Excess Fab fragment is then neutralized by the addition of a nonspecific IgG, preventing crosslabeling by the Fab fragment in experiments where primary antibodies of the same type are present. Note that the Fab fragment used for labeling need not be coupled to a fluorophore, but could instead be coupled to an enzyme (such as HRP) or to biotin.

- Biotinylated goat IgG
- Detailed protocols for conjugation, purification and determination of the degree of labeling

FluoReporter® Biotin/DNP Protein Labeling Kit

The FluoReporter® Biotin/DNP Protein Labeling Kit (F6348; Table 1.2, Table 1.3) provides the necessary reagents for labeling proteins with DNP-X-biotin-X succinimidyl ester (Figure 1.2.6). The degree of biotinylation of proteins labeled with this reagent can be assessed from the optical absorbance of DNP (EC = 15,000 cm⁻¹M⁻¹ at ~360 nm). The conjugates are recognized by both avidin derivatives (and anti-biotin antibodies) and by anti-DNP antibodies, permitting a choice of detection techniques.

Each FluoReporter® Biotin/DNP Protein Labeling Kit contains sufficient reagents for 5 to 10 labeling reactions of 0.2–2 mg of protein each, including:

- Five vials of amine-reactive DNP-X-biotin-X succinimidyl ester
- Dimethylsulfoxide (DMSO) for dissolving the succinimidyl ester
- Reaction tubes
- Spin columns and collection tubes
- Detailed protocols for conjugation, purification and determination of the degree of labeling

DSB-X™ Biotin Protein Labeling Kit

Our unique DSB-X™ biotin technology, which is described in detail in Section 4.1, permits the facile reversal of the biotin-avidin interaction under extremely gentle conditions.⁴ DSB-X™ biotin succinimidyl ester, a derivative of desthiobiotin (Figure 1.2.7) with an additional seven-atom spacer, reacts with amine groups of biomolecules to form stable amides. Like biotin conjugates, the DSB-X™ biotin conjugate can be detected

Figure 1.2.5 6-((6-((biotinoyl)amino)hexanoyl)amino)hexanoic acid, sulfosuccinimidyl ester, sodium salt (biotin-XX, SSE; B6352).

Figure 1.2.6 Biotin-X 2,4-dinitrophenyl-X-L-lysine, succinimidyl ester (DNP-X-biotin-X, SE; B2604).

with any avidin or streptavidin derivative; with DSB-X™ biotin conjugates, however, this binding is almost totally reversed by addition of free biotin (B1595, B20656; Section 4.2) at neutral pH and normal ionic strength.

The DSB-X™ Biotin Protein Labeling Kit (D20655; Table 1.2, Table 1.3) contains the reagents required for five protein conjugations of 0.5–3 mg each, including:

- Five vials of amine-reactive DSB-X™ biotin succinimidyl ester
- Dimethylsulfoxide (DMSO) for dissolving the succinimidyl ester
- Reaction tubes
- Purification resin, spin columns and collection tubes for small-scale purifications
- Dialysis tubing for larger-scale separations
- Detailed protocols for conjugation and purification

Kits for Labeling Nucleic Acids with a Fluorescent Dye

ULYSIS® Nucleic Acid Labeling Kits

The ULYSIS® Alexa Fluor® Nucleic Acid Labeling Kits (Table 1.2, Table 1.3, Table 8.6) provide a simple, reliable method for producing fluorescent hybridization probes by combining our Alexa Fluor® fluorophores with the versatile, patented Universal Linkage System (ULS®) platinum-based chemistry developed by KREATECH Biotechnology BV. The ULS® technology is based on the use of a platinum dye reagent that forms a stable adduct with the *N*-7 position of guanine and, to a lesser extent, adenine bases in DNA, RNA, peptide-nucleic acid conjugates (PNA) and oligonucleotides (Figure 1.2.8). In protein contexts, ULS® reagents are reactive with cysteine residues and other thiols.⁵

Figure 1.2.7 Comparison of the structures of D-biotin (left) and D-desthiobiotin (right).

Figure 1.2.8 Schematic diagram of the labeling method provided in our ULYSIS® Nucleic Acid Labeling Kits. The ULS® reagent in the ULYSIS® Nucleic Acid Labeling Kits reacts with the *N*-7 position of guanine residues to provide a stable coordination complex between the nucleic acid and the fluorophore label.

The labeling reaction typically takes only 15 minutes, and separation of the labeled nucleic acids from the unreacted ULS[®] reagent can be accomplished through use of a simple spin-column procedure (Figure 1.2.9).

In addition to ULYSIS[®] Alexa Fluor[®] Nucleic Acid Labeling Kits, we offer the ULYSIS[®] Oregon Green[®] 488 Nucleic Acid Labeling Kit (Section 8.2).

Each of these ULYSIS[®] Kits provides sufficient reagents for 20 labelings of 1 µg DNA each, including:

- ULS[®] labeling reagent and appropriate solvent
- Labeling buffer
- Deoxyribonuclease I (DNase I), for digesting DNA longer than 1000 base-pairs prior to labeling
- DNase I storage and reaction buffers
- Control DNA from calf thymus
- Nuclease-free H₂O
- Detailed protocols for preparing fluorescent DNA hybridization probes for chromosome *in situ* hybridization and dot-blot hybridization

Probes labeled using the ULYSIS[®] Kits are stable indefinitely and hybridize effectively to target DNA. The ULS[®] method has been used to prepare labeled probes for dot, Southern and northern blot analysis, RNA and DNA *in situ* hybridization, multicolor FISH, comparative genome hybridization (CGH) and microarray analysis.

ARES[™] DNA Labeling Kits

The ARES[™] DNA Labeling Kits (Table 1.2, Table 1.3, Table 8.6) provide a versatile, two-step method for labeling DNA with several of our premier fluorescent dyes⁶ (Figure 1.2.10). In the first step, an amine-modified nucleotide, 5-(3-aminoallyl)-dUTP (Figure 1.2.11), is incorporated into DNA using conventional enzymatic labeling methods. This step helps ensure relatively uniform labeling of the probe with primary amine groups. The aminoallyl dUTP substrate used in this reaction is taken up efficiently by reverse transcription or nick translation, for which we provide the protocols; other enzymatic methods are also likely to be compatible. In the second step, the amine-modified DNA is chemically labeled using an amine-reactive fluorescent dye. This chemical reaction varies little in its efficiency from dye to dye, so that it is possible to use any combination of the ARES[™] Kits, with their broad selection of the brightest and most photostable dyes, and obtain consistent DNA labeling. The labeling protocols provided generally

result in incorporation of about one dye per 12–15 bases, which we have determined to be optimal for fluorescence *in situ* hybridization (FISH) and dot-blot hybridization.

Each ARES[™] DNA Labeling Kit provides sufficient reagents for 5 to 10 labelings of 1–5 µg DNA each, including:

- 5-(3-Aminoallyl)-dUTP
- Amine-reactive fluorescent dye and appropriate solvent
- Sodium bicarbonate
- Nuclease-free H₂O
- Detailed protocol for labeling DNA using reverse transcription or nick translation

See Section 8.2 for a complete description of the ARES[™] Kits, as well as of the FISH Tag[™] DNA and FISH Tag[™] RNA Kits, which employ the same aminoallyl nucleotide labeling method but provide a complete workflow solution for fluorescence *in situ* hybridization (FISH) applications. Each FISH Tag[™] Kit provides all of the reagents needed for enzymatically incorporating the amine-modified nucleotide (aminoallyl dUTP or aminoallyl UTP) into DNA or RNA, followed by fluorescent labeling with an amine-reactive Alexa Fluor[®] dye and purification of the labeled probe using PureLink[™] nucleic acid purification technology (e.g., PureLink[™] PCR Purification Kit, K3100-01). FISH Tag[™] DNA and FISH Tag[™] RNA Kits are each available as single-color kits containing one of four amine-reactive Alexa Fluor[®] dyes or in a multicolor kit that contains all four reactive Alexa Fluor[®] dyes.

Alexa Fluor[®] Oligonucleotide Amine Labeling Kits

The Alexa Fluor[®] Oligonucleotide Amine Labeling Kits (Section 8.2; Table 1.2, Table 1.3, Table 8.6) provide the reagents required for labeling synthetic oligonucleotides that have amine groups incorporated at their 5'-terminus. Following purification by standard chromatographic or electrophoretic procedures, these singly labeled oligonucleotides can serve as hybridization or ligation probes for a variety of applications.⁷⁻⁹

Each Alexa Fluor[®] Oligonucleotide Amine Labeling Kit contains sufficient reagents for three labelings of 50 µg each of an amine-modified oligonucleotide, including:

- Three vials of amine-reactive dye
- Dimethylsulfoxide (DMSO)
- Three vials of labeling buffer
- Labeling protocol

Figure 1.2.9 Nucleic acid labeling method provided in our ULYSIS[®] Nucleic Acid Labeling Kits.

Biotin Quantitation Assay Kits

FluoReporter® Biotin Quantitation Assay Kit for Biotinylated Proteins

The FluoReporter® Biotin Quantitation Assay Kit for biotinylated proteins (F30751) provides a sensitive fluorometric assay designed to accurately determine the number of biotin labels on a protein. This assay is based on the displacement of a ligand tagged with a quencher dye from the biotin binding sites of Biotective™ Green reagent.¹⁰ The FluoReporter® biotin quantitation assay can detect from 4 to 80 picomoles of biotin in a sample, providing a 50-fold higher sensitivity than the spectrophotometric HABA biotin binding assay. Furthermore, unlike the HABA biotin binding assay, which requires ~1 mg of protein sample, the FluoReporter® biotin quantitation assay requires a minimum of 600 ng of a singly biotinylated IgG with molecular weight 150,000 daltons. For proteins of lower molecular weight or multiple biotin labels, less protein can be used. To expose any biotin groups in multiply labeled proteins that are sterically restricted and inaccessible to the Biotective™ Green reagent, this kit includes protease and an optional protocol for digesting the protein. With this preliminary digestion, biotin assay values agree well with MALDI-TOF determinations. With excitation/emission maxima of 495/519 nm, this assay is compatible with any fluorescence-based microplate reader capable of detecting fluorescein (FITC) or Alexa Fluor® 488 dye; it can also be scaled up for fluorometer-based experiments.

Each FluoReporter® Biotin Quantitation Assay Kit for biotinylated proteins includes:

- Biotective™ Green reagent
- Biocytin standard
- Protease
- Concentrated phosphate-buffered saline (PBS)
- Biotinylated goat anti-mouse IgG antibody for use as a positive control
- Detailed protocols

Sufficient reagents are provided for assaying 5 samples independently using eight wells in triplicate for the standard curve and three dilutions of the sample in triplicate (totaling 33 wells per assay). However, fewer wells may be used to conserve sample and a single standard curve can be used for multiple samples in the same experimental session.

Figure 1.2.10 Schematic diagram of the labeling method provided in our ARES™ DNA Labeling Kits. The ARES™ DNA Labeling Kits use a two-step method to label DNA. Step 1) The aminoallyl dUTP is enzymatically incorporated. Step 2) A reactive fluorophore is used to label the incorporated aminoallyl group.

FluoReporter® Biotin Quantitation Assay Kit for Biotinylated Nucleic Acids

The FluoReporter® Biotin Quantitation Assay Kit for biotinylated nucleic acids (F30755) provides a sensitive fluorometric assay for determining the number of biotin labels on a nucleic acid. This assay is based on the displacement of a quencher dye from the biotin binding sites of Biotective™ Green reagent. The FluoReporter® biotin quantitation assay can detect from 4 to 80 picomoles of biotin in a sample, providing a 50-fold higher sensitivity than the spectrophotometric HABA biotin binding assay. Analysis of multiply biotinylated nucleic acids requires a preliminary nuclease digestion step to avoid underestimation caused by steric restriction of avidin binding. This kit can be applied to as little as 13 ng of biotin-labeled nucleic acid and is ideal for determining the degree of biotinylation of cDNA samples used for microarray expression analysis.

Each FluoReporter® Biotin Quantitation Assay Kit for biotinylated nucleic acids includes:

- Biotective™ Green reagent
- Biotin-dUMP standard
- Nuclease
- Concentrated phosphate-buffered saline (PBS)
- Biotinylated DNA for use as a positive control
- Concentrated nucleic acid digestion buffer
- Detailed protocols

Sufficient reagents are provided for assaying 10 samples independently using eight wells in triplicate for the standard curve and three dilutions of the sample in triplicate (totaling 33 wells per assay). However, fewer wells may be used to conserve sample and a single standard curve can be used for multiple samples in the same experimental session.

1.3 Alexa Fluor® Dyes Spanning the Visible and Infrared Spectrum

Overview of the Alexa Fluor® Dyes

The Alexa Fluor® dyes produce exceptionally bright and photostable conjugates (Table 1.4, Note 1.1). The Alexa Fluor® dyes share several significant attributes, including:

- Strong absorption at wavelengths of maximal output of common excitation sources
- Bright and unusually photostable fluorescence of their bioconjugates
- Good water solubility, which makes the reactive dyes easy to conjugate and the conjugates resistant to precipitation and aggregation
- Insensitivity of their absorption and emission spectra to pH over a broad range
- Well-differentiated spectra, providing many options for multicolor detection and fluorescence resonance energy transfer (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2)
- High quantum yields and long fluorescence lifetimes (Table 1.5)
- Extremely high FRET efficiency, with calculated R_0 values of up to 84 Å between pairs of Alexa Fluor® dyes (Table 1.6) and up to 77 Å between Alexa Fluor® dyes and some nonfluorescent quenchers (Table 1.11)

Alexa Fluor® dyes set new standards for fluorophores and the bioconjugates prepared from them. The absorption spectra (Figure 1.3.1, Figure 1.3.2, Figure 1.3.3) of these superior fluorescent dyes—Alexa Fluor® 350, Alexa Fluor® 405, Alexa Fluor® 430, Alexa Fluor® 488, Alexa Fluor® 514, Alexa Fluor® 532, Alexa Fluor® 546, Alexa Fluor® 555, Alexa Fluor® 568, Alexa Fluor® 594, Alexa Fluor® 610, Alexa Fluor® 633, Alexa Fluor® 635, Alexa Fluor® 647, Alexa Fluor® 660, Alexa Fluor® 680, Alexa Fluor® 700, Alexa Fluor® 750 and Alexa Fluor® 790 dyes—span the visible and infrared spectrum (Table 1.4) and match the principal output wavelengths of common excitation sources.^{1,2} Because there are so many different Alexa Fluor® dyes, we have had to develop a systematic strategy for naming them. We identify these dyes with the registered trademark Alexa Fluor® followed by the optimal excitation wavelength in nm; for example, Alexa Fluor® 488 dye is optimally excited by the 488 nm spectral line of the argon-ion laser.

With spectra almost identical to those of fluorescein (Figure 1.3.4), but with far greater conjugate fluorescence and significantly better conjugate photostability, Alexa Fluor® 488 dye is indisputably the best green-fluorescent reactive dye available. Spectra of Alexa Fluor® 555 dye are an almost perfect match to those of Cy®3 dye (Figure 1.3.5), but conjugates of Alexa Fluor® 555 dye are more fluorescent (Figure 1.3.6) and more photostable (Figure 1.3.7) than those of Cy®3 dye. Similarly, spectra of Alexa Fluor® 647 conjugates substantially match those of the Cy®5 dye (Figure 1.3.8) and Alexa Fluor® 680 and Alexa Fluor® 750 dyes exhibit spectral properties similar to those of Cy®5.5 and Cy®7 dyes, respectively (Figure 1.3.9, Figure 1.3.10). Tandem conjugates of the long-wavelength Alexa Fluor® dyes with R-phycoerythrin or allophycocyanin (Section 6.4) further expand the utility of this dye series in multiplex flow cytometry applications^{3,4} by shifting the phycobiliprotein emission profile relative to the available detection channels (Figure 1.3.11, Figure 1.3.12).

Figure 1.3.4 Absorption and fluorescence emission spectra of fluorescein goat anti-mouse IgG antibody (F2761, (—)) and Alexa Fluor® 488 goat anti-mouse IgG antibody (A11001, (---)). The fluorescence intensity of the Alexa Fluor® 488 conjugate was significantly higher than that of the fluorescein conjugate. The data are normalized to show the spectral similarity.

Figure 1.3.5 Comparison of the absorption and fluorescence emission spectra of Alexa Fluor® 555 and Cy®3 dyes. Spectra have been normalized to the same intensity for comparison purposes.

Green-Fluorescent Alexa Fluor® Dyes

Alexa Fluor® 488 Dye: A Superior Fluorescein Substitute

Based on our testing, publications^{2,5-7} and results reported by customers, Alexa Fluor® 488 dye is by far the best fluorescein (FITC or FAM) substitute available for most applications (The Alexa Fluor® Dye Series—Note 1.1). It is probably the best dye available for single-molecule detection of bioconjugates, for fluorescence correlation spectroscopy (Fluorescence Correlation Spectroscopy (FCS)—Note 1.3) and for fluorescence polarization measurements⁸ (Fluorescence Polarization (FP)—Note 1.4).

This green-fluorescent dye exhibits several unique features:

- Fluorescence spectra almost identical to those of fluorescein, with excitation/emission maxima of 495/519 nm (Figure 1.3.4) and a fluorescence lifetime of ~4.1 nanoseconds (Table 1.5)

- Strong absorption, with an extinction coefficient greater than 65,000 cm⁻¹M⁻¹
- Much greater photostability than fluorescein (Figure 1.3.13), allowing more time for observation and image capture (Figure 1.3.14)
- pH-insensitive fluorescence between pH 4 and 10 (Figure 1.3.15)
- Water solubility, with no organic co-solvents required in labeling reactions, suggesting that the succinimidyl ester of Alexa Fluor® 488 carboxylic acid (A20000, A20100) may be the ideal reagent for labeling amines of exposed cell-surface proteins of live cells⁹
- Superior fluorescence output per protein conjugate, surpassing that of any other spectrally similar fluorophore-labeled protein, including fluorescein conjugates (Figure 1.3.16) and Cy² conjugates of antibodies (Figure 1.3.17)

NOTE 1.1

The Alexa Fluor® Dye Series

The Alexa Fluor® dyes—a series of superior fluorescent dyes that span the visible spectrum—represent a major breakthrough in the development of fluorescent labeling reagents.^{1,2} Benefits of the Alexa Fluor® dyes and their conjugates include:

Brightness—Alexa Fluor® conjugates exhibit more intense fluorescence than other spectrally similar conjugates.

Photostability—Alexa Fluor® conjugates are more photostable than most other fluorescent conjugates, allowing more time for image capture.

Instrument compatibility—Absorption spectra of the Alexa Fluor® conjugates are matched to the principal output wavelengths of common excitation sources.

Color selection—Alexa Fluor® conjugates are available in several distinct fluorescent colors, ranging from blue to red to near-infrared (Figure 1, Table 1).

pH insensitivity—Alexa Fluor® dyes remain highly fluorescent over a broad pH range.

Water solubility—Alexa Fluor® reactive dyes have good water solubility, so protein conjugations can be performed without organic solvents, and the conjugates are relatively resistant to precipitation during storage.

Conventional fluorophores and their conjugates can often be replaced with spectrally similar Alexa Fluor® dyes and conjugates without affecting optical filter choices or other instrumentation considerations (Table 2). Each of the Alexa Fluor® dyes are listed in Table 1 and described in detail in Section 1.3 and in the accompanying Section 1.3 data table.

1. J Histochem Cytochem (2003) 51:1699; 2. J Histochem Cytochem (1999) 47:1179.

Figure 1.3.13 Photobleaching resistance of the green-fluorescent Alexa Fluor® 488, Oregon Green® 488 and fluorescein dyes, as determined by laser-scanning cytometry. EL4 cells were labeled with biotin-conjugated anti-CD44 antibody and detected by Alexa Fluor® 488 (S11223), Oregon Green® 488 (S6368) or fluorescein (S869) streptavidin. The cells were then fixed in 1% formaldehyde, washed and wet-mounted. After mounting, cells were scanned 10 times on a laser-scanning cytometer; laser power levels were 25 mW for the 488 nm spectral line of the argon-ion laser. Scan durations were approximately 5 minutes, and each repetition was started immediately after completion of the previous scan. Data are expressed as percentages derived from the mean fluorescence intensity (MFI) of each scan divided by the MFI of the first scan. Data contributed by Bill Telford, Experimental Transplantation and Immunology Branch, National Cancer Institute.

Figure 1.3.14 Comparison of the photobleaching rates of the Alexa Fluor® 488 and Alexa Fluor® 546 dyes and the well-known fluorescein and Cy³ fluorophores. The cytoskeleton of bovine pulmonary artery endothelial cells (BPAEC) was labeled with (top series) Alexa Fluor® 488 phalloidin (A12379) and mouse monoclonal anti- α -tubulin antibody (A11126) in combination with Alexa Fluor® 546 goat anti-mouse IgG antibody (A11003) or (bottom series) fluorescein phalloidin (F432) and the anti- α -tubulin antibody in combination with a commercially available Cy³ goat anti-mouse IgG antibody. The pseudocolored images were taken at 30-second intervals (0, 30, 90 and 210 seconds of exposure; left to right). The images were acquired with bandpass filter sets appropriate for fluorescein and rhodamine.

* Measurements were made on free succinimidyl ester derivatives in aqueous solutions. † For Alexa Fluor® 488, Alexa Fluor® 532, Alexa Fluor® 546, Alexa Fluor® 555, Alexa Fluor® 568, Alexa Fluor® 594 and Alexa Fluor® 647 dyes, QY measurements were made in PBS (50 mM potassium phosphate, 150 mM NaCl, pH 7.2) at 22°C relative to fluorescein in 0.01 M NaOH (QY = 0.92). For Alexa Fluor® 660, Alexa Fluor® 680, Alexa Fluor® 700 and Alexa Fluor® 750 dyes, QY measurements were made in PBS (50 mM potassium phosphate, 150 mM NaCl, pH 7.2) at 22°C relative to Alexa Fluor® 647 succinimidyl ester in PBS (QY = 0.33). ‡ Except for the footnoted values, lifetime measurements were made in water at 22°C, data provided by ISS Inc. (Champaign, IL). § Lifetime measurements were provided by the SPEX Fluorescence Group, Horiba Jobin Yvon, Inc. ** Lifetime measurement was made in pH 7.5 buffer at 20°C by Pierre-Alain Muller, Max Planck Institute for Biophysical Chemistry, Göttingen.

Figure 1.3.15 Comparison of pH-dependent fluorescence of the Oregon Green® 488 (●), carboxyfluorescein (○) and Alexa Fluor® 488 (□) fluorophores. Fluorescence intensities were measured for equal concentrations of the three dyes using excitation/emission at 490/520 nm.

Figure 1.3.16 Comparison of the relative fluorescence of goat anti-mouse IgG antibody conjugates prepared from Alexa Fluor® 488 dye and from fluorescein isothiocyanate (FITC). Conjugate fluorescence is determined by measuring the fluorescence quantum yield of the conjugated dye relative to that of a reference dye and multiplying by the dye:protein labeling ratio.

Table 1.6 R_0 values for some Alexa Fluor® dyes.

Donor	Acceptor					
	Alexa Fluor® 488	Alexa Fluor® 546	Alexa Fluor® 555	Alexa Fluor® 568	Alexa Fluor® 594	Alexa Fluor® 647
Alexa Fluor® 350	50					
Alexa Fluor® 488	NA	64	70	62	60	56
Alexa Fluor® 546		NA		70	71	74
Alexa Fluor® 555			NA		47	51
Alexa Fluor® 568				NA		82
Alexa Fluor® 594					NA	85
Alexa Fluor® 647						NA

R_0 values in angstroms (Å) represent the distance at which fluorescence resonance energy transfer from the donor dye to the acceptor dye is 50% efficient (Förster radius). Values were calculated from spectroscopic data as outlined (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). NA = Not applicable.

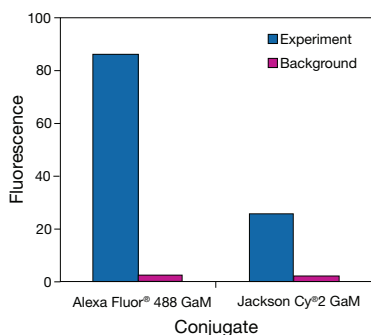

Figure 1.3.17 Brightness comparison of Molecular Probes® Alexa Fluor® 488 goat anti-mouse IgG antibody with Cy2 goat anti-mouse IgG antibody from Jackson ImmunoResearch. Human blood was blocked with normal goat serum and incubated with an anti-CD3 mouse monoclonal antibody; cells were washed, resuspended and incubated with either Alexa Fluor® 488 or Cy2 goat anti-mouse IgG antibody at equal concentration. Red blood cells were lysed, and the samples were analyzed with a flow cytometer equipped with a 488 nm argon-ion laser and a 525 ± 10 nm bandpass emission filter.

Figure 1.3.18 Alexa Fluor® 488 carboxylic acid, 2,3,5,6-tetrafluorophenyl ester (Alexa Fluor® 488 5-TFP, A30005).

The monosuccinimidyl ester of Alexa Fluor® 488 carboxylic acid is a mixture of two isomers and is available in a 1 mg or 5 mg unit size (A20000, A20100). The isomerically pure 5-isomer of Alexa Fluor® 488 dye is also available as the more hydrolytically stable tetrafluorophenyl (TFP) ester (A30005, Figure 1.3.18) and sulfodichlorophenol (SDP) ester (A30052, Figure 1.3.19).

TFP and SDP esters are an improvement over the succinimidyl ester (NHS ester or SE) chemistry typically used to attach fluorophores or haptens to the primary amines of biomolecules. All three reactive chemistries produce the same strong amide bond between the dye or hapten and the compound of interest (see reaction schemes in Section 1.1), but TFP and SDP esters are less susceptible to spontaneous hydrolysis during conjugation reactions. Both Alexa Fluor® 488 carboxylic

NOTE 1.2

Fluorescence Resonance Energy Transfer (FRET)

Fluorescence resonance energy transfer (FRET) is a distance-dependent interaction between the electronic excited states of two dye molecules in which excitation is transferred from a donor molecule to an acceptor molecule *without emission of a photon*. The efficiency of FRET is dependent on the inverse sixth power of the intermolecular separation,¹ making it useful over distances comparable to the dimensions of biological macromolecules. Thus, FRET is an important technique for investigating a variety of biological phenomena that produce changes in molecular proximity.^{2–11} When FRET is used as a contrast mechanism, colocalization of proteins and other molecules can be imaged with spatial resolution beyond the limits of conventional optical microscopy.^{12,13}

Primary Conditions for FRET

- Donor and acceptor molecules must be in close proximity (typically 10–100 Å).
- The absorption spectrum of the acceptor must overlap the fluorescence emission spectrum of the donor (Figure 1).
- Donor and acceptor transition dipole orientations must be approximately parallel.

Förster Radius

The distance at which energy transfer is 50% efficient (i.e., 50% of excited donors are deactivated by FRET) is defined by the Förster radius (R_0). The magnitude of R_0 is dependent on the spectral properties of the donor and acceptor dyes (Table 1):

$$R_0 = [8.8 \times 10^{23} \cdot \kappa^2 \cdot n^{-4} QY_D \cdot J(\lambda)]^{1/6} \text{ \AA}$$

where κ^2 = dipole orientation factor (range 0–4;
 $\kappa^2 = 2/3$ for randomly oriented donors and acceptors)
 QY_D = fluorescence quantum yield of the donor
 in the absence of the acceptor
 n = refractive index
 $J(\lambda)$ = spectral overlap integral (see figure)
 $= \int \epsilon_A(\lambda) \cdot F_D(\lambda) \cdot \lambda^4 d\lambda \text{ cm}^3 \text{ M}^{-1}$

where ϵ_A = extinction coefficient of acceptor
 F_D = fluorescence emission intensity of donor as a fraction of the total integrated intensity

Figure 1 Schematic representation of the FRET spectral overlap integral.

Table 1 Typical Values of R_0 .

Figure 2 Principle of the fluorogenic response to protease cleavage exhibited by HIV protease substrate 1 (H2930). Quenching of the EDANS fluorophore (F) by distance-dependent resonance energy transfer to the dabcyl quencher (Q) is eliminated upon cleavage of the intervening peptide linker.

acid TFP ester and Alexa Fluor® 488 SDP ester are stable for several hours at the basic pH typically used for reactions—far outlasting succinimidyl esters. Alexa Fluor® 488 carboxylic acid TFP ester is the amine-reactive dye included in most of our labeling kits for proteins, nucleic acids and oligonucleotides (Section 1.2; Table 1.2, Table 1.4), including the Alexa Fluor® 488 Microscale Protein Labeling Kit (A30006), the Alexa Fluor® 488 Monoclonal Antibody Labeling Kit (A20181), the Alexa Fluor® 488 Protein Labeling Kit (A10235), the ARES™ Alexa Fluor® 488 DNA Labeling Kit (A21665) and the Alexa Fluor® 488 Oligonucleotide Amine Labeling Kit (A20191). Alexa Fluor® 488 carboxylic acid SDP ester is the amine-reactive dye included in the APEX® Alexa Fluor® 488 Antibody Labeling Kit (A10468).

Alexa Fluor® 514 Dye: A Perfect Match to the Argon-Ion Laser

Like our Alexa Fluor® 488 dye, Alexa Fluor® 514 dye (excitation/emission maxima ~518/540 nm) is superior to fluorescein in both brightness and photostability and can be detected with standard fluorescein, Oregon Green® dye or Alexa Fluor® 488 dye filter sets. However, Alexa Fluor® 514 dye is spectrally distinguishable from Alexa Fluor® 488 dye and other green fluorophores using spectral imaging instruments with linear-unmixing software.^{10,11} Alexa Fluor® 514 dye is one of the brightest and most photostable dyes available for excitation by the 514 nm spectral line of the argon-ion laser. Alexa Fluor® 514 dye is available as a succinimidyl ester (A30002) and as antibody (Section 7.2, Table 7.1) and streptavidin (Section 7.6, Table 7.9) conjugates.

Figure 1.3.19 Alexa Fluor® 488 5-SDP ester (Alexa Fluor® 488 sulfodichlorophenol ester, A30052).

Donor/Acceptor Pairs

In most applications, the donor and acceptor dyes are different, in which case FRET can be detected by the appearance of sensitized fluorescence of the acceptor or by quenching of donor fluorescence. When the donor and acceptor are the same, FRET can be detected by the resulting fluorescence depolarization.¹⁴ Typical values of R_0 for some dye pairs are listed in Table 1 and more extensive compilations are in Table 1.6 and Table 1.11. Note that because the component factors of R_0 are dependent on the environment, the actual value observed in a specific experimental situation is somewhat variable. Extensive compilations of R_0 values can be found in the literature.^{3,8,11} Nonfluorescent acceptors such as dabcyI and QSY® dyes (Table 1.10) have the particular advantage of eliminating the potential problem of background fluorescence resulting from direct (i.e., nonsensitized) acceptor excitation. FRET efficiencies from several donor dyes to the QSY® 7 quencher in molecular beacon hybridization probes have been calculated.¹⁵ Probes incorporating fluorescent donor–nonfluorescent acceptor combinations have been developed primarily for detecting proteolysis¹⁶ (Figure 2) and nucleic acid hybridization.

Selected Applications of FRET

- Structure and conformation of proteins^{17–22}
- Spatial distribution and assembly of protein complexes^{23–27}
- Receptor/ligand interactions^{28–32}
- Immunoassays^{33,34}
- Probing interactions of single molecules³⁵
- Structure and conformation of nucleic acids^{36–41}
- Real-time PCR assays and SNP detection^{42–47}
- Detection of nucleic acid hybridization^{48–53}
- Primer-extension assays for detecting mutations⁵⁴
- Automated DNA sequencing^{55–57}
- Distribution and transport of lipids^{58–60}
- Membrane fusion assays^{61–64} (Lipid-Mixing Assays of Membrane Fusion—Note 13.1)
- Membrane potential sensing⁶⁵
- Fluorogenic protease substrates^{16,66–69}
- Indicators for cyclic AMP^{70,71} and zinc⁷²

Figure 1.3.20 A bovine pulmonary artery endothelial (BPAE) cell labeled with mouse monoclonal anti- α -tubulin antibody (A11126) in combination with Alexa Fluor® 430 goat anti-mouse IgG antibody (A11063) to stain microtubules. The image was acquired using a longpass filter set allowing excitation at 455 ± 35 nm and emission at wavelengths greater than 515 nm.

Alexa Fluor® 430 Dye: Filling the Spectral Gap Between Green and Yellow

Few reactive dyes that absorb between 400 nm and 450 nm have appreciable fluorescence beyond 500 nm in aqueous solution. Alexa Fluor® 430 dye fills this spectral gap (Figure 1.3.1, Figure 1.3.20). Excitation near its absorption maximum at 431 nm is accompanied by an extremely large Stokes shift and strong yellow-green fluorescence (emission maximum \sim 541 nm). The coumarin-based amine-reactive succinimidyl ester of Alexa Fluor® 430 carboxylic acid (A10169, Figure 1.3.21) is available, as well as Alexa Fluor® 430 conjugates of secondary antibodies (A11063, A11064; Section 7.2) and streptavidin (S11237, Section 7.6). Alexa Fluor® 430 dye-labeled Fab' fragments are provided in the Zenon® Alexa Fluor® 430 Antibody Labeling Kits (Section 7.3, Table 7.7). We also offer the Alexa Fluor® 430 Protein Labeling Kit (A10171), which is described in detail in Section 1.2 (Table 1.2, Table 1.4).

Yellow-to-Red-Fluorescent Alexa Fluor® Dyes

As with the green-fluorescent Alexa Fluor® 488 dye, the yellow-, orange- and red-fluorescent Alexa Fluor® dyes exhibit several features that distinguish them from spectrally similar fluorophores:

- Strong absorption, with extinction coefficients greater than $80,000 \text{ cm}^{-1}\text{M}^{-1}$ for Alexa Fluor® 532, Alexa Fluor® 546, Alexa Fluor® 568 and Alexa Fluor® 594 dyes and greater than $130,000 \text{ cm}^{-1}\text{M}^{-1}$ for Alexa Fluor® 555 and Alexa Fluor® 610 dyes

NOTE 1.3

Fluorescence Correlation Spectroscopy (FCS)

Fluorescence correlation spectroscopy (FCS) is a technique in which spontaneous fluorescence intensity fluctuations are measured in a microscopic detection volume of about 10^{-15} L (1 femtoliter) defined by a tightly focused laser beam.¹⁻³ Renewed interest in FCS in recent years has been stimulated by the fact that it is inherently miniaturized and therefore applicable for high-throughput screening applications.⁴ Fluorescence intensity fluctuations measured by FCS represent changes in either the number or the fluorescence quantum yield of molecules resident in the detection volume (Figure 1). Small, rapidly diffusing molecules produce rapidly fluctuating intensity patterns, whereas larger molecules produce more sustained bursts of fluorescence.

This situation is in marked contrast to conventional fluorescence photometry carried out in sample volumes of around 0.1–1.0 mL (\sim 10^8 times larger than FCS measurement volumes) that report only the macroscopic average of diffusion-dependent intensity fluctuations. In a typical FCS measurement, fluorescence intensity is recorded for a small number of molecules in the detection volume (e.g., 3 molecules/femtoliter, equivalent to \sim 5 nM macroscopic concentration) over a time range from about 1 microsecond to 1 second. The time-dependent fluorescence intensity ($F(t)$) is then analyzed in terms of its temporal autocorrelation function ($G(\tau)$), which compares the fluorescence intensity at time t with the intensity at $(t + \tau)$, where τ is a

$$G(\tau) = \frac{\langle \delta F(t) \delta F(t + \tau) \rangle}{\langle F(t) \rangle^2}$$

variable interval, averaged over all data points in the time series:

The autocorrelation function contains information about equilibrium concentrations, reaction kinetics and diffusion rates of molecules in the sample. The initial amplitude of the autocorrelation function is inversely proportional to the number of molecules in the detection volume. The autocorrelation function decays from its initial value with a time-dependence that is determined by molecular diffusion rates. For example, free

fluorescent ligands exhibit faster autocorrelation decay than slower-moving complexed ligands (Figure 2).

Probes and Applications for FCS

FCS is applicable for monitoring a multitude of biomolecular association and dissociation processes (Table 1). Because FCS is intrinsically sensitive to the mass changes occurring in these processes, probe design and selection is generally less critical than it is in assays based on macroscopic fluorescence intensity changes generated by dye–dye interactions (FRET, self-quenching etc.) or environment-dependent fluorescence enhancement. Dyes that perform well in confocal laser-scanning microscopy are usually among the best choices for FCS applications. Laser sources used for excitation in FCS include the 488 nm argon-ion spectral line and the 543 nm and 633 nm He-Ne laser spectral lines. Dyes with appreciable rates of triplet state population via intersystem crossing are generally not well suited for FCS measurement because this process results in an additional submillisecond autocorrelation decay component.⁵

Technical Developments in FCS

Two-photon excitation (TPE) has been applied to FCS for reasons similar to those that have motivated its use in fluorescence microscopy—inherent spatial confinement of excitation, diminished photobleaching and phototoxicity, less scattering and better optical penetration in turbid media.^{6,7} Dual-color cross-correlation FCS^{8,9} measures the cross-correlation of the time-dependent fluorescence intensities of two spectrally distinct dyes, instead of the conventional autocorrelation for a single dye. This approach has the advantage that cross-correlated fluorescence is only generated by molecules or complexes labeled with both dyes, allowing quantitation of interacting molecules without reference to their diffusion characteristics. In practice, discrimination based on mass in conventional FCS requires that the interacting components should have a molecular weight ratio of at least 1:7. FCS measurements using TPE in combination with dual-color cross-correlation have been reported.¹⁰

- Fluorescence that is more photostable than that of other spectrally similar dyes, allowing more time for observation and image capture
- pH-insensitive fluorescence over a broad range
- Good water solubility, permitting labeling reactions to be performed without organic solvents
- Superior fluorescence output per protein or nucleic acid conjugate, surpassing that of any other spectrally similar fluorophore-labeled protein
- Long fluorescence lifetimes (approximately 4.1, 3.6 and 3.9 nanoseconds for Alexa Fluor® 546, Alexa Fluor® 568 and Alexa Fluor® 594 dyes, respectively (Table 1.5))

Alexa Fluor® 532 Dye: Optimal Dye for 532 nm Diode Lasers

The yellow-fluorescent Alexa Fluor® 532 dye (excitation/emission maxima ~532/554 nm) absorbs in the wavelength between the green-fluorescent Alexa Fluor® 488 dye and orange-fluorescent Alexa Fluor® 546 dye (Figure 1.3.2) and provides strong visible fluorescence that contrasts well with these dyes. Five of our Alexa Fluor® dyes—Alexa Fluor® 488, Alexa Fluor® 532, Alexa Fluor® 546, Alexa Fluor® 568 and Alexa Fluor® 594 dyes—have been utilized for simultaneous seven-color fluorescence imaging in tissue samples.¹² The use of Alexa Fluor® 532 dye-labeled actin (instead of the equivalent tetramethylrhodamine conjugate) has been reported to be crucial for studying the polarity of individual filaments during the formation of actin bundles by total internal reflection fluorescence (TIRF) microscopy.¹³ The isomer-free, amine-reactive monosuccinimidyl ester of Alexa Fluor® 532 dye is available in either a 1 mg or 5 mg unit size (A20001, A20101MP) and as a

Figure 1.3.21 Alexa Fluor® 430 carboxylic acid, succinimidyl ester (A10169).

Figure 1 Physical origins of fluorescence correlation spectroscopy data. Free fluorescent ligands move in and out of the detection volume (open circle) and are detected as a series of short, randomized fluorescence bursts (top panel). Macromolecule-bound ligands are less mobile, producing a more slowly fluctuating (i.e., more highly autocorrelated) time-dependent fluorescence pattern (bottom panel).

Table 1 Applications of fluorescence correlation spectroscopy.

NOTE 1.4

Fluorescence Polarization (FP)

Principles

Fluorescence polarization measurements provide information on molecular orientation and mobility and processes that modulate them, including receptor–ligand interactions, protein–DNA interactions, proteolysis, membrane fluidity and muscle contraction (Figure 1).

Because polarization is a general property of fluorescent molecules (with certain exceptions such as lanthanide chelates), polarization-based readouts are somewhat less dye dependent and less susceptible to environmental interferences such as pH changes than assays based on fluorescence intensity measurements. Experimentally, the degree of polarization is determined from measurements of fluorescence intensities parallel and perpendicular with respect to the plane of linearly polarized excitation light, and is expressed in terms of fluorescence polarization (P) or anisotropy (r):

$$P = \frac{(F_{\parallel} - F_{\perp})}{(F_{\parallel} + F_{\perp})} \quad r = \frac{(F_{\parallel} - F_{\perp})}{(F_{\parallel} + 2F_{\perp})}$$

where F_{\parallel} = fluorescence intensity parallel to the excitation plane
 F_{\perp} = fluorescence intensity perpendicular to the excitation plane

Note that both P and r are ratio quantities with no nominal dependence on dye concentration. Because of the ratio formulation, fluorescence intensity variations due to the presence of colored sample additives tend to cancel and produce relatively minor interferences.¹ P has physically possible values ranging from –0.33 to 0.5. In practice, these limiting values are rarely attained. Measured values of P in bio-analytical applications typically range from 0.01 to 0.3 or 10 to 300 mP (mP = P/1000). This measurement range is not as narrow as it might appear to be because very precise measurements ($P \pm 0.002$ or ± 2 mP) are readily obtainable with modern instrumentation.

Figure 1 Physical basis of fluorescence polarization assays. Dye molecules with their absorption transition vectors (arrows) aligned parallel to the electric vector of linearly polarized light (along the vertical page axis) are selectively excited. For dyes attached to small, rapidly rotating molecules, the initially photoselected orientational distribution becomes randomized prior to emission, resulting in low fluorescence polarization. Conversely, binding of the low molecular weight tracer to a large, slowly rotating molecule results in high fluorescence polarization. Fluorescence polarization therefore provides a direct readout of the extent of tracer binding to proteins, nucleic acids and other biopolymers.

Dependence of Fluorescence Polarization on Molecular Mobility

Interpretation of the dependence of fluorescence polarization on molecular mobility is usually based on a model derived in 1926 from the physical theory of Brownian motion by Perrin.^{2,3}

$$\left(\frac{1}{P} - \frac{1}{3}\right) = \left(\frac{1}{P_0} - \frac{1}{3}\right) \left(1 + \frac{\tau}{\phi}\right)$$

where P_0 is the fundamental polarization of the dye (for fluorescein, rhodamine and BODIPY® dyes, P_0 is close to the theoretical maximum of 0.5), τ is the excited-state lifetime of the dye and ϕ is the rotational correlation time of the dye or dye conjugate. These relationships can be expressed in terms of fluorescence anisotropy in an equivalent and mathematically simpler manner. For a hydrodynamic sphere, ϕ can be estimated as follows:

$$\phi = \frac{\eta V}{RT}$$

where η = solvent viscosity, T = temperature, R = gas constant and V = molecular volume of the fluorescent dye or dye conjugate. In turn, V can be estimated from the molecular weight of the dye or dye conjugate with appropriate adjustments for hydration. Simulations of these relationships are shown in Figure 2, leading to the following general conclusions:

- Fluorescence polarization increases as molecular weight increases.
- Fluorescence polarization increases as solvent viscosity increases.
- Fluorescence polarization decreases as the excited state lifetime of the dye (τ) increases.

Note that these simulations assume that the dye is rigidly attached to a spherical carrier. When conventional parameter estimates for proteins in aqueous solutions are used, ϕ is found to increase by about 1 ns per 2400 dalton increase of molecular weight.⁴

Dyes for Fluorescence Polarization Assays

Tracers used in fluorescence polarization assays include peptides, drugs and cytokines that are modified by the attachment of a fluorescent dye. Depolarization due to flexibility in the attachment of the dye, sometimes referred to as the "propeller effect," distorts the relationships between P and molecular weight shown in Figure 2. For this reason, it is generally preferable to use reactive dyes without aliphatic linkers between the fluorophore and the reactive group in the preparation of tracers for fluorescence polarization assays.^{5,6}

A key factor in the performance of fluorescence polarization assays is the extent to which the biological activity of the tracer is perturbed by the dye modification. BODIPY® dyes generally produce less perturbation of receptor-binding affinity and other activity parameters than conventional dyes such as fluorescein and rhodamine.^{7,8} Furthermore, BODIPY® dyes usually have

longer excited-state lifetimes than fluorescein and rhodamine dyes, making their fluorescence polarization sensitive to binding interactions over a larger molecular weight range (Figure 2). The long-wavelength BODIPY® TMR and BODIPY® TR dyes also tend to minimize assay interferences due to intrinsically fluorescent sample contaminants.⁷

Applications

Fluorescence polarization measurements have long been a valuable biophysical research tool for investigating processes such as membrane lipid mobility, myosin reorientation and protein–protein interactions at the molecular level.^{9–12} Immunoassays that have been developed and used extensively for clinical diagnostics represent the largest group of bioanalytical applications.^{13,14} The more recent advent of microplate readers equipped with polarizing optics has led to the adoption of fluorescence polarization as a readout mode for high-throughput screening.^{15–17} Some typical bioanalytical applications of fluorescence polarization–based assays are summarized in Table 1.

Figure 2 Simulation of the relationship between molecular weight (MW) and fluorescence polarization (P). Simulations are shown for dyes with various fluorescence lifetimes (τ): 1 ns (cyanine dyes) in purple, 4 ns (fluorescein and Alexa Fluor 488 dyes) in red, 6 ns (some BODIPY dyes) in green and 20 ns (dansyl dyes) in blue. At MW = 1000, $P = 0.167$ for $\tau = 1$ ns, $P = 0.056$ for $\tau = 4$ ns, $P = 0.039$ for $\tau = 6$ ns and $P = 0.012$ for $\tau = 20$ ns. Simulations assume P_0 (the fundamental polarization) = 0.5 and rigid attachment of dyes to spherical carriers.

Figure 1.3.22 Fluorescence output from an Alexa Fluor® 546 goat anti-mouse IgG antibody (dye:protein ratio = 5.7) and a commercially available Cy³ goat anti-mouse IgG antibody (dye:protein ratio = 3.8). Antibody concentrations were adjusted to give equal absorbance at the excitation wavelength (535 nm). The relative fluorescence quantum yield of Alexa Fluor® 546 conjugates is higher than that of Cy³ conjugates, even at high dye:protein ratios that would typically result in self-quenching effects with most other protein-labeling dyes.

Figure 1.3.23 Brightness comparison of Alexa Fluor® 555 goat anti-mouse IgG antibody with commercially available Cy³ goat anti-mouse IgG antibody conjugates. Human blood was blocked with normal goat serum and incubated with a mouse monoclonal anti-CD3 antibody; cells were washed, resuspended and incubated with either Alexa Fluor® 555 or Cy³ goat anti-mouse IgG antibody at equal concentrations. Red blood cells were lysed and the samples were analyzed with a flow cytometer equipped with a 488 nm argon-ion laser and a 585 ± 21 nm bandpass emission filter.

Figure 1.3.24 Neuronal cells in a 22-hour zebrafish embryo were identified with anti-HuC/HuD mouse monoclonal antibody (A21271) and visualized with red-orange-fluorescent Alexa Fluor® 568 goat anti-mouse IgG antibody (A11004). The nuclei were stained with blue-fluorescent DAPI (D1306, D3571, D21490).

component of several labeling kits (Table 1.2, Table 1.4). The contents and utility of these protein and nucleic acid labeling kits are discussed in detail in Section 1.2.

Alexa Fluor® 546 and Alexa Fluor® 555 Dyes: Superior Alternatives to Cy³ and Tetramethylrhodamine

The orange-fluorescent Alexa Fluor® 546 (excitation/emission maxima ~556/573 nm) and Alexa Fluor® 555 (excitation/emission maxima ~555/565 nm) dyes have spectra that are similar to tetramethylrhodamine and the Cy³ dye. The spectra of Alexa Fluor® 555 dye are an almost exact match to those of the Cy³ dye (Figure 1.3.5), and therefore optical filters designed for Cy³ dye also work with Alexa Fluor® 555 dye. Conjugates of Alexa Fluor® 546 and Alexa Fluor® 555 dyes typically outperform tetramethylrhodamine (TRITC and TAMRA) and Cy³ conjugates (Figure 1.3.22, Figure 1.3.23), and Alexa Fluor® 555 conjugates are more fluorescent at a higher degree of substitution (DOS) than are Cy³ conjugates (Figure 1.3.6). Alexa Fluor® 555 dye is also more photostable than Cy³ dye (Figure 1.3.7), providing more time for image capture.

We have observed that, unlike most other Alexa Fluor® dyes, antifade reagents provide little protective effect for conjugates of Alexa Fluor® 546 dye; if photobleaching is a limitation, the spectrally similar Alexa Fluor® 555 dye should be used in place of Alexa Fluor® 546 dye. The isomeric mixture of the amine-reactive monosuccinimidyl ester of Alexa Fluor® 546 dye (A20002, A20102) and the isomer-free monosuccinimidyl ester of Alexa Fluor® 555 dye (A20009, A20109) are available in either a 1 mg or 5 mg unit size and as components of several labeling kits (Table 1.2, Table 1.4). The contents and utility of these protein and nucleic acid labeling kits are discussed in detail in Section 1.2.

Alexa Fluor® 568 Dye: A Perfect Match to 561 nm Diode Lasers

The red-orange-fluorescent Alexa Fluor® 568 dye (excitation/emission maxima ~578/603 nm, Figure 1.3.24) is optimally excited by the 561 nm diode lasers used in many confocal laser-scanning microscopes. Although Alexa Fluor® 568 conjugates exhibit absorption and fluorescence emission maxima similar to those of Lissamine rhodamine B conjugates, they are considerably brighter. The isomeric mixture of the amine-reactive monosuccinimidyl ester of Alexa Fluor® 568 dye is available in either a 1 mg or 5 mg unit size (A20003, A20103) and as a component of several labeling kits (Table 1.2, Table 1.4). The contents and utility of these protein and nucleic acid labeling kits are discussed in detail in Section 1.2.

Alexa Fluor® 594 and Alexa Fluor® 610 Dyes: Brighter Red-Fluorescent Dyes

The red-fluorescent Alexa Fluor® 594 dye (excitation/emission maxima ~590/617 nm) has absorption and fluorescence emission maxima similar to those of Texas Red® dye, making it particularly useful for multilabeling experiments in combination with green-fluorescent probes. Alexa Fluor® 594 conjugates are brighter than similarly labeled Texas Red® conjugates, can be labeled to a higher degree of substitution (DOS) (Figure 1.3.25), and are efficiently excited by 561 nm diode lasers and the 594 nm line of the orange He-Ne laser.

The bright and photostable Alexa Fluor® 610 dye (excitation/emission maxima ~612/628 nm) emits an intense red fluorescence that is easily distinguished from green fluorescence and can be visualized with the same optics used for Texas Red® and Alexa Fluor® 594 dyes. Unlike the fluorescence of Alexa Fluor® 633 dye and longer-wavelength fluorophores, Alexa Fluor® 610 fluorescence can still be seen with the human eye.

Figure 1.3.25 Comparison of the relative fluorescence of Alexa Fluor® 594 and Texas Red®-X goat anti-mouse IgG antibody F(ab')₂ fragment conjugates at different dye:protein ratios.

The isomeric mixture of the amine-reactive monosuccinimidyl ester of Alexa Fluor® 594 dye is available in either a 1 mg or 5 mg unit size (A20004, A20104) and the 6-isomer of the monosuccinimidyl ester of Alexa Fluor® 610-X dye is available in a 1 mg unit size (A30050). These red-fluorescent Alexa Fluor® dyes are also available as components of several labeling kits (Table 1.2, Table 1.4); the contents and utility of these protein and nucleic acid labeling kits are discussed in detail in Section 1.2.

Far-Red- and Near-Infrared-Fluorescent Alexa Fluor® Dyes

One of our long-term goals has been to develop superior dyes that can be excited by long-wavelength excitation sources, including the red He-Ne laser (at 633 nm), krypton-ion laser (at 647 nm) and diode lasers. Long-wavelength excitation generally provides increased optical penetration of tissues and decreased autofluorescence background, both key enabling prerequisites for *in vivo* imaging applications.¹⁴⁻¹⁶ It has been particularly challenging to prepare long-wavelength reactive dyes whose fluorescence is not significantly quenched upon conjugation. Our far-red- and near-infrared-fluorescent Alexa Fluor® dyes (Figure 1.3.3) meet our goals in several ways:^{1,17}

- Very high extinction coefficients—typically >165,000 cm⁻¹M⁻¹ but up to 290,000 cm⁻¹M⁻¹ for Alexa Fluor® 750 dye
- Excellent spectral match to common long-wavelength excitation sources
- Spectra of Alexa Fluor® 647, Alexa Fluor® 680 and Alexa Fluor® 750 conjugates that virtually match those of the Cy®5 dye (Figure 1.3.8), Cy®5.5 dye (Figure 1.3.9) and Cy®7 dye (Figure 1.3.10), respectively, resulting in an optimal match to optical filters designed for these dyes
- Photostability of Alexa Fluor® 633 and Alexa Fluor® 647 conjugates that exceeds that of Cy®5, allophycocyanin and PBXL-3 conjugates (Figure 1.3.26)
- Unusually low fluorescence quenching upon conjugation to proteins, even at relatively high degrees of substitution (Figure 1.3.27), resulting in protein conjugates that are typically at least three to four times brighter than those of Cy®5, Cy®5.5, Cy®7 and similar dyes^{18,19} but that are, in some cases, as much as 40-fold brighter at equal antibody concentrations (Figure 1.3.28, Figure 1.3.29)
- Fluorescence of the nucleotide, oligonucleotide and nucleic acid conjugates of Alexa Fluor® 647 dye that usually exceeds that of the Cy®5 dye conjugates (Section 8.2)

Figure 1.3.28 Flow cytometry was used to compare the brightness of Molecular Probes® Alexa Fluor® 647 goat anti-mouse IgG antibody (red, A21235) with commercially available Cy®5 goat anti-mouse IgG antibody from Jackson ImmunoResearch Laboratories (green) and Amersham® Biosciences Biotech (blue). Human blood was blocked with normal goat serum and incubated with an anti-CD3 mouse monoclonal antibody; cells were washed, resuspended and incubated with either an Alexa Fluor® 647 or Cy®5 goat anti-mouse IgG secondary antibody at equal concentration. Red blood cells were lysed and the samples were analyzed on a flow cytometer equipped with a 633 nm He-Ne laser and a longpass emission filter (>650 nm).

Figure 1.3.29 Brightness comparison of Molecular Probes® Alexa Fluor® 647 goat anti-mouse IgG antibody with Cy®5 goat anti-mouse IgG antibody conjugates commercially available from other companies. Human blood was blocked with normal goat serum and incubated with an anti-CD3 mouse monoclonal antibody; cells were washed, resuspended and incubated with either Alexa Fluor® 647 or Cy®5 goat anti-mouse IgG antibody at an equal concentration. Red blood cells were lysed and the samples were analyzed with a flow cytometer equipped with a 633 nm He-Ne laser and a longpass emission filter (>650 nm).

Figure 1.3.26 Photobleaching resistance of the far-red-fluorescent Alexa Fluor® 647, Alexa Fluor® 633, PBXL-3 and Cy®5 dyes and the allophycocyanin fluorescent protein, as determined by laser-scanning cytometry. EL4 cells were labeled with biotin-conjugated anti-CD44 antibody and detected by Alexa Fluor® 647 (S21374), Alexa Fluor® 633 (S21375), PBXL-3, Cy®5 or allophycocyanin (APC, S868) streptavidin. The cells were then fixed in 1% formaldehyde, washed and wet-mounted. After mounting, cells were scanned eight times on a laser-scanning cytometer; laser power levels were 18 mW for the 633 nm spectral line of the He-Ne laser. Scan durations were approximately 5 minutes apiece, and each repetition was started immediately after completion of the previous scan. Data are expressed as percentages derived from the mean fluorescence intensity (MFI) of each scan divided by the MFI of the first scan. Data contributed by Bill Telford, Experimental Transplantation and Immunology Branch, National Cancer Institute.

Figure 1.3.27 Comparison of the brightness of Alexa Fluor® 647 and Cy®5 dye antibody conjugates (prepared in our laboratories). More Alexa Fluor® 647 dye molecules can be attached to proteins and nucleic acids without significant quenching, thus yielding conjugates that are much brighter than those possible using the Cy®5 dye.

Figure 1.3.30 The absorption spectra of Cy⁵ dye conjugates of both proteins and nucleic acids show an additional peak at about 600 nm when compared to the spectrum of the free dye. However, the light absorbed by Cy⁵ conjugates at this wavelength does not result in fluorescence. Alexa Fluor[®] 647 protein conjugates do not exhibit this spectral anomaly. Spectra have been normalized to the same peak intensity for comparison purposes.

Figure 1.3.31 Absorption and fluorescence emission spectra of Alexa Fluor[®] 635 goat anti-mouse IgG antibody in pH 7.2 buffer.

- Unlike the Cy⁵ dye, very little change in absorption or fluorescence spectra when conjugated to most proteins, oligonucleotides and nucleic acids (Figure 1.3.30), thus yielding significantly greater total fluorescence at the same degrees of substitution (Figure 1.3.27, Figure 1.3.28, Figure 1.3.29)
- Reasonable water solubility of their succinimidyl esters, permitting conjugations to be done without addition of organic solvents if desired
- Chemistry that permits synthesis of pure, monofunctional reactive dyes, thus avoiding crosslinking reactions

The lifetimes and fluorescence quantum yields of far-red and near-infrared Alexa Fluor[®] dyes are generally shorter and lower, respectively, than their counterparts in the green-orange-red visible wavelength (488–594 nm) excitation range (Table 1.5). However, the lower quantum yields are compensated by larger extinction coefficients in terms of total fluorescence output. Fluorescence of these long-wavelength Alexa Fluor[®] dyes is not visible to the human eye but is readily detected by most imaging systems. Pictures of these dyes throughout *The Molecular Probes[®] Handbook* have been pseudocolored to represent the staining that is observed with sensitive detection equipment.

Alexa Fluor[®] 633 and Alexa Fluor[®] 635 Dyes: Optimal Excitation with the He-Ne Laser

These far-red-fluorescent Alexa Fluor[®] dyes are important labels for fluorescence imaging because their spectra are beyond the range of most sample autofluorescence. With an excitation maximum of 633 nm and 635 nm, respectively, Alexa Fluor[®] 633 and Alexa Fluor[®] 635 dyes are a perfect match to the 633 nm spectral line of the He-Ne laser and the 635 nm spectral line of red diode lasers. Although their fluorescence is not visible to the human eye, Alexa Fluor[®] 633 and Alexa Fluor[®] 635 conjugates are bright and photostable (Figure 1.3.26), with peak emission at 647 nm.

An isomeric mixture of the amine-reactive succinimidyl ester of Alexa Fluor[®] 633 dye is available as a stand-alone reagent in either a 1 mg or 5 mg unit size (A20005, A20105) and as a component of several labeling kits (Table 1.2, Table 1.4), which are described in detail in Section 1.2. Alexa Fluor[®] 635 dye, which is currently only available as antibody (Table 7.1, Figure 1.3.31) and streptavidin (Table 7.9) conjugates, typically produces brighter protein conjugates than does Alexa Fluor[®] 633 dye because it is less susceptible to self-quenching.

Alexa Fluor[®] 647 Dye: A Superior Alternative to Cy⁵ Dye

Spectra of Alexa Fluor[®] 647 conjugates are virtually identical to those of the Cy⁵ dye (Figure 1.3.8), resulting in an optimal match to optical filters designed for that dye. Total fluorescence of Alexa Fluor[®] 647 secondary antibody conjugates, however, is significantly higher than that of Cy⁵ conjugates commercially available from other suppliers (Figure 1.3.27, Figure 1.3.28, Figure 1.3.29). Also, unlike Cy⁵ dye, Alexa Fluor[®] 647 dye has very little change in absorption or fluorescence spectra upon conjugation to most proteins and nucleic acids (Figure 1.3.30), thus yielding greater total fluorescence at the same degree of substitution.¹ The spectral characteristics of thirteen different red-fluorescent fluorophores, including Alexa Fluor[®] 647 and BODIPY[®] 630/660 (Section 1.4) dyes, have been evaluated in different surrounding media to assess the influence of polarity, viscosity and detergent concentration and to facilitate probe choice in fluorescence-based assays.¹⁷ The monosuccinimidyl ester of Alexa Fluor[®] 647 dye is available as a stand-alone reagent in either a 1 mg or 5 mg unit size (A20006, A20106) and as a component of several labeling kits (Table 1.2, Table 1.4), which are described in detail in Section 1.2.

Alexa Fluor[®] 660 Dye: A Match for the Krypton-Ion Laser

Alexa Fluor[®] 660 is optimally excited by the 647 nm spectral line of the krypton-ion laser and well excited by the 633 nm spectral line of the He-Ne laser. Protein conjugates of Alexa Fluor[®] 660 dye produce bright near-infrared fluorescence, with a peak at 690 nm. This long-wavelength emission is well separated from that of other fluorophores, including Alexa Fluor[®] 546 and Cy³ dyes and phycoerythrin conjugates. Alexa Fluor[®] 660 dye is also the dye of choice as a second label for use with allophycocyanin (APC) conjugates in flow cytometry applications. The monosuccinimidyl ester of Alexa Fluor[®] 660 dye is available as a 1 mg stand-alone reagent (A20007) and as a component of several labeling kits (Table 1.2, Table 1.4), which are described in detail in Section 1.2.

Alexa Fluor® 680 Dye: An Alternative to the Cy®5.5 Dye

With a peak excitation at 679 nm and maximum emission at 702 nm, Alexa Fluor® 680 dye is spectrally similar to the Cy®5.5 dye¹⁴ (Figure 1.3.9). Fluorescence emission of Alexa Fluor® 680 dye is well separated from that of other commonly used red fluorophores, such as the tetramethylrhodamine, Texas Red®, R-phycoerythrin, Alexa Fluor® 594 and Alexa Fluor® 647 dyes, making it ideal for three- and four-color labeling. The monosuccinimidyl ester of Alexa Fluor® 680 dye is available as a stand-alone reagent in either a 1 mg or 5 mg unit size (A20008, A20108) and as a component of several labeling kits (Table 1.2, Table 1.4), which are described in detail in Section 1.2.

Alexa Fluor® 700, Alexa Fluor® 750 and Alexa Fluor® 790 Dyes: Our Longest-Wavelength Dyes

With an absorption maximum at 702 nm, Alexa Fluor® 700 dye can be excited with a xenon-arc lamp, far-red diode lasers or dye-pumped lasers operating in the 675–700 nm range. Alexa Fluor® 700 dye provides near-infrared fluorescence emission, with a peak at 723 nm. Alexa Fluor® 750 dye exhibits fluorescence spectra that are very similar to those of Cy®7 dye (Figure 1.3.10). Its fluorescence emission maximum at 775 nm is well separated from commonly used far-red fluorophores such as Alexa Fluor® 647, Alexa Fluor® 660 or allophycocyanin (APC), facilitating multicolor analysis. With a peak excitation at 749 nm, conjugates of Alexa Fluor® 750 dye are well excited by a xenon-arc lamp or dye-pumped lasers operating in the 720–750 nm range. The monosuccinimidyl esters of Alexa Fluor® 700 (A20010, A20110) and Alexa Fluor® 750 (A20011, A20111) dyes are available as stand-alone reagents in either a 1 mg or 5 mg unit size, and as components of labeling kit (Table 1.2, Table 1.4), which are described in detail in Section 1.2.

Alexa Fluor® 790 dye is the longest-wavelength Alexa Fluor® dye available. With excitation/emission maxima of 784/814 nm, Alexa Fluor® 790 dye has spectral properties similar to those of indocyanine green (ICG) and IRDye® 800 dyes (LI-COR Biosciences). This fluorophore is especially useful for researchers who require an amine-reactive, near-infrared label for small animal *in vivo* imaging (SAIVI) applications, as well as for multicolor analysis with Alexa Fluor® 680 dye and the LI-COR Odyssey® infrared imaging system.^{20,21} The monosuccinimidyl ester of Alexa Fluor® 790 dye is supplied in a 100 µg unit size (A30051), enough to label ~1 mg of IgG antibody.

Figure 1.3.32 A10168 Alexa Fluor® 350 carboxylic acid, succinimidyl ester

Figure 1.3.33 Comparison of the relative fluorescence of 7-amino-4-methylcoumarin-3-acetic acid (AMCA) streptavidin (○) and Alexa Fluor® 350 streptavidin, a sulfonated AMCA derivative (S11249, ●). Conjugate fluorescence is determined by measuring the fluorescence quantum yield of the conjugated dye relative to that of the free dye and multiplying by the number of fluorophores per protein.

Blue-Fluorescent Alexa Fluor® Dyes

Because their structures are closely related to those of the coumarins and pyrenes, the blue-fluorescent Alexa Fluor® 350 and Alexa Fluor® 405 dyes, as well as the yellow-green-fluorescent Alexa Fluor® 430 dye described above, are also included in Section 1.7. We summarize their properties here to complete our discussion of the Alexa Fluor® dye series.

Alexa Fluor® 350 Dye: Brighter Blue Fluorescence

The blue-fluorescent Alexa Fluor® 350 carboxylic acid succinimidyl ester (A10168, Figure 1.3.32) is a sulfonated coumarin derivative that is more water soluble than either AMCA succinimidyl ester or AMCA-X succinimidyl ester (A6118, Section 1.7) and yields protein conjugates that are typically 50% more fluorescent than those prepared from its nonsulfonated analog (Figure 1.3.33). Alexa Fluor® 350 protein conjugates are optimally excited at 346 nm and exhibit bright blue fluorescence at wavelengths slightly shorter than AMCA or AMCA-X conjugates (442 nm versus 448 nm), which reduces the dye's spectral overlap with the emission of fluorescein. We also prepare Alexa Fluor® 350 conjugates of secondary antibodies (Section 7.2, Table 7.1) and streptavidin (Section 7.6, Table 7.9), as well as several Alexa Fluor® 350 protein labeling kits, which are described in detail in Section 1.2 (Table 1.2, Table 1.4).

Alexa Fluor® 405 Dye: Near-Perfect Match to the Violet Diode Laser

With excitation/emission maxima of 402/421 nm (Figure 1.3.1), the blue-fluorescent Alexa Fluor® 405 dye is well matched to the 405 nm spectral line of violet diode lasers now widely implemented in fluorescence microscopy and flow cytometry. Alexa Fluor® 405 succinimidyl ester is an amine-reactive derivative of our Cascade Blue® dye, which was previously available in amine-reactive form only as its acetyl azide (C2284, Section 1.7). Not only is it offered at higher purity than the alternative Cascade Blue® acetyl azide, but Alexa Fluor® 405 succinimidyl ester also contains a 4-piperidinecarboxylic acid spacer that separates the fluorophore from its reactive moiety

Figure 1.3.34 Alexa Fluor® 405 carboxylic acid, succinimidyl ester (A30000).

Figure 1.3.36 Fixed and permeabilized bovine pulmonary artery endothelial (BPAE) cells labeled with mouse monoclonal anti- α -tubulin antibody (A11126) and detected using TSA™ Kit #7 with the HRP conjugate of goat anti-mouse IgG antibody and Alexa Fluor® 350 tyramide (T20912).

(Figure 1.3.34). This spacer enhances the reactivity of the succinimidyl ester and minimizes any interactions between the fluorophore and the biomolecule to which it is conjugated.

As with Cascade Blue® acetyl azide, Alexa Fluor® 405 dye shows minimal spectral overlap with green fluorophores, making it ideal for multicolor applications.^{3,22} Alexa Fluor® 405 dye is available as a succinimidyl ester (A30000, A30100) and a cadaverine derivative (A30675, Section 3.4), as well as conjugated to secondary antibodies (Section 7.2, Table 7.1) and streptavidin (Section 7.6, Table 7.9).

Alexa Fluor® 405 dye is also recognized by our anti-Alexa Fluor® 405/Cascade Blue® dye antibody (A5760, Section 7.4). In addition, Alexa Fluor® 405 dye-labeled Fab' fragments are provided in the Zenon® Alexa Fluor® 405 Antibody Labeling Kits (Section 7.3, Table 7.7).

Alexa Fluor® Protein and Nucleic Acid Labeling Kits

Alexa Fluor® Labeling Kits

As described above, all of our Alexa Fluor® dyes are available as amine-reactive succinimidyl esters (Table 1.2, Table 1.4), and the Alexa Fluor® 488 dye is additionally available as its single-isomer, hydrolysis-resistant tetrafluorophenyl (TFP) ester (A30005). Most of these amine-reactive Alexa Fluor® dyes are also offered as components of several protein and nucleic acid labeling kits (Table 1.2), which are described thoroughly in Section 1.2 and include:

- APEX® Antibody Labeling Kits
- Microscale Protein Labeling Kits
- Monoclonal Antibody Labeling Kits
- SAIVI™ Rapid Antibody Labeling Kits
- Alexa Fluor® Protein Labeling Kits
- Zenon® Antibody Labeling Kits (Section 7.3, Table 7.7)
- ARES™ DNA Labeling Kits (Section 8.2)
- FISH Tag™ DNA Kits and FISH Tag™ RNA Kits (Section 8.2)
- Alexa Fluor® Oligonucleotide Amine Labeling Kits (Section 8.2, Table 8.6)
- ULYSIS® Nucleic Acid Labeling Kits (Section 8.2, Table 8.6)

The purity of the Alexa Fluor® carboxylic acid succinimidyl esters dyes when prepared and packaged in a 5 mg unit size is usually >80–95% by HPLC. However, Alexa Fluor® dyes tenaciously bind water, and packaging of these products in smaller unit sizes—such as the multiple vials used in the Alexa Fluor® labeling kits and the 1 mg stand-alone reagents—may result in some loss of reactivity. Our specifications for Alexa Fluor® carboxylic acid succinimidyl esters provided as kit components or as stand-alone reagents require that the product has $\geq 50\%$ reactivity after packaging.

Alexa Fluor® Decapacks for Labeling Amine-Modified DNA or RNA

For labeling amine-modified DNA or RNA probes in microarray-based experiments, we offer the Alexa Fluor® 488 reactive dye decapack (A32750), Alexa Fluor® 555 reactive dye decapack

Figure 1.3.35 Schematic representation of TSA™ detection methods applied to immunolabeling of an antigen. The antigen is detected by a primary antibody, followed by a horseradish peroxidase-labeled secondary antibody in conjunction with a dye-labeled (or hapten-labeled) tyramide, resulting in localized deposition of the activated tyramide derivative (Stage 1). Further dye deposition, and therefore higher levels of signal amplification, can be generated by detecting dye deposited in Stage 1 with a horseradish peroxidase-labeled anti-dye antibody in conjunction with a dye-labeled tyramide (Stage 2).

(A32756) and Alexa Fluor® 647 reactive dye decapack (A32757), which provide the corresponding Alexa Fluor® succinimidyl ester conveniently packaged in 10 single-use vials. These specially packaged amine-reactive Alexa Fluor® dyes can be used in conjunction with the aminoallyl dUTP (A21664, Section 8.2) nucleotide²³ or with commercially available aminoallyl nucleotide-based nucleic acid labeling kits.

Each single-use vial contains sufficient Alexa Fluor® succinimidyl ester to optimally label the amount of cDNA produced from reverse transcription of either 20 µg of total RNA or 1–5 µg of poly(A)+ RNA, in the presence of aminoallyl dUTP. For added convenience, we offer a combination set of the Alexa Fluor® 555 and Alexa Fluor® 647 reactive dye decapacks (A32755) that contains 10 vials of each succinimidyl ester and is sufficient for 10 two-color labeling reactions. The Alexa Fluor® 555/Alexa Fluor® 647 dye pair has been shown to display higher signal correlation coefficients than the Cy³/Cy⁵ dye pair in two-color DNA microarray assays.^{24–26}

Other Reactive Alexa Fluor® Derivatives

Several Alexa Fluor® dyes are also available as thiol-reactive maleimides (Section 2.2, Table 2.1), as alkynes and azides for bioorthogonal "click" reactions (Section 3.1) and as aldehyde- and ketone-reactive hydrazides and hydroxylamines (Section 3.3, Table 3.2). The Alexa Fluor® hydrazides and hydroxylamines are also important probes for intracellular tracing (Section 14.3). Although some of the Alexa Fluor® dyes are mixtures of two isomers, all the reactive Alexa Fluor® dyes have only a single reactive substituent linked to each fluorophore.

Alexa Fluor® Tandem Conjugates and Other Bioconjugates

Alexa Fluor® Dye–Phycobiliprotein Tandem Conjugates

We have conjugated R-phycoerythrin with Alexa Fluor® 610, Alexa Fluor® 647 or Alexa Fluor® 680 dye—and in turn conjugated these fluorescent proteins to antibodies or streptavidin, yielding tandem conjugates that permit simultaneous multicolor labeling and detection of multiple targets using a single excitation source (the 488 nm spectral line of the argon-ion laser) and monitoring emission at 628 nm, 668 nm or 702 nm, respectively^{3,4} (Section 6.4, Figure 1.3.11). Additionally, we have conjugated allophycocyanin to Alexa Fluor® 680, Alexa Fluor® 700 or Alexa Fluor® 750 dyes to create tandem conjugates for multicolor measurements using excitation sources in the 633 to 650 nm range (Figure 1.3.12). Zenon® Antibody Labeling Kits for the rapid and quantitative labeling of antibodies with the phycobiliprotein tandem dyes are also available (Section 7.3, Table 7.7).

Other Alexa Fluor® Bioconjugates

For immunofluorescence, receptor labeling, nucleic acid synthesis, cell tracing and many other applications, we offer a wide variety of Alexa Fluor® conjugates, including labeled antibodies (Section 7.2, Table 7.1), streptavidin (Section 7.6, Table 7.9) and many other proteins, ligands and nucleotides.

Signal Amplification with Alexa Fluor® Dyes

Tyramide Signal Amplification

Tyramide signal amplification (TSA™) technology, which was developed by NEN (now a part of PerkinElmer Corporation) and licensed for in-cell and in-tissue applications, permits significant amplification of cellular targets by a horseradish peroxidase (HRP)–mediated scheme (Figure 1.3.35). We have introduced several TSA™ Kits (Section 6.2, Table 6.1), including kits that utilize one of the following Alexa Fluor® tyramides:

- Alexa Fluor® 350 tyramide (Figure 1.3.36)
- Alexa Fluor® 488 tyramide (Figure 1.3.37)
- Alexa Fluor® 546 tyramide
- Alexa Fluor® 555 tyramide
- Alexa Fluor® 568 tyramide (Figure 1.3.38)
- Alexa Fluor® 594 tyramide
- Alexa Fluor® 647 tyramide (Figure 1.3.39)

Figure 1.3.37 A zebrafish retina cryosection labeled with the mouse monoclonal antibody FRet 43 and detected using TSA™ Kit #2 with the HRP conjugate of goat anti-mouse IgG antibody and green-fluorescent Alexa Fluor® 488 tyramide (T20912). The nuclei were counterstained with blue-fluorescent Hoechst 33258 (H1398, H3569, H21491).

Figure 1.3.38 Fixed and permeabilized bovine pulmonary artery endothelial cell (BPAEC) labeled with anti-OxPhos Complex IV subunit I (human) antibody (anti-cytochrome oxidase subunit I) and detected using TSA™ Kit #4 with the HRP conjugate of goat anti-mouse IgG antibody and Alexa Fluor® 568 tyramide (T20914).

Figure 1.3.39 Fixed and permeabilized bovine pulmonary artery endothelial cell (BPAEC) labeled with anti-OxPhos Complex IV subunit I (human) antibody (anti-cytochrome oxidase subunit I) and detected using TSA™ Kit #6 with the HRP conjugate of goat anti-mouse IgG antibody and Alexa Fluor® 647 tyramide (T20916). The image was deconvolved using Huygens software (Scientific Volume Imaging, <http://www.svi.nl/>).

Figure 1.3.40 Detection of epidermal growth factor (EGF) receptors directly or with signal amplification. Cells expressing high (A431 cells, panel A) and low (NIH 3T3 cells, panel B) levels of EGF receptors were either directly labeled with the preformed Alexa Fluor® 488 complex of biotinylated epidermal growth factor (E13345, blue) or indirectly labeled with biotinylated EGF (E3477) followed by either Alexa Fluor® 488 streptavidin (S11223, green) or HRP-conjugated streptavidin and Alexa Fluor® 488 tyramide (purple), components of our TSA™ Kit #22 (T20932).

Figure 1.3.41 An example of flow cytometry results obtained using the Alexa Fluor® 488 Signal Amplification Kit for Fluorescein- and Oregon Green® Dye-Conjugated Probes (A11053). Human T cell leukemia cells (Jurkat) were stained with fluorescein (FITC) mouse anti-CD4 antibody and, as indicated, with Alexa Fluor® 488 rabbit anti-fluorescein/Oregon Green® antibody (A11090) and Alexa Fluor® 488 goat anti-rabbit IgG antibody (A11008). The fluorescence values of the negative controls, in which the FITC anti-CD4 antibody was omitted, are shown (black) together with the fluorescence values of the experimental samples (green). The fluorescence values represent the average signals from the population of cells analyzed.

Figure 1.3.42 Demonstration of the amplification obtained with the Alexa Fluor® 488 Signal Amplification Kit for Fluorescein- and Oregon Green® Dye-Conjugated Probes (A11053). Bovine pulmonary artery endothelial cells were labeled with anti- α -tubulin antibody (A11126) in combination with fluorescein goat anti-mouse IgG antibody (F2761) (left panel). The center panel shows the cells after treatment with Alexa Fluor® 488 rabbit anti-fluorescein/Oregon Green® antibody (A11090), and the right panel shows the cells after additional labeling with Alexa Fluor® 488 goat anti-rabbit IgG antibody (A11008). The images were acquired using identical exposure times, and a bandpass filter set appropriate for fluorescein.

The HRP-catalyzed immobilization of a fluorescent tyramide can yield far greater total fluorescence than would ever be possible with direct labeling of the target, enabling detection of very low-abundance receptors (Figure 1.3.40). Furthermore, TSA™ can be used in either live- or fixed-cell preparations, and the increased sensitivity of this signal amplification method often permits use of greatly decreased quantities of antibodies or nucleic acid probes. Our complete selection of TSA™ Kits are listed in Table 6.1 and are extensively discussed in Section 6.2.

Antibody-Based Signal Amplification Kits

Although the direct fluorescence signal of Alexa Fluor® conjugates tends to be significantly greater than that of other dyes with comparable spectra, we have also developed two kits that take further advantage of the superior brightness and photostability of Alexa Fluor® 488 dye- and Alexa Fluor® 594 dye-labeled reagents. These Alexa Fluor® Signal Amplification Kits are designed to substantially increase the signals obtained by immunofluorescence techniques (Figure 1.3.41), thus permitting detection of low-abundance targets.²⁷ The Alexa Fluor® 488 Signal Amplification Kit for Fluorescein-Conjugated Probes (A11053) provides methods and reagents for two-stage amplification of fluorescein (FITC)-labeled primary antibodies and also overwrites the fluorescein fluorescence signal with that of the brighter and more photostable Alexa Fluor® 488 dye (Figure 1.3.42). The Alexa Fluor® 488 Signal Amplification Kit for Mouse Antibodies (A11054) provides two-stage amplification of immunocytochemical labeling generated by mouse primary antibodies. The similar Alexa Fluor® 568 and Alexa Fluor® 594 Signal Amplification Kits for Mouse Antibodies (A11066, A11067) provide ultrasensitive immunofluorescent detection at longer wavelengths. For additional details about these kits, see Section 7.2.

Alexa Fluor® Conjugates of Anti-Fluorescein/Oregon Green® Antibody

Alexa Fluor® 488 dye-labeled rabbit anti-fluorescein/Oregon Green® antibody (A11090, Section 7.4) can be used to enhance the green-fluorescent signal of the fluorescein (or Oregon Green®) hapten without changing its fluorescence color. Thus, this conjugate allows researchers to take advantage of the superior photostability of Alexa Fluor® 488 dye, while utilizing existing fluorescein- or Oregon Green® dye-labeled probes and fluorescein-compatible optics. Alexa Fluor® 594 dye-labeled rabbit anti-fluorescein/Oregon Green® antibody (A11091) can be used to convert the green fluorescence of fluorescein or Oregon Green® conjugates into exceptionally photostable red fluorescence (Figure 1.3.43), and to amplify the signal from fluorescein and Oregon Green® conjugates by as much as 100-fold (Figure 1.3.44).

Figure 1.3.43 Fixed and permeabilized bovine pulmonary artery endothelial cells were labeled with the filamentous actin (F-actin) stain, fluorescein phalloidin (F432, right). An Alexa Fluor® 594 anti-fluorescein/Oregon Green® rabbit IgG antibody (A11091) converted the green fluorescence to red (left).

Antibodies to Alexa Fluor® 488 and Alexa Fluor® 405 Dyes

We offer a rabbit polyclonal antibody to Alexa Fluor® 488 dye (A11094, Section 7.4) that quenches the dye's fluorescence and can be used in various signal amplification schemes, including further amplification of the signal from Alexa Fluor® conjugates of proteins or nucleic acids or potentially from Alexa Fluor® 488 tyramide in the corresponding TSA™ Kits (T20912, T20922, T20932; Section 6.2).

As expected, the rabbit polyclonal antibody to the Cascade Blue® dye (A5760, Section 7.4) strongly interacts with Alexa Fluor® 405 dye, making it useful for various fluorescence quenching and amplification schemes. Our Zenon® Rabbit IgG Labeling Kits (Section 7.3, Table 7.7) can also be used to prepare fluorescent dye-, biotin- or enzyme-labeled complexes of these rabbit IgG antibodies for use in various detection and amplification schemes.

Figure 1.3.44 Color-shifting using a labeled anti-fluorescein/Oregon Green® antibody. Jurkat cells were first stained with a primary mouse anti-human CD3 antibody, followed by fluorescein goat anti-mouse IgG antibody (F2761), with the resultant fluorescence detected in the R-phycoerythrin (red-orange fluorescence) channel of a flow cytometer (blue curve). The weak signal was then shifted to better suit the R-phycoerythrin channel by the addition of an R-phycoerythrin conjugate of anti-fluorescein/Oregon Green® antibody (A21250). The resulting signal intensity is approximately two orders of magnitude greater (red curve) than the direct fluorescence from the first staining step (blue curve).

Notes

- This sulfonated succinimidyl ester derivative is water soluble and may be dissolved in buffer at ~pH 8 for reaction with amines. Long-term storage in water is NOT recommended due to hydrolysis.
- The fluorescence lifetime (τ) of the Alexa Fluor® 488 dye in pH 7.4 buffer at 20°C is 4.1 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
- The fluorescence quantum yield of Alexa Fluor® 488 carboxylic acid, succinimidyl ester in 50 mM potassium phosphate, 150 mM NaCl pH 7.2 at 22°C is 0.92.
- Abs and Em of the Alexa Fluor® 488 dye are red-shifted by as much as 16 nm and 25 nm, respectively, on microarrays relative to aqueous solution values. The magnitude of the spectral shift depends on the array substrate material. (Biotechniques (2005) 38:127)
- The fluorescence quantum yield of Alexa Fluor® 532 carboxylic acid, succinimidyl ester in 50 mM potassium phosphate, 150 mM NaCl pH 7.2 at 22°C is 0.61.
- The fluorescence quantum yield of Alexa Fluor® 546 carboxylic acid, succinimidyl ester in 50 mM potassium phosphate, 150 mM NaCl pH 7.2 at 22°C is 0.79.
- The fluorescence lifetime (τ) of the Alexa Fluor® 568 dye in pH 7.4 buffer at 20°C is 3.6 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
- The fluorescence quantum yield of Alexa Fluor® 568 carboxylic acid, succinimidyl ester in 50 mM potassium phosphate, 150 mM NaCl pH 7.2 at 22°C is 0.69.
- The fluorescence lifetime (τ) of the Alexa Fluor® 594 dye in pH 7.4 buffer at 20°C is 3.9 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
- The fluorescence quantum yield of Alexa Fluor® 594 carboxylic acid, succinimidyl ester in 50 mM potassium phosphate, 150 mM NaCl pH 7.2 at 22°C is 0.66.
- Alexa Fluor® 633 dye-labeled proteins typically exhibit two absorption peaks at about ~580 and ~630 nm. Fluorescence excitation is more efficient at the 630 nm absorption peak.
- The fluorescence lifetime (τ) of the Alexa Fluor® 633 dye in H₂O at 20°C is 3.2 nanoseconds. Data provided by L.J.L. BioSystems/Molecular Devices Corporation.
- The fluorescence lifetime (τ) of the Alexa Fluor® 647 dye in H₂O at 20°C is 1.0 nanoseconds and 1.5 nanoseconds in EtOH. (Bioconjug Chem (2003) 14:195)

22. The fluorescence lifetime (τ) of the Alexa Fluor® 750 dye in H₂O at 22°C is 0.7 nanoseconds. Data provided by ISS Inc. (Champaign, IL).
23. The fluorescence quantum yield of Alexa Fluor® 750 carboxylic acid, succinimidyl ester in 50 mM potassium phosphate, 150 mM NaCl pH 7.2 at 22°C is 0.12.
24. The Alexa Fluor® 405 and Cascade Blue® dyes have a second absorption peak at about 376 nm with EC ~80% of the 395–400 nm peak.
25. TFP and SDP ester derivatives are water soluble and may be dissolved in buffer at ~pH 8 for reaction with amines. Long-term storage in water is NOT recommended due to hydrolysis.

PRODUCT LIST 1.3 ALEXA FLUOR® DYES SPANNING THE VISIBLE AND INFRARED SPECTRUM

Cat. No.	Product	Quantity
A10168	Alexa Fluor® 350 carboxylic acid, succinimidyl ester	5 mg
A30000	Alexa Fluor® 405 carboxylic acid, succinimidyl ester	1 mg
A30100	Alexa Fluor® 405 carboxylic acid, succinimidyl ester	5 mg
A10169	Alexa Fluor® 430 carboxylic acid, succinimidyl ester	5 mg
A20000	Alexa Fluor® 488 carboxylic acid, succinimidyl ester *mixed isomers*	1 mg
A20100	Alexa Fluor® 488 carboxylic acid, succinimidyl ester *mixed isomers*	5 mg
A30005	Alexa Fluor® 488 carboxylic acid, 2,3,5,6-tetrafluorophenyl ester (Alexa Fluor® 488 5-TFP) *5-isomer*	1 mg
A30002	Alexa Fluor® 514 carboxylic acid, succinimidyl ester *mixed isomers*	1 mg

1.4 BODIPY® Dye Series

Overview of the BODIPY® Fluorophores

The BODIPY® fluorophores have spectral characteristics that are often superior to those of fluorescein, tetramethylrhodamine, Texas Red® and longer-wavelength dyes. With derivatives that span the visible spectrum (Figure 1.4.1), BODIPY® dyes are extremely versatile.¹ We use them to generate fluorescent conjugates of proteins, nucleotides, oligonucleotides and dextrans, as well as to prepare fluorescent enzyme substrates, fatty acids, phospholipids, lipopolysaccharides, receptor ligands and polystyrene microspheres.

BODIPY® dyes are unusual in that they are relatively nonpolar and the chromophore is electrically neutral (Figure 1.4.2). These properties tend to minimize dye-induced perturbation of conjugate functional properties. BODIPY® dyes are therefore often the preferred choice for labeling nucleotides, amino acids and other low molecular weight ligands.²⁻⁴ BODIPY® dye conjugates of low molecular weight molecules also tend to be more permeant to live cells than are conjugates of charged fluorophores (Section 14.2). With their high peak intensity, reactive BODIPY® dyes are among the most detectable amine-derivatization reagents available for HPLC and capillary electrophoresis.⁵⁻⁸ BODIPY® dyes are also more useful than most other long-wavelength dyes, including fluoresceins and carbocyanines, for assays that measure fluorescence polarization⁹⁻¹² (Fluorescence Polarization (FP)—Note 1.4), and they have large cross-sections for excitation by multiphoton excitation sources^{13,14} (Fluorescent Probes for Two-Photon Microscopy—Note 1.5).

The core structure of the BODIPY® fluorophore is shown in Figure 1.4.2. Solutions of the alkyl-substituted derivatives have a green, fluorescein-like fluorescence. However, when substituents that yield additional conjugation are added to the parent molecule, both the absorption and emission spectra of the resulting derivatives can shift to significantly longer wavelengths, with emission maxima of greater than 750 nm now possible with some BODIPY® derivatives. Our goal has been to develop BODIPY® dyes that are optimal for the major excitation sources and that match the common optical filter sets. Accordingly, our recommended BODIPY® substitutes for the fluorescein, rhodamine 6G, tetramethylrhodamine and Texas Red® fluorophores are named BODIPY® FL, BODIPY® R6G, BODIPY® TMR and BODIPY® TR, respectively (Figure 1.4.3). Because there are so many different BODIPY® dyes, we have had to develop a systematic strategy for naming them. Except for BODIPY® FL, BODIPY® R6G, BODIPY® TMR and BODIPY® TR, we identify these dyes with the registered trademark BODIPY® followed by the approximate absorption/emission maxima in nm (determined in methanol); for example, the BODIPY® 581/591 dye.

Amine-reactive BODIPY® dyes (Table 1.7) are discussed below; thiol-reactive BODIPY® dyes are included in Section 2.2. Other reactive BODIPY® dyes useful for derivatizing aldehydes, ketones and carboxylic acids are described in Section 3.3 and Section 3.4. Applications of some thiol-reactive BODIPY® dyes for cell tracing are discussed in Section 14.2.

BODIPY® FL Dye: A Substitute for Fluorescein

With the most fluorescein-like spectra of the BODIPY® dyes, the green-fluorescent BODIPY® FL fluorophore (Figure 1.4.4) (excitation/emission maxima ~503/512 nm) has several characteristics^{15,16} that make it potentially superior to fluorescein in some applications. These include:

- High extinction coefficient ($EC > 80,000 \text{ cm}^{-1}\text{M}^{-1}$) and high fluorescence quantum yield (often approaching 1.0, even in water)
- Lack of ionic charge and spectra that are relatively insensitive to solvent polarity and pH^{15}
- Narrow emission bandwidth (Figure 1.4.3), resulting in a higher peak intensity than that of fluorescein

Figure 1.4.2 The structure and numbering of the BODIPY® fluorophore, 4,4-difluoro-4-bora-3a,4a-diaza-5-indacene.

Figure 1.4.1 Normalized fluorescence emission spectra of 1) BODIPY® FL, 2) BODIPY® R6G, 3) BODIPY® TMR, 4) BODIPY® 581/591, 5) BODIPY® TR, 6) BODIPY® 630/650 and 7) BODIPY® 650/665 fluorophores in methanol.

Figure 1.4.3 Normalized fluorescence emission spectra of goat anti-mouse IgG antibody conjugates of fluorescein (FL), tetramethylrhodamine (TMR) and the Texas Red® (TR) dyes, shown by dashed lines (---), as compared with goat anti-mouse IgG antibody conjugates of BODIPY® FL, BODIPY® TMR and BODIPY® TR dyes, respectively, shown by solid lines (—).

Figure 1.4.4 Absorption and fluorescence emission spectra of BODIPY® FL propionic acid, succinimidyl ester in methanol.

- Red shift in fluorescence emission at high dye concentrations—a property that can be used to detect regions of high probe density¹⁷ (Figure 1.4.5)
- Relatively long excited-state lifetime (typically 5 nanoseconds or longer), which is useful for fluorescence polarization-based assays (Fluorescence Polarization (FP)—Note 1.4)
- Little or no spectral overlap with longer-wavelength dyes such as tetramethylrhodamine and Texas Red® dye (Figure 1.4.3), making BODIPY® FL one of the preferred green-fluorescent dyes for multicolor applications¹⁸
- Greater photostability than fluorescein in some environments¹⁹
- Large two-photon cross-section for multiphoton excitation^{13,14} (Fluorescent Probes for Two-Photon Microscopy—Note 1.5)

Longer-Wavelength BODIPY® Dyes

It is possible to synthesize BODIPY® fluorophores with altered spectral properties by simply changing the substituents on the parent molecule. This discovery has led to creation of a series of longer-wavelength BODIPY® dyes with fluorescence spectra that span the visible spectrum (Figure 1.4.1). The BODIPY® R6G (excitation/emission maxima ~528/547 nm), BODIPY® TMR (excitation/emission maxima ~543/569 nm) and BODIPY® TR (excitation/emission maxima ~592/618 nm) fluorophores are spectrally similar to the rhodamine 6G, tetramethylrhodamine and Texas Red® fluorophores, respectively, and are thus compatible with standard optical filter sets designed for these important dyes.

The BODIPY® 630/650-X and BODIPY® 650/665-X fluorophores are the longest-wavelength amine-reactive BODIPY® fluorophores currently available. The spectral properties of these longer-wavelength BODIPY® derivatives retain most of the advantages of the BODIPY® FL fluorophore, including narrow bandwidths, high extinction coefficients, good fluorescence quantum yields and relatively long excited-state lifetimes (>3 nanoseconds for the BODIPY® 630/650 dye^{20,21}). Like the BODIPY® FL fluorophore, however, most of these dyes have a small

Stokes shift, which may require that they be excited or detected at suboptimal wavelengths. The spectral characteristics of 13 different red-fluorescent fluorophores, including the Alexa Fluor® 647 (Section 1.3) and BODIPY® 630/650 dyes, have been evaluated in different surrounding media to assess the influence of polarity, viscosity and detergent concentration and to facilitate probe choice in fluorescence-based assays.²⁰

Amine-Reactive BODIPY® Dyes

BODIPY® Succinimidyl Esters

We offer an extensive selection of amine-reactive BODIPY® dyes (Table 1.7). These include succinimidyl esters of several BODIPY® propionic acids and of BODIPY® FL pentanoic acid:

- BODIPY® FL C₃ succinimidyl ester (D2184)
- BODIPY® FL C₅ succinimidyl ester (D6184)
- BODIPY® R6G C₃ succinimidyl ester (D6180)
- BODIPY® 493/503 C₃ succinimidyl ester (D2191)
- BODIPY® 530/550 C₃ succinimidyl ester (D2187)
- BODIPY® 558/568 C₃ succinimidyl ester (D2219)
- BODIPY® 564/570 C₃ succinimidyl ester (D2222)
- BODIPY® 576/589 C₃ succinimidyl ester (D2225)
- BODIPY® 581/591 C₃ succinimidyl ester (D2228)

We have also prepared reactive BODIPY® X succinimidyl esters that contain an additional seven-atom aminohexanoyl spacer ("X") between the fluorophore and the succinimidyl ester group. This spacer helps to separate the fluorophore from its point of attachment, potentially reducing the interaction of the fluorophore with the biomolecule to which it is conjugated and making it more accessible to secondary detection reagents such as anti-dye antibodies.^{22–24} These BODIPY® X succinimidyl esters include:

Table 1.7 Amine-reactive BODIPY® dyes.

BODIPY® Dye	Abs *	Em *	COOH	STP	Succinimidyl Ester
BODIPY® 493/503	500	506			D2191
BODIPY® FL	505	513	D2183 (C ₃) D3834 (C ₅)	B10006	D2184 (C ₃) D6140 (SSE) D6102 (X) D6184 (C ₅)
BODIPY® R6G	528	550			D6180

BODIPY® 630/650-X †	625	640			D10000
BODIPY® 650/655-X †	646	660			D10001

* Approximate absorption (Abs) and fluorescence (Em) maxima, in nm, for the goat anti-mouse IgG antibody or dextran conjugates in aqueous buffer. † Not recommended for derivatizing proteins. (C₃) = Propionic acid. (C₅) = Pentanoic acid. (COOH) = Carboxylic acid. (SSE) = Sulfo succinimidyl ester. (STP) = 4-Sulfotetrafluorophenyl ester. (X) = Aminohexanoyl spacer separating the dye and the SE.

Figure 1.4.5 Selective staining of the Golgi apparatus using the green-fluorescent BODIPY® FL C₅-ceramide (D3521) (left). At high concentrations, the BODIPY® FL fluorophore forms excimers that can be visualized using a red longpass optical filter (right). The BODIPY® FL C₅-ceramide accumulation in the trans-Golgi is sufficient for excimer formation (J Cell Biol (1991) 113:1267). Images contributed by Richard Pagano, Mayo Foundation.

- BODIPY® FL-X succinimidyl ester (D6102)
- BODIPY® TMR-X succinimidyl ester (D6117)
- BODIPY® TR-X succinimidyl ester (D6116)
- BODIPY® 630/650-X succinimidyl ester (D10000)
- BODIPY® 650/665-X succinimidyl ester (D10001)

BODIPY® succinimidyl esters are particularly useful for preparing conjugates of peptides, nucleotides, oligonucleotides, drugs, toxins, sphingolipids and other low molecular weight ligands that contain aliphatic amines.^{2,25} Several BODIPY® succinimidyl esters have been conjugated to aminoacyl tRNAs for metabolic incorporation into proteins through *in vitro* translation.^{26–29}

BODIPY® TMR-X SE has been reacted with a series of peptide ligands for use in a high-throughput fluorescence polarization assay of ligand binding to G protein-coupled receptors.³⁰ The red fluorescence of the BODIPY® 581/591 fluorophore shifts to green fluorescence upon peroxidation, a unique feature that has been exploited for ratiometric measurements of lipid oxidation in live cells (Section 18.2). BODIPY® 630/650-X and BODIPY® 650/665-X succinimidyl esters (D10000, D10001) are quite fluorescent when conjugated to nucleotides³¹ and oligonucleotides and can be excited with near-infrared excitation sources.

For amplifying the BODIPY® FL dye signal or converting it into an electron-dense signal, we offer an unlabeled anti-BODIPY® FL rabbit polyclonal antibody (A5770, Section 7.4). This antibody cross-reacts with some other BODIPY® dyes, but not with other fluorophores, and therefore should not be used for simultaneous detection of more than one dye based on the BODIPY® fluorophore.

Water-Soluble BODIPY® Sulfonated Succinimidyl Esters

The moderate lipophilicity of the BODIPY® propionic acid succinimidyl esters discussed above requires their dissolution in an organic solvent before use in conjugations. Although these reactive dyes are very useful for preparing conjugates of amines in organic solvents, they are less suitable for reaction with proteins.

To address the solubility in aqueous solution, we have prepared the sulfosuccinimidyl ester of BODIPY® FL propionic acid (BODIPY® FL SSE; D6140), as well as the STP ester of BODIPY® FL propionic acid (B10006). STP esters,³² which are prepared by coupling a carboxylic acid and 4-sulfo-2,3,5,6-tetrafluorophenol (S10490, Section 3.4, Figure 1.4.6), are more readily purified than sulfosuccinimidyl esters but equally amine reactive. BODIPY® FL SSE and BODIPY® FL STP ester are quite soluble in water and more suitable than the corresponding BODIPY® succinimidyl esters for amine conjugation in aqueous solution. These sulfonated succinimidyl esters are useful for preparing conjugates of proteins, amine-modified oligonucleotides and other biomolecules.³³

BODIPY® Carboxylic Acids

Two green-fluorescent BODIPY® carboxylic acids (D2183, D3834) are available. These carboxylic acid derivatives can be converted to fluorescent esters,³⁴ acid halides or amides using standard chemical techniques.

BODIPY® Dye Conjugates and Their Applications

The versatility of the BODIPY® fluorophore is demonstrated by its incorporation into literally hundreds of products listed in this *Handbook*, including many of our FluoSpheres® and TransFluoSpheres® microspheres

(Section 6.5), enzyme substrates (Chapter 10) and several of our imaging and flow cytometry standards (Section 23.1, Section 23.2). Some examples of our BODIPY® dye conjugates are described below.

BODIPY® Peptide, Protein and Polysaccharide Conjugates

As is common with many fluorescent dyes, conjugation of BODIPY® dyes to proteins is sometimes accompanied by significant fluorescence quenching.³⁵ Because of this potential problem, we do *not* recommend using the simple BODIPY® propionic acid succinimidyl esters discussed above for preparing most protein conjugates, although peptides labeled with a single BODIPY® dye can be quite fluorescent and are quite useful for fluorescence polarization-based assays^{36,37} (Labeling Small Peptides with Amine Reactive Dyes in Organic Solvents—Note 9.2). We prepare conjugates of its BODIPY® dyes with an exceptionally wide variety of peptides, proteins and polysaccharides, including:

- Pepstatin A, a membrane-permeant analog of this important cathepsin D inhibitor (P12271, Section 10.4)
- Antibodies (Section 7.4; Table 7.1)
- Phalloidin and phalloidin for staining F-actin filaments (B607, B3475, B12382; Section 11.1; Table 11.2)
- Bovine serum albumin, for use as a tracer (A2750, Section 14.7)
- Acetylated and non-acetylated low-density lipoproteins (L3485, L3483; Section 16.1)
- *Escherichia coli* and *Staphylococcus aureus* BioParticles® conjugates (E2864, S2854; Section 16.1; Table 16.3)
- Lipopolysaccharide (L23350, Section 16.1; Table 16.1)
- Dextran (D7168, Section 14.5)

In addition, we prepare conjugates of proteins (and of starch) that are so heavily labeled that they are almost nonfluorescent (Figure 1.4.7). Use of the EnzChek® Kits and DQ™ reagents that incorporate these bioconjugates as fluorogenic enzyme substrates is described later in this section and in Section 10.4.

Figure 1.4.6 Reaction of a primary amine with an STP ester.

Figure 1.4.7 Principle of enzyme detection via the disruption of intramolecular self-quenching. Enzyme-catalyzed hydrolysis of the heavily labeled and almost totally quenched substrates provided in our EnzChek® Protease Assay Kits relieves the intramolecular self-quenching, yielding brightly fluorescent reaction products.

NOTE 1.5

Fluorescent Probes for Two-Photon Microscopy

Defining Characteristics of Two-Photon Excitation

Two-photon excitation (TPE) is a nonlinear optical process first predicted theoretically by Maria Göppert-Mayer in 1931.¹ Its application to fluorescence microscopy was pioneered much more recently by Denk, Strickler and Webb.² In TPE, a fluorophore is excited via near simultaneous absorption of two photons, each having half the energy (twice the wavelength) required for the transition from the ground to the first singlet excited state (Figure 1). The prerequisite for near-simultaneous absorption and the timescale of molecular light absorption (~10–16 seconds) dictates the use of specialized excitation sources; in current instruments, this is typically a mode-locked Ti:Sapphire, Nd:YAG laser delivering infrared light pulses of femtosecond duration at high repetition rates.³ Two-photon excited fluorescence has a characteristic dependence on the square of the excitation light intensity; doubling the excitation intensity quadruples the fluorescence signal. In contrast, fluorescence derived from conventional one-photon absorption exhibits linear dependence on excitation light intensity.

There are many practical benefits to using TPE, given the transparency of tissues to infrared excitation light:

- Spatial confinement of fluorescence to a very small volume (~0.1 μm^3) defined by the focused excitation light, providing inherent 3D imaging capability (Figure 2)
- Capacity for imaging at increased depths in tissues⁴
- Confinement of photodamage and photobleaching effects to the excitation volume, resulting in increased viability of live specimens.^{5,6}

However, in addition to requiring specialized (and therefore fairly expensive) excitation sources, TPE produces photodamage and photobleaching effects within the confined excitation volume that are often more acute than those produced by laser scanning confocal microscopy.^{7–10} The advantages of TPE primarily relate to imaging of live specimens. Accordingly, neuroscience—specifically structural and functional imaging of the nervous system—is the largest field of current applications (Table 1). In addition to providing benefits for fluorescence microscopy, TPE offers advantages in other biophotonic techniques such as fluorescence correlation spectroscopy,¹¹ controlled photoablation,¹² photodynamic therapy¹³ and activation of “caged” compounds.¹⁴ To learn more about the technical foundations and applications of TPE microscopy, researchers should consult the growing collection of available review literature.^{15–20}

Fluorescence Excitation and Emission Spectra

One-photon and two-photon excitation of a given fluorophore generally result in identical fluorescence emission spectra, as the originating excited state and the photon emission process are the same (Figure 1.1). However, two-photon excitation spectra differ from their one-photon counterparts to an extent that depends on the molecular orbital symmetry of the fluorophore (greater difference for higher symmetry fluorophores).¹⁸ Consequently, most two-photon excitation spectra are blue-shifted and broader compared to the corresponding one-photon spectra plotted on a doubled wavelength axis. Simply stated, a fluorophore with a one-photon excitation peak at 500 nm will probably have a two-photon excitation maximum at <1,000 nm (Figure 3).

Because two-photon excitation spectra are relatively broad, multiplex detection schemes in which two or more fluorophores are excited at a single wavelength and discriminated on the basis of different emission spectra are relatively easy to implement (some examples are included in Table 1). The two-photon absorption cross-section (σ) in units of GM (for Göppert-Mayer; 1 GM = 10^{-50} cm⁴ seconds) quantifies the efficiency of TPE for different fluorophores and is plotted on the y-axis of excitation spectra (Figure 3). There are several published collections of two-photon excitation spectra and cross-sections that provide guidance on compatibility of dyes and probes with excitation sources.^{21–25} Excitation wavelengths used in selected published TPE microscopy applications are listed in Table 1.

Figure 1 Excited-state energy diagram showing two-photon excitation (1), followed by nonradiative vibrational relaxation (2) and spontaneous fluorescence photon emission (3). In conventional fluorescence detection systems, excitation is achieved by absorption of a single photon of energy ($h\nu_{EX}$); processes (2) and (3) are essentially the same.

Figure 2 An experiment illustrating ordinary (single-photon) excitation of fluorescence and two-photon excitation of fluorescence. The cuvette contains a solution of the dye safranin O, which normally emits yellow light when excited by green light. The upper lens focuses green (543 nm) light from a CW helium–neon laser into the cuvette, producing the expected conical pattern of excitation (fading to the left). The lower lens focuses pulsed infrared (1046 nm) light from a neodymium–YLF laser. In two-photon absorption, the excitation is proportional to the square of the intensity; thus, the emission is confined to a small point focus (see arrow), which can be positioned anywhere in the cuvette by moving the illuminating beam. Image contributed by Brad Amos, Science Photo Library, London.

Figure 3 Two-photon excitation spectra of Alexa Fluor® 350, Alexa Fluor® 488, Alexa Fluor® 568 and Alexa Fluor® 594 dyes. The y-axis units are products of fluorescence quantum yields (Φ_F) and two-photon absorption cross-sections (σ). Data courtesy of Warren Zipfel, Cornell University.

Fluorescent Probes for TPE Microscopy

TPE has added a new spectral dimension to fluorescence microscopy. Probes such as fura-2 (for Ca²⁺), SBFI (for Na⁺), monochlorobimane (for glutathione), and DAPI (for nuclear DNA) were previously of limited utility in confocal microscopy due to their requirements for ultraviolet excitation; now, however, these probes have a new lease on life (Table 1). Furthermore, *in situ* imaging of small endogenous fluorophores, such as serotonin and NADH, that are almost inaccessible to one-photon excitation has now become practicable.²⁶ Organic fluorophores and fluorescent proteins typically have two-photon absorption cross-sections in the range 1–100 GM. However, fluorophores with smaller cross-sections (e.g., NADH, $\sigma < 0.1$ GM) can still generate sufficient TPE fluorescence for imaging purposes.²⁶ At the opposite extreme, Qdot® nanocrystals have cross-sections exceeding 10,000 GM, promising even further expansion of TPE imaging, particularly in the area of *in vivo* applications.^{27,28}

* Used in combination with fluo-4, fluo-5F or fluo-4FF to obtain ratio signals that are insensitive to small changes in resting Ca²⁺ and are independent of subcellular compartment volume. † Multiplexed (single excitation/dual channel emission) combination of CFSE and CMTMR. § Techniques also applicable to fluo-4 and fluo-4FF indicators. ‡ Multiplexed (single excitation/dual channel emission) combination of TMRE and CM-H₂DCFDA. ** Multiplexed (single excitation/dual channel emission) combination of Qdot® 585 and Qdot® 655 nanocrystals. PHD = pleckstrin homology domain.

BODIPY® Nucleotide and Oligonucleotide Conjugates

With the exception of guanosine nucleotides, fluorescence quenching is usually not a problem if the BODIPY® derivative is conjugated to nucleotides, oligonucleotides, peptides or low molecular weight amines in which the stoichiometry of modification is 1:1. BODIPY® FL dye–labeled oligonucleotide primers also have lower photodestruction rates than fluorescein-labeled primers, improving the detectability of labeled DNA in sequencing gels.³⁸ Oligonucleotide conjugates of several of our BODIPY® dyes have been shown to be useful for DNA sequencing^{39,40} (Section 8.2, Table 8.7), in part because the dye exhibits minimal effect on the mobility of the fragment during electrophoresis.⁴¹ We also offer a ChromaTide® BODIPY® FL-14-dUTP for enzyme-mediated incorporation into nucleic acids (C7614, Section 8.2, Table 8.5).

In addition, we have prepared BODIPY® FL conjugates of ATP and GTP that are labeled through the ribose moieties and serve as structural probes of nucleotide-binding proteins (A12410, G12411; Section 17.3). The fluorescence of BODIPY® dyes is quenched by photoinduced electron transfer from proximal guanine bases.^{42,43} BODIPY® FL GTP therefore shows significant fluorescence quenching (Figure 1.4.8) that is relieved by binding to GTP-binding proteins (G-proteins). Longer-wavelength BODIPY® TR conjugates of ATP and GTP are also available (A22352, G22351; Section 17.3).

For protein-binding studies that require nonhydrolyzable nucleotides, we offer the BODIPY® FL fluorophore linked through the γ -thiol of ATP- γ -S (A22184, Figure 1.4.9) and the BODIPY® FL, BODIPY® 515/530 and BODIPY® TR fluorophores linked through the γ -thiol of GTP- γ -S⁴⁴ (G22183, G35779, G35780; Section 17.3). Like BODIPY® FL

GTP, the fluorescence of the BODIPY® GTP- γ -S thioesters is quenched ~90% relative to that of the free dye but is recovered upon protein binding to at least some G-proteins.⁴⁴ The green-fluorescent BODIPY® FL GTP- γ -S has been used to detect GTP-binding proteins separated by capillary electrophoresis.⁴⁵ BODIPY® 515/530 GTP- γ -S thioester also exhibits green fluorescence and has a greater fluorescence increase upon protein binding, as compared with the BODIPY® FL GTP- γ -S thioester. The BODIPY® TR GTP- γ -S thioester is a red-fluorescent analog with spectral properties similar to those of the Texas Red® dye.

We also offer the green-fluorescent BODIPY® FL GTP- γ -NH amide (G35778, Section 17.3) as another choice for protein-binding studies. Although this analog exhibits less fluorescence enhancement upon protein binding, it is reportedly the best of the three green-fluorescent GTP- γ analogs for directly monitoring nucleotide exchange.⁴⁶ The different linker lengths of the green-fluorescent GTP- γ analogs (six-carbon for BODIPY® FL GTP- γ -NH amide, four-carbon for BODIPY® FL GTP- γ -S and one-carbon for BODIPY® 515/530 GTP- γ -S) may be useful for understanding protein active-site geometries.

In addition to their potential use for binding studies, the BODIPY® FL ATP- γ -S and BODIPY® FL GTP- γ -S thioesters are important substrates for Fhit (Figure 1.4.10), a member of the histidine triad superfamily of nucleotide-binding proteins that bind and cleave diadenosine polyphosphates.^{47–49} Fhit, one of the most frequently inactivated proteins in lung cancer, functions as a tumor suppressor by inducing apoptosis.^{48,50,51} These BODIPY® nucleotides should be especially useful for screening potential Fhit inhibitors and activators.

Figure 1.4.8 Fluorescence emission spectra of (1) free BODIPY® FL dye in phosphate-buffered saline, pH 7.2; (2) BODIPY® FL ATP (A12410); and (3) BODIPY® FL GTP (G12411). Samples were prepared with equal absorbance at the excitation wavelength (488 nm). The areas under the curves are therefore proportional to the relative fluorescence quantum yields, clearly showing the quenching effect caused by interaction of the BODIPY® FL fluorophore with the guanine base of GTP.

Figure 1.4.9 Adenosine 5'-O-(3-thiotriphosphate), BODIPY® FL thioester, sodium salt (BODIPY® FL ATP- γ -S, thioester, A22184).

Figure 1.4.10 Principle of fluorescence-based detection of the diadenosine triphosphate hydrolase activity of Fhit using BODIPY® FL GTP- γ -S thioester (G22183) as a substrate analog.

BODIPY® Lipids and BODIPY® Receptor Ligand Conjugates

BODIPY® dye conjugates of lipids, toxins, steroids, drug analogs and receptor probes typically have quantum yields approaching unity, especially in organic solvents. The low polarity of the BODIPY® fluorophore makes probes containing these dyes excellent analogs of biological lipids (Chapter 13). Consequently, these probes are well tolerated by enzymes that metabolize lipids, including phospholipases and sphingomyelinases (Section 17.4, Table 17.3). In most cases, lack of a spectral shift in the metabolic product's fluorescence requires use of an easy extraction and chromatographic separation step to detect product formation, with quantitation possible by photography or with a fluorescence- or absorption-based scanner. BODIPY® derivatives of lipids and low molecular weight ligands include analogs of:

- Phospholipids and fatty acids, numerous versions of which are described in Section 13.2
- Sphingolipids, including several ceramide derivatives (Section 13.3)
- Cholesterol (C3927MP, Section 13.3)
- Cytochalasin D, an actin-polymerization inhibitor (C12377, Section 11.1)
- Paclitaxel (Taxol®), for staining tubulin in isolated preparations (P7500, P7501; Section 11.2)
- Vinblastine, a microtubule-disrupting agent (V12390, Section 11.2)
- Vancomycin, an antibiotic (V34850, Section 15.2)
- Penicillin V (B13233, B13234; Section 15.2)
- Verapamil, for investigating multidrug resistance (B7431, Section 15.6)
- Forskolin, an adenylate cyclase activator (B7469, Section 15.6)
- Prazosin, an α_1 -adrenergic receptor probe (B7433, Section 16.2)
- Ouabain, a cardiac glycoside (B23461, Section 16.3)
- Glibenclamide, a probe for potassium channels (E34250, E34251; Section 16.3)
- Dihydropyridine derivative that is selective for Ca^{2+} channels (D7443, S7445; Section 16.3)
- Thapsigargin, which promotes Ca^{2+} release by inhibiting the endoplasmic reticulum Ca^{2+} -ATPase (B7487, B13800; Section 17.2)

In addition to the BODIPY® dye conjugates of receptor ligands in the list above, we have utilized BODIPY® dyes for synthesis of several LysoTracker® and LysoSensor™ dyes, as well as BODIPY® FL histamine (B22461, Figure 1.4.11), which are extremely useful probes for labeling acidic organelles in live cells. These products are discussed in Section 12.3.

DQ™ Reagents: Heavily Labeled BODIPY® Dye Conjugates as Fluorogenic Enzyme Substrates

We have found BODIPY® dye conjugates to be very useful reagents for numerous bioanalytical screening applications. In particular, we have utilized the tendency of BODIPY® dyes to quench their fluorescence on conjugation to certain biopolymers to our advantage (Figure 1.4.7) in the following enzyme-assay kits and reagents:

- EnzChek® Protease Assay Kits, which contain almost nonfluorescent casein derivatives that are heavily labeled with either the green-fluorescent BODIPY® FL dye (E6638; Section 10.4) or red-fluorescent BODIPY® TR-X dye (E6639, R22132; Section 10.4)
- EnzChek® Elastase Assay Kit (E12056, Section 10.4), with DQ™ elastin, a quenched BODIPY® FL conjugate

- EnzChek® Ultra Amylase Assay Kit (E33651, Section 10.2), containing a highly quenched BODIPY® FL starch derivative
- DQ™ Green BSA (D12050, Section 10.4) and DQ™ Red BSA (D12051, Section 10.4), heavily labeled and almost nonfluorescent BODIPY® BSA conjugates that yield intense green or red fluorescence upon proteolytic digestion
- DQ™ ovalbumin (D12053, Section 10.4), a heavily labeled and almost nonfluorescent BODIPY® FL ovalbumin conjugate

Conjugation of either the BODIPY® FL dye (excitation/emission maxima ~500/506 nm) or BODIPY® TR dye (excitation/emission maxima ~589/617 nm) to a biopolymer at high degrees of substitution (DOS) results in almost total quenching of the conjugate's fluorescence; they typically exhibit <3% of the fluorescence of the corresponding free dyes. Enzyme-catalyzed hydrolysis relieves this quenching, yielding brightly fluorescent BODIPY® FL dye- or BODIPY® TR-X dye-labeled peptides (Figure 1.4.7), or, in the case of the BODIPY® FL amylose substrate in the EnzChek® Ultra Amylase Assay Kit, BODIPY® FL dye-labeled carbohydrates. The increase in fluorescence, which can be measured with a spectrofluorometer, minifluorometer or fluorescence microplate reader, is proportional to enzymatic activity. The DQ™ BSA and DQ™ ovalbumin substrates are particularly suitable for the study of receptor labeling and antigen processing. DQ™ BSA conjugates can be targeted to Fc receptors after they are complexed with our anti-BSA antibody (A11133, Section 7.5). Ovalbumin is efficiently processed through mannose receptor-mediated endocytosis by antigen-presenting cells and is widely used for studying antigen processing. Upon endocytosis and proteolysis, highly fluorescent peptides are released within intracellular vacuoles. DQ™ ovalbumin appears to be an excellent indicator of macrophage-mediated antigen processing in flow cytometry and microscopy assays.

Figure 1.4.11 Viable bovine pulmonary artery endothelial cells simultaneously stained with BODIPY® FL histamine (B22461), MitoTracker® Red CMXRos (M7512) and Hoechst 33342 (H1399, H3570, H21492). Green-fluorescent BODIPY® FL histamine localized to lysosomes, red-fluorescent MitoTracker® Red CMXRos accumulated in the mitochondria and the blue-fluorescent Hoechst 33342 dye stained the nuclei. This multiple-exposure image was acquired with band-pass filters appropriate for fluorescein, the Texas Red® dye and DAPI.

BODIPY® Dye Conjugates for Fluorescence Polarization–Based Assays

When a fluorescent molecule tethered to a protein is excited by polarized fluorescent light, the polarization of fluorescence emission is dependent on the rate of molecular tumbling. Upon proteolytic cleavage of the fluorescently labeled protein, the smaller peptides that result tumble faster and the emitted light is depolarized relative to the light measured from the intact conjugate (Fluorescence Polarization (FP)—Note 1.4). Fluorescence polarization technology is more sensitive than many other nonradioactive assays for proteases and allows measurements to be taken in real time, permitting the collection of kinetic data.

The relatively long fluorescence lifetimes (typically >5 nanoseconds) at visible wavelengths, good anisotropy properties, high molar absorptivity and fluorescence intensity and lack of pH sensitivity in the spectra of the BODIPY® dyes have been shown to make these dyes the preferred fluorophores for high-throughput fluorescence polarization–based assays. The EnzChek® Polarization Assay Kit for Proteases (E6658, Section 10.4) contains green-fluorescent BODIPY® FL casein with an optimal degree of labeling for fluorescence polarization–based protease assays. BODIPY® dye conjugates of nucleotides, peptides and drug analogs are available or are readily prepared from the chemically reactive BODIPY® dyes. Fluorescence polarization–based assays for G-protein–coupled receptors, kinases and phosphatases and for high-affinity receptors are particularly important when screening for new drug candidates.

Figure 1.4.12 The green-fluorescent BODIPY® FL 1-deoxychloramphenicol substrate in our FAST CAT® Green (deoxy) Chloramphenicol Acetyltransferase Assay Kit (F6616). CAT-mediated acetylation of this substrate and of the BODIPY® TMR 1-deoxychloramphenicol in our original FAST CAT® Yellow (deoxy) Chloramphenicol Acetyltransferase Assay Kit (F6617) results in single fluorescent products because these substrates contain only one hydroxyl group that can be acetylated. In contrast, the BODIPY® FL chloramphenicol substrate in our original FAST CAT® Kit (F2900) contains a second hydroxyl group at the 1-position (indicated by the labeled arrow). This hydroxyl group undergoes a nonenzymatic transacetylation step, restoring the original hydroxyl for a second acetylation. CAT-mediated acetylation of this chloramphenicol substrate produces three fluorescent products, thus complicating the analysis.

BODIPY® Substrates for Chloramphenicol Acetyltransferase

Chloramphenicol acetyltransferase (CAT), an enzyme that is encoded by an important reporter gene, can acetylate chloramphenicol derivatives that incorporate the BODIPY® fluorophore (Figure 1.4.12). The acetylated products are readily separated from the substrate by thin-layer chromatography (Figure 1.4.13) and quantitated by photography, fluorometry or with a plate scanner. Our original FAST CAT® Chloramphenicol Acetyltransferase Assay Kit^{52,53} (F2900) and improved FAST CAT® (deoxy) Chloramphenicol Acetyltransferase Assay Kit (F6616) utilize a green-fluorescent BODIPY® FL substrate, and the FAST CAT® Yellow (deoxy) Chloramphenicol Acetyltransferase Assay Kit (F6617) employs a yellow-fluorescent BODIPY® TMR 1-deoxychloramphenicol substrate. These products are described in detail in Section 10.6.

Additional Methods of Analysis Using BODIPY® Dye Conjugates

In addition to their general utility for the intensity-based and fluorescence polarization–based assays described above, the BODIPY® dyes are near optimal for a variety of other bioanalytical techniques:

- The spectral variety and high absorbance of the BODIPY® dyes (Figure 1.4.1) permits their use as efficient donor or acceptor dyes for numerous assays that use fluorescence resonance energy transfer, including internally quenched endopeptidase substrates⁵⁴ (Section 10.4), nucleic acid hybridization assays and receptor-binding assays (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2).
- BODIPY® dye conjugates of peptides are readily separated by chromatographic means and can be used to detect the activity of enzymes that catalyze secondary modifications, such as phosphorylation/dephosphorylation, glycosylation/deglycosylation, oxidation/reduction, myristoylation, farnesylation and peptide–peptide crosslinking.
- Hydrolysis of peptides that are singly labeled with BODIPY® dyes to smaller peptides can be detected chromatographically with extremely high sensitivity.
- With their high peak intensity and narrow emission spectra, reactive BODIPY® dyes are among the most detectable amine-derivatization reagents available for HPLC and capillary electrophoresis; thus, amine-containing metabolites can be derivatized with succinimidyl esters of the BODIPY® dyes (Table 1.7) for ultrasensitive analysis.^{7,55}

Figure 1.4.13 Chloramphenicol acetyltransferase (CAT) assays using our FAST CAT® Yellow (deoxy) Chloramphenicol Acetyltransferase Assay Kit (F6617). Decreasing amounts of purified CAT enzyme (2-fold dilutions) were incubated with the corresponding deoxy substrate in the presence of acetyl CoA; the reaction mixture was then separated with standard thin-layer chromatography (TLC) methods and visualized with 366 nm epi-illumination. The bottom row of fluorescent spots in each TLC represents the substrate; the top, the monoacetylated reaction product.

Notes

- The absorption and fluorescence spectra of BODIPY® derivatives are relatively insensitive to the solvent.
- This sulfotetrafluorophenyl (STP) ester derivative is water soluble and may be dissolved in buffer at ~pH 8 for reaction with amines. Long-term storage in water is NOT recommended due to hydrolysis.
- The fluorescence lifetime (τ) of D2184 in MeOH at 20°C is 5.7 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
- Oxidation of the polyunsaturated butadienyl portion of the BODIPY® 581/591 dye results in a shift of the fluorescence emission peak from ~590 nm to ~510 nm. (*Methods Enzymol* (2000) 319:603; *FEBS Lett* (1999) 453:278)
- The fluorescence lifetime (τ) of D6116 in MeOH at 20°C is 5.4 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
- This sulfonated succinimidyl ester derivative is water soluble and may be dissolved in buffer at ~pH 8 for reaction with amines. Long-term storage in water is NOT recommended due to hydrolysis.
- The fluorescence lifetime (τ) of the BODIPY® 630/650 dye at 20°C is 3.9 nanoseconds in H₂O and 4.4 nanoseconds in EtOH. (*Bioconjug Chem* (2003) 14:195)

PRODUCT LIST 1.4 BODIPY® DYE SERIES

Cat. No.	Product	Quantity
B10006	BODIPY® FL, STP ester, sodium salt	5 mg
D3834	4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-pentanoic acid (BODIPY® FL C ₅)	1 mg
D6184	4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-pentanoic acid, succinimidyl ester (BODIPY® FL C ₅ , SE)	5 mg
D2183	4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-propionic acid (BODIPY® FL)	5 mg
D2184	4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-propionic acid, succinimidyl ester (BODIPY® FL, SE)	5 mg
D6140	4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-propionic acid, sulfosuccinimidyl ester, sodium salt (BODIPY® FL, SSE)	5 mg
D6102	6-(((4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-propionyl)amino)hexanoic acid, succinimidyl ester (BODIPY® FL-X, SE)	5 mg
D6117	6-(((4,4-difluoro-1,3,5,7-tetramethyl-5-(4-methoxyphenyl)-4-bora-3a,4a-diaza-s-indacene-2-propionyl)amino)hexanoic acid, succinimidyl ester (BODIPY® TMR-X, SE)	5 mg
D2187	4,4-difluoro-5,7-diphenyl-4-bora-3a,4a-diaza-s-indacene-3-propionic acid, succinimidyl ester (BODIPY® 530/550, SE)	5 mg
D6180	4,4-difluoro-5-phenyl-4-bora-3a,4a-diaza-s-indacene-3-propionic acid, succinimidyl ester (BODIPY® R6G, SE)	5 mg
D2228	4,4-difluoro-5-(4-phenyl-1,3-butadienyl)-4-bora-3a,4a-diaza-s-indacene-3-propionic acid, succinimidyl ester (BODIPY® 581/591, SE)	5 mg
D2225	4,4-difluoro-5-(2-pyrrolyl)-4-bora-3a,4a-diaza-s-indacene-3-propionic acid, succinimidyl ester (BODIPY® 576/589, SE)	5 mg
D10001	6-(((4,4-difluoro-5-(2-pyrrolyl)-4-bora-3a,4a-diaza-s-indacene-3-yl)styryloxy)acetyl)amino)hexanoic acid, succinimidyl ester (BODIPY® 650/665-X, SE)	5 mg
D2222	4,4-difluoro-5-styryl-4-bora-3a,4a-diaza-s-indacene-3-propionic acid, succinimidyl ester (BODIPY® 564/570, SE)	5 mg
D2191	4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-s-indacene-8-propionic acid, succinimidyl ester (BODIPY® 493/503, SE)	5 mg
D2219	4,4-difluoro-5-(2-thienyl)-4-bora-3a,4a-diaza-s-indacene-3-propionic acid, succinimidyl ester (BODIPY® 558/568, SE)	5 mg
D6116	6-(((4,4-difluoro-5-(2-thienyl)-4-bora-3a,4a-diaza-s-indacene-3-yl)phenoxy)acetyl)amino)hexanoic acid, succinimidyl ester (BODIPY® TR-X, SE)	5 mg
D10000	6-(((4,4-difluoro-5-(2-thienyl)-4-bora-3a,4a-diaza-s-indacene-3-yl)styryloxy)acetyl)amino)hexanoic acid, succinimidyl ester (BODIPY® 630/650-X, SE)	5 mg

1.5 Fluorescein, Oregon Green® and Rhodamine Green™ Dyes

Fluorescein

Figure 1.5.1 Absorption and fluorescence emission spectra of fluorescein in pH 9.0 buffer.

The amine-reactive fluorescein derivatives (Table 1.8) have been the most common fluorescent derivatization reagents for covalently labeling proteins. In addition to its relatively high absorptivity, excellent fluorescence quantum yield and good water solubility, fluorescein (F1300, Figure 1.5.1) has an excitation maximum (494 nm) that closely matches the 488 nm spectral line of the argon-ion laser, making it an important fluorophore for confocal laser-scanning microscopy¹ and flow cytometry applications. In addition, fluorescein's protein conjugates are not inordinately susceptible to precipitation. Because it can be prepared in high purity, fluorescein is one of the five dyes in the Reference Dye Sampler Kit² (R14782, Section 23.1). We are also the source of the NIST-traceable fluorescein standard (F36915) described below.

NIST-Traceable Fluorescein Standard

The National Institute of Standards and Technology (NIST) chose a high-grade fluorescein synthesized in our laboratories to create Standard Reference Material 1932 (SRM® 1932), a certified fluorescein solution. We now offer a NIST-traceable fluorescein standard (F36915) that not only meets the stringent criteria established by NIST, but is also directly traceable to SRM® 1932. We supply our NIST-traceable fluorescein standard as a calibrated 50 μM solution of fluorescein in 100 mM sodium borate buffer, pH 9.5; under these conditions, fluorescein is completely ionized³ and is therefore in its most fluorescent form (Figure 1.5.2), exhibiting an extremely high quantum yield of 0.93 (Section 20.2).

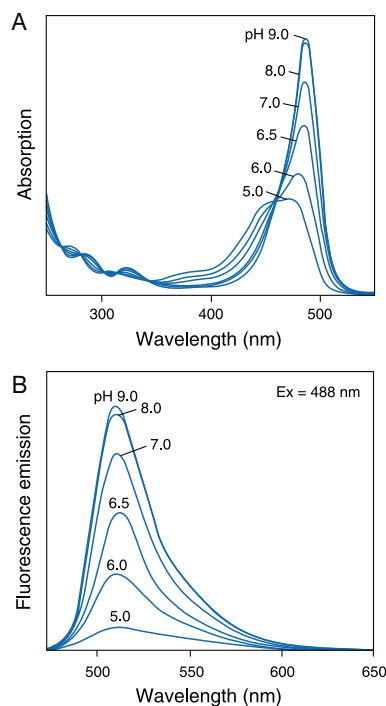

Figure 1.5.2 The pH-dependent spectra of fluorescein (F1300): A) absorption spectra, B) emission spectra.

Academic researchers and industry scientists alike can use our NIST-traceable fluorescein standard to assess day-to-day or experiment-to-experiment variation in fluorescence-based instrumentation, as well as to determine the Molecules of Equivalent Soluble Fluorophore (MESF) value for an experimental solution. The MESF value is defined not as the actual number of dye molecules present, but rather as the number of fluorophores that would yield a fluorescence intensity equivalent to that of the experimental solution when analyzed on the same instrument under the same conditions.⁴⁻⁶ Consequently, the MESF value is an important tool for characterizing the fluorescence intensity of a solution containing spectrally similar dye molecules attached to antibodies, nucleic acids, microspheres or other substrates that might enhance or diminish the fluorescence. When its pH is carefully matched with that of the experimental solution, our NIST-traceable fluorescein standard can be used for accurate MESF determinations of a wide range of green-fluorescent dye solutions and on an assortment of fluorescence-based instruments.

Limitations of Fluorescein

Even though fluorescein has been used to derivatize biomolecules for decades, fluorescein-based dyes and their conjugates have several significant drawbacks, including:

- A relatively high rate of photobleaching⁷⁻⁹ (Figure 1.5.3, Figure 1.5.4)
- pH-sensitive fluorescence^{10,11} ($pK_a \sim 6.4$) that is significantly reduced below pH 7 (Figure 1.5.5)
- A relatively broad fluorescence emission spectrum, limiting their utility in some multicolor applications
- A tendency toward quenching of their fluorescence on conjugation to biopolymers, particularly at high degrees of labeling (Figure 1.5.6)

Figure 1.5.4 Bovine pulmonary artery endothelial cells (BPAEC) were labeled with fluorescein phalloidin (left panels, F432), or Alexa Fluor® 488 phalloidin (right panels, A12379), which labels filamentous actin, and mounted in PBS. The cells were placed under constant illumination on the microscope with an FITC filter set using a 60× objective. Images were acquired at 1-second intervals for 30 seconds. Under these illumination conditions, fluorescein photobleached to about 20% of its initial value in 30 seconds; the fluorescence of Alexa Fluor® 488 phalloidin stayed at the initial value under the same illumination conditions.

Figure 1.5.3 Comparison of photostability of green-fluorescent antibody conjugates. The following fluorescent goat anti-mouse IgG antibody conjugates were used to detect mouse anti-human IgG antibody labeling of human anti-nuclear antibodies in HEp-2 cells on prefixed test slides (INOVA Diagnostics Corp.): Oregon Green® 514 (O6383, ■), Alexa Fluor® 488 (A11001, ○), BODIPY® FL (B2752, △), Oregon Green® 488 (O6380, □) or fluorescein (F2761, ●). Samples were continuously illuminated and viewed on a fluorescence microscope using a fluorescein longpass filter set. Images were acquired every 5 seconds. For each conjugate, three data sets, representing different fields of view, were averaged and then normalized to the same initial fluorescence intensity value to facilitate comparison.

Figure 1.5.5 Comparison of pH-dependent fluorescence of the Oregon Green® 488 (●), carboxyfluorescein (○) and Alexa Fluor® 488 (□) fluorophores. Fluorescence intensities were measured for equal concentrations of the three dyes using excitation/emission at 490/520 nm.

Figure 1.5.6 Comparison of relative fluorescence as a function of the number of fluorophores attached per protein for goat anti-mouse IgG antibody conjugates prepared using Oregon Green® 514 carboxylic acid succinimidyl ester (O6139, ■), Oregon Green® 488 carboxylic acid succinimidyl ester (O6147, ●), fluorescein-5-EX succinimidyl ester (F6130, ○) and fluorescein isothiocyanate (FITC, F143, F1906, F1907, □). Conjugate fluorescence is determined by measuring the fluorescence quantum yield of the conjugated dye relative to that of the free dye and multiplying by the number of fluorophores per protein.

Figure 1.5.7 Fluorescein-5-isothiocyanate (FITC 'Isomer I', F143).

Figure 1.5.8 Two proteobacterial symbionts localized with phylotype-specific 16S rRNA-directed oligonucleotide probes labeled with either fluorescein-5-isothiocyanate (F143, F1906, F1907) or Texas Red® sulfonil chloride (T353, T1905). The filamentous bacteria are attached to a hair-like structure secreted from a pore on the dorsal surface of the deep-sea hydrothermal vent polychaete *Alvinella pompejana*. Image contributed by M. Cottrell and C. Cary, College of Marine Studies, University of Delaware.

Figure 1.5.9 6-carboxy-4',5'-dichloro-2',7'-dimethoxyfluorescein, succinimidyl ester (6-JOE, SE; C6171MP).

The photobleaching and pH sensitivity of fluorescein make quantitative measurements with this fluorophore problematic. Furthermore, fluorescein's relatively high photobleaching rate limits the sensitivity that can be obtained, a significant disadvantage for applications requiring ultrasensitive detection, such as DNA sequencing, fluorescence *in situ* hybridization and localization of low-abundance receptors. These limitations have encouraged the development of alternative fluorophores.

There are no new dyes available that completely solve fluorescein's photobleaching problems, but we have developed some excellent dyes whose spectra mimic those of fluorescein—the Alexa Fluor® 488 (Section 1.3), BODIPY® FL (Section 1.4), Oregon Green® 488, Oregon Green® 514 and Rhodamine Green™ dyes (this section). These dyes are much more photostable than fluorescein and have less or no pH sensitivity in the physiological pH range. When compared with fluorescein, all of these dyes exhibit the same or slightly longer-wavelength spectra (absorption maxima ~490–515 nm) and comparably high fluorescence quantum yields. Alternatively, where they can be used, our yellow-green fluorescent FluoSpheres® microspheres and our Qdot® nanocrystals (Section 6.5, Section 6.6, respectively) provide a means of preparing bioconjugates that have a combination of fluorescence intensity and photostability far superior to that of any simple dye conjugate.

Single-Isomer Fluorescein Isothiocyanate (FITC) Preparations

Despite the availability of alternative amine-reactive fluorescein derivatives that yield conjugates with superior stability and comparable spectra, fluorescein isothiocyanate (FITC) remains one of the most popular fluorescent labeling reagents.¹² The synthesis of fluorescein isothiocyanate, carboxyfluorescein (FAM) and similar fluorescein-derived reagents yields a mixture of isomers at the 5- and 6-positions of fluorescein's carboxyphenyl ("bottom") ring (Figure 1.5.7). Spectra of the two isomers are almost indistinguishable in both wavelength and intensity. The isomers, however, may differ in the geometry of their binding to proteins, and the conjugates may elute under different chromatographic conditions or migrate differently in an electrophoretic gel. Thus, certain applications may require the single-isomer preparations. Many fluorescein (and rhodamine) probes are available either as a mixture of isomers or as purified single isomers.

The 5-isomer or "isomer I" of FITC (F143, Figure 1.5.7, Figure 1.5.8) is the most widely used FITC isomer, probably because it is easier to isolate in pure form. Because isothiocyanates may deteriorate during storage, we recommend purchasing the 5-isomer of FITC specially packaged in individual vials (F1906, F1907). FITC is readily soluble in aqueous solutions that have a pH above 6. FITC is also available in our FluoReporter® FITC Protein Labeling Kit (F6434, Table 1.2), which is described in Section 1.2.

Mixed-Isomer and Single-Isomer Preparations of FAM and JOE Succinimidyl Esters

Although many other companies still prepare their fluorescein bioconjugates with FITC, we prefer to use amine-reactive succinimidyl esters of carboxyfluorescein (commonly called FAM), which yield carboxamides that are more resistant to hydrolysis. We offer both mixed-isomer and single-isomer preparations of FAM (C1904, C1359, C1360) and FAM succinimidyl esters (C1311, C2210, C6164). A study comparing the relative conjugation rate of several reactive fluorescein derivatives with a protein or L-lysine and the stability of the resulting conjugates concluded that the succinimidyl ester of carboxyfluorescein showed superior performance, followed by fluorescein dichlorotriazine (DTAF). FITC was both the slowest to react and yielded the least stable conjugates;¹³ however, the degree of labeling was most easily controlled with FITC.¹³ The succinimidyl ester of 5-FAM (C2210) is reported to react much faster than FITC when used to derivatize small biomolecules prior to separation by capillary electrophoresis.¹⁴ We also offer a single-isomer preparation of the succinimidyl ester of 6-carboxy-4',5'-dichloro-2',7'-dimethoxyfluorescein (6-JOE, SE; C6171MP; Figure 1.5.9). 6-JOE is one of the four fluorophores (i.e., 5-FAM, 6-JOE, 6-TAMRA and 6-ROX) used in first-generation electrophoretic DNA sequencing instruments.

Succinimidyl Esters of Fluorescein with Spacer Groups

We also prepare succinimidyl esters of fluorescein that contain aliphatic spacers between the fluorophore and the reactive group. These include mixed-isomer (F2181, F6129) and single-isomer

(F6106) preparations of fluorescein-X succinimidyl ester (SFX), which contains a seven-atom aminohexanoyl spacer ("X") between the FAM fluorophore and the succinimidyl ester (Figure 1.5.10). In addition, we offer fluorescein-5-EX succinimidyl ester (F6130), which contains a seven-atom spacer that is somewhat more hydrophilic than is the spacer in SFX (Figure 1.5.11). These spacers separate the fluorophore from the biomolecule to which it is conjugated, potentially reducing the quenching that typically occurs upon conjugation. We have determined that conjugates of some proteins prepared with fluorescein-5-EX succinimidyl ester are up to twice as fluorescent as the corresponding conjugates labeled with FITC at the same degree of labeling (Figure 1.5.6). Consequently, we now recommend this fluorescein derivative as the preferred dye for preparing most fluoresceinated proteins. Fluorescein-5-EX succinimidyl ester is also available in our convenient FluoReporter® Fluorescein-EX Protein Labeling Kit (F6433) and Fluorescein-EX Protein Labeling Kit (F10240). See Section 1.2 and Table 1.3 for more details about these labeling kits.

The spacers in our SFX and fluorescein-5-EX succinimidyl esters may also make the fluorophore more accessible to secondary detection reagents.^{15–17} For example, the spacers should make the fluorescein moiety more available for quenching by our polyclonal and monoclonal anti-fluorescein/Oregon Green® antibodies, a technique used to determine the accessibility of the fluorophore in proteins, membranes and cells.^{16,18} Fluorescein is frequently used as a hapten on a primary detection reagent that can be either amplified or converted into a longer-wavelength or electron-dense signal with the appropriate secondary detection reagent. Section 7.4 describes our extensive selection of antibodies to fluorescein and other dyes.

Fluorescein Dichlorotriazine (DTAF)

The 5-isomer of fluorescein dichlorotriazine (5-DTAF, D16) is highly reactive with proteins^{19,20} and is commonly used to prepare biologically active fluorescein tubulin.²¹ Unlike other reactive fluoresceins, 5-DTAF also reacts directly with polysaccharides and other alcohols in aqueous solution at pH above 9, but cannot be used to modify alcohols in the presence of better nucleophiles such as amines or thiols.²² Polysaccharides that have been modified by DTAF (or other fluorescein derivatives) are readily radioiodinated.²³

Caged Fluorescein Succinimidyl Ester

Caged probes are those that can liberate an active species upon illumination with ultraviolet light (Section 5.3). Caged fluorescent dyes can be utilized as polar tracers whose fluorescence can be spatially and temporally activated by illumination. Conjugation of the succinimidyl ester of our water-soluble, caged carboxyfluorescein β -alanine-carboxamide (C20050, Figure 1.5.12) to a biomolecule of interest produces an essentially nonfluorescent probe that yields a green-fluorescent fluorescein-labeled product only after ultraviolet photoactivation. Furthermore, caged fluorescein probes are immunochemically cryptic (i.e., the probe is immunoreactive with anti-fluorescein/Oregon Green® antibodies after but not before photoactivation). Caged fluorescein succinimidyl ester is also a key starting material for preparing probes for super-resolution photoactivation microscopy.^{24,25}

Figure 1.5.12 5-carboxyfluorescein-bis(5-carboxymethoxy-2-nitrobenzyl) ether, β -alanine-carboxamide, succinimidyl ester (CMNB-caged carboxyfluorescein, SE; C20050).

Figure 1.5.13 Absorption and fluorescence emission spectra of Oregon Green® 488 goat anti-mouse IgG antibody in pH 8.0 buffer.

Figure 1.5.14 Photostability comparison for Oregon Green® 514 phalloidin (O7465) and fluorescein phalloidin (F432). CRE BAG 2 fibroblasts were fixed with formaldehyde, permeabilized with acetone and then stained with the fluorescent phallotoxins. Samples were continuously illuminated and images were acquired every 5 seconds using a Star 1 CCD camera (Photometrics®); the average fluorescence intensity in the field of view was calculated with Image-1 software (Universal Imaging Corp.) and expressed as a fraction of the initial intensity. Three data sets, representing different fields of view, were averaged for each labeled phalloidin to obtain the plotted time courses.

Oregon Green® 488 and Oregon Green® 514 Dyes

Oregon Green® 488 and Oregon Green® 514 dyes are fluorinated analogs of fluoresceins.²⁶ The absorption and emission spectra of Oregon Green® 488 dye (2',7'-difluorofluorescein; D6145; Figure 1.5.13) is designed to perfectly match those of fluorescein. With additional fluorination of the carboxyphenyl ("bottom") ring of fluorescein, Oregon Green® 514 dye exhibits a moderate shift in its absorption and fluorescence spectra of about 15 nm relative to those of fluorescein or Oregon Green® 488 dye. Because of the near match of their absorption maxima on proteins (~498 nm and ~512 nm) to the strong 488 nm and 514 nm spectral lines of the argon-ion laser, the Oregon Green® 488 and Oregon Green® 514 fluorophores are important dyes for both confocal laser-scanning microscopy and flow cytometry applications. Furthermore, spectral imaging systems with linear-unmixing analysis software^{27–29} permit the resolution of Oregon Green® 514 dye from other green-fluorescent dyes.

Bioconjugates prepared from Oregon Green® 488 and Oregon Green® 514 dyes share several advantages over those of other fluorescein dyes. These include:

- Fluorescence of protein conjugates prepared from Oregon Green® 488 and Oregon Green® 514 dyes is not appreciably quenched, even at relatively high degrees of labeling (Figure 1.5.6).
- Conjugates of Oregon Green® 488 and Oregon Green® 514 fluorophores are more photostable than those of fluorescein (Figure 1.5.3, Figure 1.5.14), allowing increased acquisition of photons before photodestruction of the dye and making Oregon Green® dyes particularly useful substitutes for fluoresceins for fluorescence imaging applications (Figure 1.5.15).
- Oregon Green® dyes have a lower pK_a ($pK_a = 4.7$ versus 6.4 for fluorescein) (Figure 1.5.5), making their fluorescence essentially pH insensitive in the physiological pH range. However, the pH sensitivity of Oregon Green® dyes in the weakly acidic range (pH 4 to 6) also makes these dyes useful as pH indicators for acidic organelles of live cells^{30,31} (Section 20.3).
- Oregon Green® dyes are excellent haptens for anti-fluorescein/Oregon Green® antibodies (Section 7.4, Table 4.2), making Oregon Green® bioconjugates useful in a variety of signal amplification schemes.

Both Oregon Green® 488 and Oregon Green® 514 dyes have also proven useful as fluorescence anisotropy probes for measuring protein–protein and protein–nucleic acid interactions.³²

Reactive Oregon Green® Dyes

We have prepared a variety of amine-reactive derivatives that enable researchers to take advantage of the spectral properties of Oregon Green® 488 and Oregon Green® 514 dyes

Figure 1.5.15 Photostability comparison of Oregon Green® 514 phalloidin (O7465, upper series) and fluorescein phalloidin (F432, lower series). CRE BAG 2 fibroblasts were fixed with formaldehyde, then permeabilized with acetone and stained with the fluorescent phallotoxin. Samples were illuminated continuously and viewed on a fluorescence microscope equipped with a fluorescein longpass optical filter set. Images acquired at 1, 10, 20 and 30 seconds after the start of illumination (left to right) demonstrate the superior photostability of the Oregon Green® 514 fluorophore.

(Table 1.8). These include the FITC analog, Oregon Green® 488 isothiocyanate (F₂FITC, O6080), and the single-isomer succinimidyl esters of Oregon Green® 488 carboxylic acid (O6147, O6149) and Oregon Green® 514 carboxylic acid (O6139). In addition, we offer the 5-isomer of Oregon Green® 488 carboxylic acid (O6146, Figure 1.5.16) and the mixed-isomer preparation of Oregon Green® 514 carboxylic acid (O6138, Figure 1.5.17). The 6-isomer of Oregon Green® 488-X succinimidyl ester (O6185, Figure 1.5.18) contains a seven-atom aminohexanoyl spacer ("X") between the fluorophore and the succinimidyl ester group. This spacer helps to separate the fluorophore from its point of attachment, reducing the interaction of the fluorophore with the biomolecule to which it is conjugated³³ and making it more accessible to secondary detection reagents.

Oregon Green® Protein and Nucleic Acid Labeling Kits

When directly compared with their fluorescein analogs, Oregon Green® 488 and Oregon Green® 514 conjugates typically have higher fluorescence yields and greater resistance to photobleaching. We have used succinimidyl esters of the Oregon Green® 488 and Oregon Green® 514 carboxylic acids to prepare conjugates of antibodies (Section 7.2, Table 7.1), streptavidin (Section 7.6, Table 7.9) and a variety of other proteins and ligands.

To facilitate direct labeling of biomolecules with Oregon Green® dyes, we offer several kits that are easy to use and produce reliable conjugations in minimal time. Our Oregon Green® protein and nucleic acid labeling kits, which are described in detail in the indicated sections, include:

- APEX® Oregon Green® 488 Antibody Labeling Kit (A10476, Section 1.2)
- FluReporter® Oregon Green® 488 Protein Labeling Kit (F6153, Section 1.2)
- Oregon Green® 488 Protein Labeling Kit (O10241, Section 1.2)
- ULYSIS® Oregon Green® 488 Nucleic Acid Labeling Kit (U21659, Section 8.2)

Rhodamine Green™ and Rhodamine Green™-X Dyes

Carboxyrhodamine 110, which we have named Rhodamine Green™ dye, is the nonsulfonated analog of Alexa Fluor® 488 dye. Rhodamine Green™ dye offers a combination of desirable properties, including good photostability, a high extinction coefficient (>75,000 cm⁻¹M⁻¹) and a high fluorescence quantum yield, particularly in its nucleotide and nucleic acid conjugates. The Rhodamine Green™ fluorophore is even more photostable than the Oregon Green® 488 dye and about equivalent in photostability to the Oregon Green® 514 dye (Figure 1.5.3). Moreover, the fluorescence of its conjugates is completely insensitive to pH between 4 and 9.

Reactive versions of the Rhodamine Green™ dye (Table 1.8) were originally developed in our laboratories for use in DNA sequencing and other applications. Rhodamine Green™ conjugates can be prepared using the amine-reactive succinimidyl ester of Rhodamine Green™ dye (5(6)-CR 110, SE; R6107) or the succinimidyl ester of the Rhodamine Green™-X dye (R6113), which has an additional seven-atom aminohexanoyl spacer ("X") to reduce interaction of the fluorophore and its reaction site. The absorption and fluorescence emission maxima of Rhodamine Green™ conjugates are red-shifted about 7 nm compared with those of fluorescein; however, they remain compatible with standard fluorescein optical filter sets.

Although the Rhodamine Green™ dye is one of the most photostable of the fluorescein substitutes, its fluorescence when conjugated to proteins is often substantially quenched, and these conjugates also tend to precipitate from solution. Therefore, we do not recommend any of the Rhodamine Green™ succinimidyl esters for preparing protein conjugates. However, when conjugated to dextrans,³⁴ nucleotides and oligonucleotides,³⁵ the Rhodamine Green™ fluorophore remains highly fluorescent, and we currently offer two Rhodamine Green™ dextrans (D7153, D7163; Section 14.5, Table 14.4). In addition, Rhodamine Green™ dye-labeled probes have been frequently used for fluorescence correlation spectroscopy³⁶⁻³⁸ (Fluorescence Correlation Spectroscopy (FCS)—Note 1.3).

Figure 1.5.16 Oregon Green® 488 carboxylic acid (O6146).

Figure 1.5.18 Oregon Green® 488-X, succinimidyl ester (O6185).

Figure 1.5.19 Eosin-5-isothiocyanate (E18).

Eosin

Eosin (2',4',5',7'-tetrabromofluorescein, Figure 1.5.19) is usually not chosen for its fluorescence properties—the fluorescence quantum yield is typically only about 10–20% that of fluorescein—but rather for its ability to act as phosphorescent probe or as a fluorescence quencher.³⁹ With its high quantum yield (~0.57) for singlet oxygen generation, eosin and its conjugates can be used as effective photosensitizers of diamino-benzidine (DAB) oxidation in high-resolution electron microscopy

studies (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2). Like its thiol-reactive maleimide counterpart (E118, Section 2.2), eosin isothiocyanate (E18) is particularly useful as a phosphorescent probe for measuring the rotational properties of proteins, virus particles and other biomolecules in solution and in membranes.⁴⁰ In addition, eosin conjugates are employed for fluorescence resonance energy transfer (FRET) studies (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2) and for fluorescence recovery after photobleaching (FRAP) measurements of lateral diffusion.

For definitions of the contents of this data table, see "Using The Molecular Probes® Handbook" in the introductory pages.

Notes

- Absorption and fluorescence of fluorescein derivatives are pH dependent. Extinction coefficients and fluorescence quantum yields decrease markedly at pH <7.
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- Absorption and fluorescence of C6171MP are pH dependent (pK_a ~11.5). Fluorescence is maximal at pH >12.
- All photoactivatable probes are sensitive to light. They should be protected from illumination except when photolysis is intended.
- This product is colorless and nonfluorescent until it is activated by ultraviolet photolysis. Photoactivation generates a fluorescein derivative with spectral characteristics similar to C1359.
- Unstable in water. Use immediately.
- Absorption and fluorescence of Oregon Green® 488 derivatives are pH dependent only in moderately acidic solutions (pH <5).
- Isothiocyanates are unstable in water and should not be stored in aqueous solution.
- Eosin derivatives also exhibit phosphorescence with an emission maximum at ~680 nm. The phosphorescence lifetime is ~1 millisecond for eosin. (Biochem J (1979) 183:561, Spectroscopy (1990) 5:20) Fluorescence lifetime (τ) is 1.4 nanoseconds (QY = 0.2) for eosin. (J Am Chem Soc (1977) 99:4306)
- The extinction coefficient of fluorescein isothiocyanate decreases about 10% on protein conjugation. (J Immunol Methods (1974) 5:103) The fluorescence lifetime (τ) is 3.8 nanoseconds.
- F36915 consists of a fluorescein solution in 100 mM sodium borate buffer pH 9.5. The concentration of fluorescein is set spectrophotometrically to be equivalent to that of NIST Standard Reference Material (SRM®) 1932.
- Absorption and fluorescence of Oregon Green® 514 derivatives are pH dependent only in moderately acidic solutions (pH <5).
- The fluorescence lifetime (τ) of the Oregon Green® 514 dye in pH 9.0 buffer at 20°C is 4.2 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
- The fluorescence lifetime (τ) of the Oregon Green® 488 dye (O6146) in pH 9.0 buffer at 20°C is 4.1 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.

PRODUCT LIST 1.5 FLUORESCHEIN, OREGON GREEN® AND RHODAMINE GREEN™ DYES

Cat. No.	Product	Quantity
A10476	APEX® Oregon Green® 488 Antibody Labeling Kit	1 kit
C6171MP	6-carboxy-4',5'-dichloro-2',7'-dimethoxyfluorescein, succinimidyl ester (6-JOE, SE)	5 mg
C1359	5-carboxyfluorescein (5-FAM) *single isomer*	100 mg
C1360	6-carboxyfluorescein (6-FAM) *single isomer*	100 mg
C1904	5-(and-6)-carboxyfluorescein (5(6)-FAM) *FluoroPure™ grade* *mixed isomers*	100 mg
C2210	5-carboxyfluorescein, succinimidyl ester (5-FAM, SE) *single isomer*	10 mg
C6164	6-carboxyfluorescein, succinimidyl ester (6-FAM, SE) *single isomer*	10 mg
C1311	5-(and-6)-carboxyfluorescein, succinimidyl ester (5(6)-FAM, SE) *mixed isomers*	100 mg
C20050	5-carboxyfluorescein-bis-(5-carboxymethoxy-2-nitrobenzyl) ether, β-alanine-carboxamide, succinimidyl ester (CMNB-caged carboxyfluorescein, SE)	1 mg
D16	5-(4,6-dichlorotriazinyl)aminofluorescein (5-DTAF) *single isomer*	100 mg
D6145	2',7'-difluorofluorescein (Oregon Green® 488)	10 mg
E18	eosin-5-isothiocyanate	100 mg
F6434	FluoReporter® FITC Protein Labeling Kit *5–10 labelings*	1 kit
F6433	FluoReporter® Fluorescein-EX Protein Labeling Kit *5–10 labelings*	1 kit

1.6 Long-Wavelength Rhodamines, Texas Red® Dyes and QSY® Quenchers

This section includes dyes that have absorption maxima beyond about 520 nm, extending to nearly 800 nm. Significant exceptions, however, are the long-wavelength Alexa Fluor® dyes, which are all discussed in Section 1.3, the long-wavelength BODIPY® dyes—BODIPY® TMR, BODIPY® TR, BODIPY® 630/650 and BODIPY® 650/665—which are described in Section 1.4 and the 2',4',5',7'-tetrabromofluorescein (eosin) and JOE dyes, which also absorb maximally beyond 520 nm but are discussed with other fluoresceins in Section 1.5. In many applications, the versatile Alexa Fluor® and BODIPY® dyes provide demonstrably superior performance relative to the dyes in this section.

Julolidine

Sulforhodamine 101

Figure 1.6.1 The amine substituents of X-rhodamine, sulforhodamine 101 and Texas Red® dyes are rigidified in a julolidine ring structure.

Rhodamine dyes (Table 1.9) are among the most photostable fluorescent labeling reagents available. Moreover, spectra of most of these dyes are not affected by changes in pH between 4 and 10, an important advantage over the fluoresceins for many biological applications.¹ The most common members of this group have been the tetramethylrhodamines—including the reactive isothiocyanate (TRITC) and carboxylic acid (TAMRA) derivatives—as well as the X-rhodamines. The X prefix of the X-rhodamines, which include Texas Red® derivatives, refers to the fluorophore's extra julolidine rings (Figure 1.6.1). These rings prevent rotation about the nitrogen atoms, resulting in a shift in the fluorophore's spectra to longer wavelengths and usually an increase in its fluorescence quantum yield.

QSY® 7, QSY® 9 and QSY® 21 dyes are essentially nonfluorescent diarylrhodamine chromophores with strong absorption in the visible wavelength region, and they have proven to be extremely effective fluorescence quenchers.^{2,3} QSY® 7, QSY® 9 and QSY® 21 dyes complement the QSY® 35 dye, a nonfluorescent quencher based on the NBD fluorophore that absorbs maximally near 475 nm, and the dabcyl quencher, both of which are described in Section 1.8.

Table 1.9 Amine-reactive, orange- and red-fluorescent fluorophores in this section.

Fluorophore (Abs/Em) *	Succinimidyl Ester	Other	Protein Labeling Kits	Notes
Lissamine rhodamine B (570/590)		L20 (SC) ^M L1908 (SC) ^M		• Optimal for 568 nm excitation • Photostable
Naphthofluorescein (602/672)	C653 ^M	C652 (COOH) ^M		• Very long-wavelength excitation and emission • pH-sensitive fluorescence, with a high pK _a (~7.6)
Rhodamine 6G (525/555)	C6127 ^S C6128 ⁶ C6157 ^M			• Excited by the 514 nm spectral line of the argon-ion laser • Spectra intermediate between those of fluorescein and tetramethylrhodamine
Rhodamine Red™-X (580/590)	R6160 (X) ^S		F6161 (F)	• Conjugates of Rhodamine Red™-X are generally more fluorescent than those of Lissamine rhodamine B, and the succinimidyl ester is more stable in H ₂ O
Tetramethylrhodamine (555/580)	C2211 ^S C6123 ⁶ C1171 ^M T6105 (X) ^M	C6121 (COOH) ^S C6122 (COOH) ⁶ C300 (COOH) ^M T1480 (ITC) ^S T1481 (ITC) ⁶ T490 (ITC) ^M		• pH-insensitive fluorescence • Good photostability • Conjugates are prone to aggregation • Succinimidyl ester derivative (6-TAMRA, SE; C6123) is widely used for oligonucleotide labeling
Texas Red® dye (595/615)	T6134 (X) ^M T20175 (X) ^S	T353 (SC) ^M T1905 (SC) ^M T30200 (DTA) ^M	F6162 (F) T10244 (P) Z25045 (Z)	• Good spectral separation from green fluorophores • Texas Red®-X succinimidyl ester typically yields greater fluorescence per attached dye than Texas Red® sulfonyl chloride and is more stable in H ₂ O
X-rhodamine (580/605)	C6125 ^S C6126 ⁶ C1309 ^M	C6124 (COOH) ^S C6156 (COOH) ⁶ X491 (ITC) ^M		• Succinimidyl ester derivative (6-ROX, SE; C6126) is widely used for oligonucleotide labeling

* The numbers in parentheses reflect the absorption (Abs) and fluorescence emission (Em) maxima, in nm, of the goat anti-mouse IgG antibody or dextran conjugates in aqueous buffer.

(P) = Easy-to-Use Protein Labeling Kit (Section 1.2). (S) = Single isomer. (SC) = Sulfonyl chloride. (X) = Aminohexanoyl spacer separating the dye and the SE. (Z) = Zenon® Antibody Labeling Kit (Section 7.3).

Tetramethylrhodamine

Tetramethylrhodamine (TMR) has been an important fluorophore for preparing protein conjugates, especially the fluorescent antibody and avidin derivatives used in immunochemistry. Under the name TAMRA, the carboxylic acid of TMR has also achieved prominence as a dye for oligonucleotide labeling^{3,4} (Section 8.2, Table 8.7) and single-molecule detection applications.^{5,6} Because it can be prepared in high purity, the 5-isomer of TAMRA (C6121) is one of the five dyes in our Reference Dye Sampler Kit (R14782, Section 23.1). TMR is efficiently excited by the 543 nm spectral line of the green He-Ne laser, which is increasingly being used for analytical instrumentation; diode lasers with 561 nm output⁷ are slightly suboptimal but still effective.

TMR dyes such as TAMRA and TRITC are quite hydrophobic (Figure 1.6.2) when compared with their fluorescein counterparts FAM and FITC. As a result, they have a tendency to aggregate in aqueous solutions under conditions where the labeling density is sufficient to permit dye-dye interactions. A further consequence of these interactions is fluorescence self-quenching, which reduces the fluorescence output of the conjugate. Dye-dye interactions and self-quenching are much less prevalent with the more polar and water-soluble Alexa Fluor® dyes.⁸ Another indication of intermolecular interactions of TMR dyes is that the absorption spectrum of TMR-labeled proteins is frequently complex (Figure 1.6.3), usually splitting into two absorption peaks at about 520 and 550 nm,⁹ so that the actual degree of labeling is difficult to determine. Excitation at wavelengths in the range of the short-wavelength peak fails to yield the expected amount of fluorescence, indicating that it arises from a nonfluorescent dye aggregate. Furthermore, when the TMR-labeled protein conjugate is denatured by guanidine hydrochloride, the long-wavelength absorption increases, the short-wavelength peak mostly disappears and the fluorescence yield almost doubles¹⁰ (Figure 1.6.3). The absorption spectra of TMR-labeled nucleotides and of other probes such as our rhodamine phalloidin (R415, Section 11.1) do *not* split into two peaks, indicating a labeling ratio of one dye molecule per biomolecule. The emission spectrum of TMR conjugates does not vary much with the degree of labeling.⁹ An improved method for estimating the degree of substitution of TRITC conjugates has been described.¹⁰

Mixed-Isomer and Single-Isomer TRITC Preparations

Our tetramethylrhodamine isothiocyanate (TRITC) is of the highest quality available from any commercial source. Both the mixed-isomer (T490) and single-isomer (T1480, T1481) TRITC preparations typically have extinction coefficients above 80,000 cm⁻¹M⁻¹, whereas some competitive sources of TRITC have extinction coefficients reported to be below 50,000 cm⁻¹M⁻¹. TRITC is widely used by other companies to prepare most of their so-called "rhodamine" immunoconjugates; however, they also often employ reactive versions of rhodamine B or Lissamine rhodamine B, which have somewhat different spectra, resulting in some confusion in matching the product name to the correct fluorophore.

Succinimidyl Esters of Carboxytetramethylrhodamine

Almost all Molecular Probes® TMR conjugates are prepared using succinimidyl esters of carboxytetramethylrhodamine (TAMRA™ dye), rather than TRITC, because bioconjugates from succinimidyl esters are more stable and often more fluorescent. We offer the mixed-isomer (C300) and single-isomer (C6121, C6122) preparations of carboxymethylrhodamine, as well as the corresponding mixed-isomer (C1171) and single-isomer (C2211, C6123) succinimidyl esters. The single-isomer preparations are most important for high-resolution techniques such as DNA sequencing¹¹ and separation of labeled carbohydrates by capillary electrophoresis.¹² 6-TAMRA™ dye is one of the traditional fluorophores (5-FAM™, 6-JOE™, 6-TET™, 6-HEX™, 6-TAMRA™ and 6-ROX™ dyes) used in first-generation electrophoresis-based DNA sequencing^{11,13-15} (Section 8.2, Table 8.7).

We have also prepared the mixed-isomer TAMRA-X succinimidyl ester (5(6)-TAMRA-X, SE; T6105), which contains a seven-atom aminohexanoyl spacer ("X") between the reactive group and the fluorophore (Figure 1.6.4). This spacer helps to separate the fluorophore from its point of attachment, reducing the interaction of the fluorophore with the biomolecule to which it is conjugated, making it more accessible to secondary detection reagents and facilitating orientational averaging in fluorescence resonance energy transfer (FRET) applications¹⁶ (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). Polyclonal anti-tetramethylrhodamine and anti-Texas Red® dye antibodies that recognize the tetramethylrhodamine, Rhodamine Red™-X, X-rhodamine and Texas Red® fluorophores are available (Section 7.4).

Figure 1.6.2 5-carboxytetramethylrhodamine, succinimidyl ester (5-TAMRA, SE; C2211).

Figure 1.6.3 Effect of protein conjugation on the absorption spectrum of tetramethylrhodamine. The absorption spectrum of tetramethylrhodamine conjugated to goat anti-mouse IgG antibody (TMR-GAM, T2762) shows an additional peak at about 520 nm when compared with the spectrum of the same concentration of the free dye (TMR). Partial unfolding of the protein in the presence of 4.8 M guanidine hydrochloride (TMR-GAM + GuHCl) results in a spectrum more similar to that of the free dye.

Figure 1.6.4 6-(tetramethylrhodamine-5-(and-6)-carboxamido)hexanoic acid, succinimidyl ester (5(6)-TAMRA-X, SE; T6105).

Figure 1.6.6 Normalized fluorescence emission spectra of goat anti-mouse IgG antibody conjugates of 1) fluorescein, 2) rhodamine 6G, 3) tetramethylrhodamine, 4) Lissamine rhodamine B and 5) Texas Red® dyes.

Figure 1.6.7 Rhodamine Red™-X, succinimidyl ester (R6160).

Figure 1.6.8 Comparison of the relative fluorescence of goat anti-mouse IgG antibody conjugates of Rhodamine Red™-X succinimidyl ester (R6160, ●) and Lissamine rhodamine B sulfonfyl chloride (L20, L1908, ○). Conjugate fluorescence is determined by measuring the fluorescence quantum yield of the conjugated dye relative to that of the free dye and multiplying by the number of fluorophores per protein. Higher numbers of fluorophores attached per protein are attainable with Rhodamine Red™-X dye due to the lesser tendency of this dye to induce protein precipitation.

Figure 1.6.9 X-rhodamine-5-(and-6)-isothiocyanate (5(6)-XRITC, X491).

Figure 1.6.10 Absorption and fluorescence emission spectra of 5-carboxy-X-rhodamine (5-ROX) in pH 7.0 buffer.

Lissamine Rhodamine B and Rhodamine Red™-X Dyes

Lissamine Rhodamine B Sulfonfyl Chloride

Lissamine rhodamine B sulfonfyl chloride (L20, L1908; Figure 1.6.5) is much less expensive than Texas Red® sulfonfyl chloride, and the fluorescence emission spectrum of its protein conjugates lies between those of tetramethylrhodamine and Texas Red® conjugates¹⁷ (Figure 1.6.6). It is more frequently employed as a synthetic precursor for preparing affinity labeling reagents than as a labeling reagent for protein conjugation.^{18–20}

Rhodamine Red™-X Succinimidyl Ester

Lissamine rhodamine B sulfonfyl chloride is unstable, particularly in aqueous solution, making it somewhat difficult to achieve reproducible conjugations using this dye. Unlike Lissamine rhodamine B sulfonfyl chloride, which is a mixture of isomeric sulfonfyl chlorides (Figure 1.6.5), Rhodamine Red™-X succinimidyl ester (R6160, Figure 1.6.7) is isomerically pure and is hydrolytically stable for practical purposes at the mild alkaline pH levels typically used for amine-reactive protein conjugation. Rhodamine Red™-X succinimidyl ester incorporates a spacer between the fluorophore and the reactive site, resulting in minimized perturbation of the conjugation partner's functional properties.²¹ Moreover, we have found that protein conjugates of Rhodamine Red™-X dye are frequently brighter than those of Lissamine rhodamine B (Figure 1.6.8), and less likely to precipitate during storage.²² Rhodamine Red™-X succinimidyl ester is used in the FluoReporter® Rhodamine Red™-X Protein Labeling Kit (F6161); see Section 1.2 for further information on preparing red-fluorescent protein conjugates with this kit.

X-Rhodamine

The derivatives of carboxy-X-rhodamine (ROX™ dye)—a dye originally developed in our laboratories in 1986—are widely used for oligonucleotide labeling and DNA sequencing applications (Section 8.2, Table 8.7). Conjugates of this dye and of the similar isothiocyanate (5(6)-XRITC, X491; Figure 1.6.9) have longer-wavelength spectra (Figure 1.6.10) than the spectra of Lissamine rhodamine B, but somewhat shorter-wavelength spectra than those of Texas Red® conjugates. Both the pure 5-isomer (C6124) and 6-isomer (C6156) of carboxy-X-rhodamine are available, as are mixed-isomer (C1309, Figure 1.6.11) and single-isomer (C6125, C6126) preparations of the succinimidyl ester.

Texas Red® and Texas Red®-X Dyes

The Texas Red® fluorophore emits at a longer wavelength than do either tetramethylrhodamine or Lissamine rhodamine B (Figure 1.6.6), making Texas Red® conjugates among the most commonly used long-wavelength "third labels" in fluorescence microscopy (Figure 1.6.12, Figure 1.6.13). Unlike the other rhodamines, the Texas Red® fluorophore exhibits very little spectral overlap with fluorescein (Figure 1.6.6), and its fluorescence can be distinguished from that of

Figure 1.6.17 Comparison of the relative fluorescence of goat anti-mouse IgG antibody conjugates of Texas Red®-X succinimidyl ester (T6134, ■) and Texas Red® sulfonyl chloride (T353, □). Conjugate fluorescence was determined by measuring the fluorescence quantum yield of the conjugated dye relative to that of the free dye and multiplying by the number of fluorophores per protein. Higher numbers of fluorophores attached per protein are attainable with the Texas Red®-X dye due to the lesser tendency of this dye to induce protein precipitation.

Figure 1.6.18 5-(and-6)-carboxynaphthofluorescein, succinimidyl ester (C653).

Figure 1.6.19 Absorption and fluorescence emission spectra of 5-(and-6)-carboxynaphthofluorescein in pH 10.0 buffer.

Red®-X succinimidyl ester offers significant advantages over Texas Red® sulfonyl chloride for the preparation of bioconjugates:

- In the absence of amines, greater than 80% of Texas Red®-X succinimidyl ester's reactivity is retained in pH 8.3 solution after one hour at room temperature.²²
- Much less Texas Red®-X succinimidyl ester (usually half or less of the amount of Texas Red® sulfonyl chloride) is required to yield the same degree of labeling, making the effective costs of these two reagents about the same.
- Conjugations with Texas Red®-X succinimidyl ester are more reproducible.
- Unlike Texas Red® sulfonyl chloride, which can form unstable products with tyrosine, histidine, cysteine and other residues in proteins, the Texas Red®-X succinimidyl ester reacts almost exclusively with amines.
- Protein conjugates prepared with Texas Red®-X succinimidyl ester have a higher fluorescence yield than those with the same labeling ratio prepared with Texas Red® sulfonyl chloride (Figure 1.6.17).
- Texas Red®-X protein conjugates show a decreased tendency to precipitate during the reaction or upon storage.

Texas Red® C₂-Dichlorotriazine

Texas Red® C₂-dichlorotriazine (T30200) is a reactive dye with absorption/emission maxima of ~588/601 nm. Dichlorotriazines readily modify amines in proteins, and they are among the few reactive groups that are reported to react directly with polysaccharides²⁷ and other alcohols in aqueous solution, provided that the pH is >9 and that other nucleophiles are absent.

Texas Red®-X Conjugates and Texas Red®-X Labeling Kits

Because of the advantages of Texas Red®-X succinimidyl ester, we have converted some of our Texas Red® conjugates to the Texas Red®-X conjugates. We have prepared Texas Red®-X conjugates of:

- Antibodies (Section 7.2, Table 7.1)
- Streptavidin (S6370, Section 7.6, Table 7.9)
- Phalloidin (T7471, Section 11.1, Table 11.2)
- Wheat germ agglutinin (W21405, Section 7.7)
- dUTP (C7631, Section 8.2)

Protein conjugates of the Texas Red®-X dye are readily prepared using our FluoReporter® Texas Red®-X Protein Labeling Kit (F6162) and Texas Red®-X Protein Labeling Kit (T10244); see Section 1.2 for further information on preparing fluorescent protein conjugates with these kits. Zenon® Texas Red®-X Antibody Labeling Kit for mouse IgG₁ antibodies (Z25045, Section 7.3) permits the rapid and quantitative labeling of antibodies from a purified antibody fraction or from a crude antibody preparation such as serum, ascites fluid or a hybridoma supernatant with the Texas Red®-X dye.²⁸ Polyclonal anti-tetramethylrhodamine and anti-Texas Red® antibodies that recognize tetramethylrhodamine, Rhodamine Red™, X-rhodamine and Texas Red® fluorophores are available (Section 7.4, Table 7.8).

Naphthofluorescein

Naphthofluorescein carboxylic acid and its succinimidyl ester (C652, C653; Figure 1.6.18) have emission maxima of approximately 670 nm in aqueous solution at pH 10 (Figure 1.6.19). However, the fluorescence of naphthofluorescein is pH dependent ($pK_a \sim 7.6$), requiring a relatively alkaline pH for maximal fluorescence.

Carboxyrhodamine 6G

The excitation and emission spectra of carboxyrhodamine 6G (CR 6G) fall between those of fluorescein and tetramethylrhodamine (Figure 1.6.6). With a peak absorption at ~520 nm, conjugates prepared from the mixed-isomer (C6157) or single-isomer (C6127, C6128) preparations

of CR 6G succinimidyl esters are an excellent match to the 514 nm spectral line of the argon-ion laser. They also tend to exhibit a higher fluorescence quantum yield than tetramethylrhodamine conjugates, as well as excellent photostability. As with Rhodamine Green™ dyes, carboxyrhodamine 6G dyes are more suitable for preparing nucleotide and oligonucleotide conjugates than for preparing protein conjugates. Oligonucleotide conjugates of CR 6G have spectroscopic and electrophoretic properties that are superior to the JOE dye (C6171MP, Section 1.5) that is often used for DNA sequencing (Section 8.2, Table 8.7).

QSY® Dyes: Fluorescence Quenchers

Dyes that quench the fluorescence of visible light-excited fluorophores are increasingly important for use in fluorescence resonance energy transfer (FRET) proximity assays (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2), such as those based on DNA hybridization.^{29–31} Nonfluorescent acceptors are advantageous in FRET assays because they avoid the complications of proximity-independent signals resulting from direct excitation of fluorescent acceptors. Our QSY® 7, QSY® 9 and QSY® 21 dyes (Table 1.10) are diarylrhodamine derivatives that have several properties that make them superior to the commonly used dabcyI chromophore (Section 1.8) when preparing bioconjugates for use in FRET-based assays:

- Broad absorption in the visible-light spectrum, with an absorption maximum near 560 nm for both the QSY® 7 and QSY® 9 dyes and near 660 nm for the QSY® 21 dye (Figure 1.6.20)
- Extinction coefficients that are typically in excess of 90,000 cm⁻¹M⁻¹
- Absorption spectra of the conjugates that are insensitive to pH between 4 and 10
- Fluorescence quantum yields typically <0.001 in aqueous solution (in a few isolated cases, we have observed that some QSY® dyes can exhibit fluorescence when placed in a rigidifying environment such as glycerol.)
- Efficient quenching of the fluorescence emission of donor dyes by the QSY® 7 and QSY® 9 dyes, including blue-fluorescent coumarins, green- or orange-fluorescent dyes, and red-fluorescent Texas Red® and Alexa Fluor® 594 conjugates
- Quenching of red-fluorescent dyes, including Alexa Fluor® 647 dye, by the long-wavelength light-absorbing QSY® 21 dye³² (Table 1.11)
- Quenching of most green and red fluorophores that is more effective at far greater distances than is possible with dabcyI quenchers (Figure 1.6.21)
- Residual fluorescence of the conjugates, at close spatial separations, that is typically lower than in conjugates that use dabcyI as the quencher
- High chemical stability of the conjugates and very good resistance to photobleaching

Figure 1.6.20 Normalized absorption spectra of the QSY® 35 (blue), QSY® 7 (red) and QSY® 21 (orange) dyes. The QSY® 7 and QSY® 9 dyes have essentially identical spectra.

Figure 1.6.21 Fluorescence quenching of 5'-tetramethylrhodamine-labeled M13 primers by nonfluorescent dyes attached at the 3'-end. The comparison represents equal concentrations of oligonucleotides with 1) no 3'-quencher (control), 2) 3'-dabcyI quencher, and 3) 3'-QSY® 7 quencher.

Table 1.10 Molecular Probes® nonfluorescent quenchers and photosensitizers.

Figure 1.6.23 Absorption spectrum of malachite green isothiocyanate in acetonitrile.

Figure 1.6.24 Malachite green isothiocyanate (M689).

A particularly frequent and effective application of QSY® dyes is as components of fluorogenic protease and peptidase substrates consisting of a fluorescent dye and a QSY® quencher attached to opposite ends of a peptide sequence that is specifically recognized and cleaved by the enzyme.^{2,32,33} QSY® 7 dye has been used to create activatable targeted probes comprising a fluorophore–quencher pair and a targeting protein moiety (avidin, which targets the D-galactose receptor, or trastuzumab, a monoclonal antibody that recognizes the human epithelial growth factor receptor type 2 or HER2/neu) for use in *in vivo* tumor imaging. The fluorophore–quencher interaction, in this case between tetramethylrhodamine and QSY® 7 dyes, is disrupted when the probe is internalized in a tumor by receptor-mediated uptake, thereby activating the fluorescence.³⁴ In this imaging application, QSY® 7 was reported to be superior to azobenzene quenchers (e.g., dabcyll derivatives) because azobenzene dyes are vulnerable to reductive cleavage *in vivo*, producing a false positive signal. Both the amine-reactive and thiol-reactive QSY® 7 derivatives (Q10193, Q10257) have been used to create molecular beacon probes for following the transport of mRNAs in *Drosophila melanogaster* oocytes.³⁵

The distance at which energy transfer is 50% efficient (i.e., 50% of excited donors are deactivated by fluorescence resonance energy transfer) is defined by the Förster radius (R_0). The magnitude of R_0 is dependent on the spectral properties of the donor and acceptor dyes. R_0 values calculated for energy transfer from various Alexa Fluor® dyes to QSY® and dabcyll quenchers are listed in Table 1.11. FRET efficiencies from several donor dyes to the QSY® 7 quencher in molecular beacon hybridization probes have also been calculated.³

For preparing bioconjugates, we offer several reactive versions of these QSY® dyes:

- Amine-reactive QSY® 7 (Figure 1.6.22), QSY® 9 and QSY® 21 succinimidyl esters (Q10193, Q20131, Q20132)
- Thiol-reactive QSY® 7 C₅-maleimide and QSY® 9 C₅-maleimide (Q10257, Q30457; Section 2.2)
- QSY® 7 aliphatic amine (Q10464, Section 3.4), which can be coupled to carbodiimide-activated carboxylic acids and other functional groups
- α-FMOC-ε-QSY® 7-L-lysine (Q21930, Section 9.5), for automated synthesis of peptides containing the QSY® 7 quencher

In addition to the QSY® 7, QSY® 9 and QSY® 21 dyes, we offer other quenchers that absorb maximally below 500 nm, including the QSY® 35 and dabcyll dyes (Table 1.10). These products are described in Section 1.8.

Nonfluorescent Malachite Green

Malachite green is a nonfluorescent photosensitizer that absorbs at long wavelengths (~630 nm, Figure 1.6.23). Its photosensitizing action can be targeted to particular cellular sites by conjugating malachite green isothiocyanate (M689, Figure 1.6.24) to specific antibodies. Enzymes and other proteins within ~10 Å of the binding site of the malachite green–labeled antibody can then be selectively destroyed upon irradiation with long-wavelength light.^{36,37} Studies by Jay and colleagues have demonstrated that this photoinduced destruction of enzymes in the immediate vicinity of the chromophore is apparently the result of localized production of hydroxyl radicals, which have short lifetimes that limit their diffusion from the site of their generation.³⁸ Earlier studies had supported a thermal mechanism of action.^{39–41}

Table 1.11 R_0 values for QSY® and dabcyI quenchers.

Donor	Acceptor			
	QSY® 35	dabcyI	QSY® 7 and QSY® 9	QSY® 21
Alexa Fluor® 350	47	50		
Alexa Fluor® 488	44	49	64	
Alexa Fluor® 546	25	29	67	
Alexa Fluor® 555			45	
Alexa Fluor® 568			56	75
Alexa Fluor® 594				77
Alexa Fluor® 647				69

R_0 values in angstroms (Å) represent the distance at which fluorescence resonance energy transfer from the donor dye to the acceptor dye is 50% efficient (Förster radius). Values were calculated from spectroscopic data as outlined (see Fluorescence Resonance Energy Transfer (FRET)—Note 1.2).

T20175	816.94	F,D,L	DMF, DMSO	587	96,000	602	MeOH	
T30200	796.74	F,D,L	DMF, DMSO	583	87,000	604	MeOH	
X491	547.67	F,DD,L	DMF, DMSO	572	92,000	596	MeOH	5

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Abs and Em for TAMRA and ROX dyes in pH 8 buffer are red-shifted approximately 8 nm compared to MeOH, with EC lower by ~10%.
- Absorption and fluorescence of naphthofluorescein derivatives are pH dependent. Both the absorption and emission spectra shift to much shorter wavelengths at pH <8. Fluorescence quantum yield ~0.14 at pH 9.5.
- Tetramethylrhodamine protein conjugates often exhibit two absorption peaks at about 520 and 545 nm. The 520 nm peak is due to nonfluorescent dye aggregates. (J Immunol Methods (1991) 143:263, J Phys Chem B (1998) 102:1820)
- Do NOT dissolve in DMSO.
- Isothiocyanates are unstable in water and should not be stored in aqueous solution.
- This sulfonated succinimidyl ester derivative is water soluble and may be dissolved in buffer at ~pH 8 for reaction with amines. Long-term storage in water is NOT recommended due to hydrolysis.

PRODUCT LIST 1.6 LONG-WAVELENGTH RHODAMINES, TEXAS RED DYES AND QSY QUENCHERS

Cat No.	Product	Quantity
C652	5-(and-6)-carboxynaphthofluorescein *mixed isomers*	100 mg
C653	5-(and-6)-carboxynaphthofluorescein, succinimidyl ester *mixed isomers*	25 mg
C6127	5-carboxyrhodamine 6G, succinimidyl ester (5-CR 6G, SE) *single isomer*	5 mg
C6128	6-carboxyrhodamine 6G, succinimidyl ester (6-CR 6G, SE) *single isomer*	5 mg
C6157	5-(and-6)-carboxyrhodamine 6G, succinimidyl ester (5(6)-CR 6G, SE) *mixed isomers*	5 mg
C6121	5-carboxytetramethylrhodamine (5-TAMRA) *single isomer*	10 mg
C6122	6-carboxytetramethylrhodamine (6-TAMRA) *single isomer*	10 mg
C300	5-(and-6)-carboxytetramethylrhodamine (5(6)-TAMRA) *mixed isomers*	100 mg
C2211	5-carboxytetramethylrhodamine, succinimidyl ester (5-TAMRA, SE) *single isomer*	5 mg
C6123	6-carboxytetramethylrhodamine, succinimidyl ester (6-TAMRA, SE) *single isomer*	5 mg
C1171	5-(and-6)-carboxytetramethylrhodamine, succinimidyl ester (5(6)-TAMRA, SE) *mixed isomers*	25 mg
C6124	5-carboxy-X-rhodamine, triethylammonium salt (5-ROX) *single isomer*	10 mg
C6156	6-carboxy-X-rhodamine (6-ROX) *single isomer*	10 mg
C6125	5-carboxy-X-rhodamine, succinimidyl ester (5-ROX, SE) *single isomer*	5 mg
C6126	6-carboxy-X-rhodamine, succinimidyl ester (6-ROX, SE) *single isomer*	5 mg
C1309	5-(and-6)-carboxy-X-rhodamine, succinimidyl ester (5(6)-ROX, SE) *mixed isomers*	25 mg
F6161	FluoReporter® Rhodamine Red™-X Protein Labeling Kit *5–10 labelings*	1 kit
F6162	FluoReporter® Texas Red®-X Protein Labeling Kit *5–10 labelings*	1 kit
L20	Lissamine rhodamine B sulfonyl chloride *mixed isomers*	1 g
L1908	Lissamine rhodamine B sulfonyl chloride *mixed isomers* *special packaging*	10 x 10 mg
M689	malachite green isothiocyanate	10 mg
Q10193	QSY® 7 carboxylic acid, succinimidyl ester	5 mg
Q20131	QSY® 9 carboxylic acid, succinimidyl ester	5 mg
Q20132	QSY® 21 carboxylic acid, succinimidyl ester	5 mg
R6160	Rhodamine Red™-X, succinimidyl ester *5-isomer*	5 mg
T6105	6-(tetramethylrhodamine-5-(and-6)-carboxamido)hexanoic acid, succinimidyl ester (5(6)-TAMRA-X, SE) *mixed isomers*	10 mg
T1480	tetramethylrhodamine-5-isothiocyanate (5-TRITC; G isomer)	5 mg
T1481	tetramethylrhodamine-6-isothiocyanate (6-TRITC; R isomer)	5 mg
T490	tetramethylrhodamine-5-(and-6)-isothiocyanate (5(6)-TRITC) *mixed isomers*	10 mg
T30200	Texas Red® C ₂ -dichlorotriazine	5 mg
T353	Texas Red® sulfonyl chloride *mixed isomers*	10 mg
T1905	Texas Red® sulfonyl chloride *mixed isomers* *special packaging*	10 x ~1 mg
T10244	Texas Red®-X Protein Labeling Kit *3 labelings*	1 kit
T6134	Texas Red®-X, succinimidyl ester *mixed isomers*	5 mg
T20175	Texas Red®-X, succinimidyl ester *single isomer*	2 mg
X491	X-rhodamine-5-(and-6)-isothiocyanate (5(6)-XRITC) *mixed isomers*	10 mg
Z25045	Zenon® Texas Red®-X Mouse IgG ₁ Labeling Kit *50 labelings*	1 kit

1.7 Coumarins, Pyrenes and Other Ultraviolet Light-Excitable Fluorophores

Shorter-wavelength amine-reactive fluorophores are less frequently used for preparing bioconjugates because dyes excited with longer wavelengths, and therefore lower energy, are widely available and less likely to cause photodamage to labeled biomolecules. Moreover, many cells and tissues autofluoresce when excited with ultraviolet (UV) light, producing detection-confounding background signals. However, for certain multicolor fluorescence applications—including immunofluorescence, nucleic acid and protein microarrays, *in situ* hybridization and neuronal tracing—a blue-fluorescent probe provides a contrasting color that is clearly resolved from the green, yellow, orange or red fluorescence of the longer-wavelength probes.

The short-wavelength reactive dyes that we recommend for preparing the brightest blue-fluorescent bioconjugates are the Alexa

Fluor® 350, Alexa Fluor® 405, AMCA-X, Marina Blue®, Pacific Blue™ and Cascade Blue® derivatives (Table 1.12). Alexa Fluor® 430, Pacific Orange™ and Cascade Yellow™ dyes fill a spectral void because they exhibit the rare combination of absorption between 400 nm and 450 nm and fluorescence emission beyond 500 nm. The amine-reactive naphthalene, pyrene and Dapoxyl® derivatives are important for the production of environment-sensitive probes in protein structure and function studies (Table 1.13); their thiol-reactive counterparts are discussed in Section 2.3. Many of our UV light-excitable reactive dyes are more commonly employed for such bioanalytical techniques as HPLC derivatization, amino acid sequencing and protein determination and are therefore discussed in Section 1.8.

Table 1.12 Amine-reactive, ultraviolet light-excitable fluorophores for labeling proteins and nucleic acids.

Figure 1.7.2 6-((7-amino-4-methylcoumarin-3-acetyl)amino)hexanoic acid, succinimidyl ester (AMCA-X, SE; A6118).

Figure 1.7.3 Comparison of the relative fluorescence of 7-amino-4-methylcoumarin-3-acetic acid (AMCA) streptavidin (O) and Alexa Fluor® 350 streptavidin, a sulfonated AMCA derivative (S11249, ●). Conjugate fluorescence is determined by measuring the fluorescence quantum yield of the conjugated dye relative to that of the free dye and multiplying by the number of fluorophores per protein.

Figure 1.7.4 Absorption spectra of our ultraviolet and blue light-absorbing Alexa Fluor® dyes.

Alexa Fluor® 350 and Other Coumarin Derivatives

Alexa Fluor® 350 and AMCA-X Dyes

Derivatives of 7-aminocoumarin dyes are widely used labeling reagents for preparing protein and nucleic acid conjugates,¹ and we offer two important amine-reactive 7-aminocoumarin derivatives: Alexa Fluor® 350 carboxylic acid succinimidyl ester^{2,3} (A10168) and AMCA-X succinimidyl ester (AMCA-X, SE; A6118).

The sulfonated coumarin derivative, Alexa Fluor® 350 carboxylic acid succinimidyl ester (Figure 1.7.1), is more water soluble than either AMCA succinimidyl ester or AMCA-X succinimidyl ester (Figure 1.7.2) and yields protein conjugates that are more fluorescent than those prepared from its nonsulfonated analog (Figure 1.7.3). Alexa Fluor® 350 protein conjugates are optimally excited at 346 nm and have bright blue fluorescence emission (Figure 1.7.4, Figure 1.7.5) at wavelengths slightly shorter than AMCA or AMCA-X conjugates (Figure 1.7.6) (442 nm versus 448 nm), which reduces the dye's spectral overlap with the emission of fluorescein. We offer several reactive versions of Alexa Fluor® 350 dye, including:

- Amine-reactive succinimidyl ester (A10168)
- Thiol-reactive maleimide (A30505, Section 2.3)
- Aldehyde- and ketone-reactive hydrazide and hydroxylamine (A10439, A30627; Section 3.3)
- Aldehyde- and ketone-reactive cadaverine (A30674, Section 3.4)

AMCA-X succinimidyl ester (A6118) contains a seven-atom aminohexanoyl spacer ("X") between the fluorophore and the reactive group. This spacer separates the fluorophore from the biomolecule to which it is conjugated, potentially reducing the quenching that typically occurs upon conjugation and making the dye more available for recognition by secondary detection reagents. Slightly longer-wavelength conjugates can be prepared from the isothiocyanate (DACITC, D10166), succinimidyl esters (D374, D1412) or free acids (D126, D1421) of 7-dialkylaminocoumarins.^{4,5}

Alexa Fluor® 430 Dye

Few reactive dyes that absorb between 400 nm and 450 nm have appreciable fluorescence beyond 500 nm in aqueous solution. Alexa Fluor® 430 dye fills this spectral gap.² Excitation near its absorption maximum at 431 nm (Figure 1.7.4) is accompanied by strong green fluorescence with an emission maximum at 541 nm. The amine-reactive succinimidyl ester of Alexa Fluor® 430 carboxylic acid (A10169, Figure 1.7.7) is available, as well as Alexa Fluor® 430 conjugates of secondary antibodies (A11063, A11064; Section 7.2, Table 7.1) and streptavidin (S11237, Section 7.6, Table 7.9).

Marina Blue® and Pacific Blue™ Dyes

Marina Blue® and Pacific Blue™ dyes, both of which are based on the 6,8-difluoro-7-hydroxycoumarin fluorophore, exhibit bright blue fluorescence emission near 460 nm⁶ (Table 1.12). The Marina Blue® dye is optimally detected using optical filters configured for DAPI, whereas

Figure 1.7.5 The microtubules of fixed bovine pulmonary artery endothelial cells (BPAEC) localized with mouse monoclonal anti- α -tubulin antibody (A11126), which was visualized with Alexa Fluor® 350 goat anti-mouse IgG antibody (A11045). The image was acquired using a longpass filter set appropriate for DAPI.

the Pacific Blue™ dye is ideally suited for 405 nm violet diode laser excitation on the Applied Biosystems® Attune™ Acoustic Focusing cytometer and similarly equipped fluorescence microscopes (Figure 1.7.8). Significantly, the pK_a values of these 6,8-difluoro-7-hydroxycoumarin derivatives are 2–3 log units lower than those of the corresponding 7-hydroxycoumarins (Figure 1.7.9). Thus, the Marina Blue® and Pacific Blue™ dyes yield conjugates that are strongly fluorescent, even at neutral pH. For preparing bioconjugates, we offer amine-reactive succinimidyl esters of the Marina Blue® and Pacific Blue™ dyes (M10165, Figure 1.7.10; P10163, Figure 1.7.11).

Other Hydroxycoumarin and Alkoxy Coumarin Derivatives

The hydroxycoumarins (H185, H1193, H1428) exhibit pH-sensitive spectral properties, but the methoxycoumarins (M1410, M1420MP) do not.^{7,8} Hydroxycoumarins are often used to prepare reactive intermediates for the synthesis of radioiodinated materials.⁹ The spectral properties of the hydroxycoumarins allow their quantitation prior to radioiodination.⁹

Alexa Fluor® 350, Alexa Fluor® 430 and Pacific Blue™ Protein Labeling Kits

For easy and trouble-free labeling of proteins with succinimidyl esters of the Alexa Fluor® 350, Alexa Fluor® 430 and Pacific Blue™ dyes, we offer Alexa Fluor® 350, Alexa Fluor® 430 and Pacific Blue™ Protein Labeling Kits (A10170, A10171, A10171; Table 1.2). These kits, which are described in greater detail in Section 1.2, contain everything that is required to perform three separate labeling reactions and to purify the resulting conjugates (Table 1.3). The Alexa Fluor® 350 and Pacific Blue™ Monoclonal Antibody Labeling Kits (A20180, P30013) can be used to prepare blue-fluorescent conjugates of monoclonal antibodies, as well as of other proteins in limited quantities (five labeling reactions of ~100 µg each). The APEX® Pacific Blue™ Antibody Labeling Kit (A10478) utilizes a solid-phase technique to label 10–20 µg IgG antibody, even in the presence of stabilizing proteins or amine-containing buffers.

The Zenon® Alexa Fluor® 350, Zenon® Alexa Fluor® 430 and Zenon® Pacific Blue™ Antibody Labeling Kits (Table 7.7) permit the rapid and quantitative labeling of antibodies—even submicrogram amounts—using a purified antibody fraction or a crude antibody preparation such as serum, ascites fluid or a hybridoma supernatant. These kits, along with Zenon® technology, are described in detail in Section 7.3.

Pacific Orange™ Dye

The succinimidyl ester of the Pacific Orange™ dye (P30253) yields conjugates with excitation/emission maxima of ~400/551 nm, making it ideal for use with 405 nm violet diode laser-equipped flow cytometers¹⁰ and fluorescence microscopes. Moreover, Pacific Blue™ and Pacific Orange™ conjugates can be simultaneously excited at 405 nm and emit at 455 and 551 nm, respectively, facilitating two-color analysis.

Several of our kits facilitate protein labeling with the Pacific Orange™ succinimidyl ester, including the Pacific Orange™ Protein Labeling Kit (P30016), the Pacific Orange™ Monoclonal Antibody Labeling Kit (P30014) and the Zenon® Antibody Labeling Kits (Table 7.7), all of which are described in greater detail in Section 1.2.

Figure 1.7.6 Fluorescence excitation and emission spectra of Alexa Fluor® 350 goat anti-mouse IgG antibody in pH 8.0 buffer.

Figure 1.7.7 Alexa Fluor® 430 carboxylic acid, succinimidyl ester (A10169).

Figure 1.7.8 Normalized fluorescence emission spectra of Pacific Blue™ goat anti-mouse IgG antibody (P10993) and a Cascade Yellow™ goat anti-mouse IgG antibody conjugate prepared with the Cascade Yellow™ succinimidyl ester (C10164). Both fluorescent conjugates are excited at 405 nm. When samples containing equal concentrations of antibody are compared, the peak fluorescence intensity of the Pacific Blue™ conjugate at 456 nm is nine times greater than that of the Cascade Yellow™ conjugate at 548 nm.

Figure 1.7.9 Comparison of the pH-dependent fluorescence changes produced by attachment of electron-withdrawing fluorine atoms to a hydroxycoumarin. 7-Hydroxy-4-methylcoumarin-3-acetic acid (○, H1428) and 6,8-difluoro-7-hydroxy-4-methylcoumarin (●, D6566). Fluorescence intensities were measured for equal concentrations of the two dyes using excitation/emission at 360/450 nm.

Cascade Blue® and Other Pyrene Derivatives

Cascade Blue® Acetyl Azide

Cascade Blue® acetyl azide is the amine-reactive sulfonated pyrene derivative¹¹ that we use to prepare blue-fluorescent Cascade Blue® dye-labeled proteins and dextrans. The polar nature of this reagent makes it difficult to purify to homogeneity; however, we offer a Cascade Blue® acetyl azide preparation (C2284, Table 1.12, Figure 1.7.12) that is ~60% reactive and packaged according to the net weight of the reactive dye. The remaining constituents are inorganic salts or unreactive forms of the dye that can readily be removed following conjugation.

As compared with the aminocoumarin derivatives, the Cascade Blue® fluorophore shows less spectral overlap with fluorescein (Figure 1.7.13), an important advantage for multicolor applications. In addition, this reactive Cascade Blue® derivative has high absorptivity (Figure 1.7.14), is highly fluorescent and resists quenching upon protein conjugation (Figure 1.7.15). Even at low degrees of labeling, Cascade Blue® conjugates are significantly more fluorescent than are those of 7-amino-4-methylcoumarin-3-acetic acid (AMCA),¹¹ and they remain preferred reagents for multicolor flow cytometry.^{12–14}

Alexa Fluor® 405 Dye

With excitation/emission maxima of 402/421 nm (Figure 1.7.4), Alexa Fluor® 405 dye is well matched to the 405 nm spectral line of violet diode lasers for fluorescence microscopy and flow cytometry.^{10,15,16} Alexa Fluor® 405 succinimidyl ester is an amine-reactive derivative of our Cascade Blue® dye. Not only is it offered at higher purity than the alternative Cascade Blue® acetyl azide, but Alexa Fluor® 405 succinimidyl ester also contains a 4-piperidincarboxylic acid spacer that separates the fluorophore from its reactive moiety (Figure 1.7.16). This spacer enhances the reactivity of the succinimidyl ester and minimizes any interactions between the fluorophore and the biomolecule to which it is conjugated.

As with Cascade Blue® acetyl azide, Alexa Fluor® 405 dye shows minimal spectral overlap with green fluorophores, making it ideal for multicolor applications.^{15,17} However, the violet fluorescence of Cascade Blue® and Alexa Fluor® 405 dyes is less visible to the human eye in fluorescence microscopy applications than the blue fluorescence of Alexa Fluor® 350 and AMCA-X dyes. Alexa Fluor® 405 dye is available as:

- Amine-reactive succinimidyl ester (A30000, A30100)
- Aldehyde- and ketone-reactive cadaverine (A30675, Section 3.4)

We also prepare Alexa Fluor® 405 conjugates of secondary antibodies (Section 7.2, Table 7.1) and streptavidin (Section 7.6, Table 7.9). Alexa Fluor® 405 conjugates are recognized by the anti-Alexa Fluor® 405/Cascade Blue® dye antibody (A5760, Section 7.4).

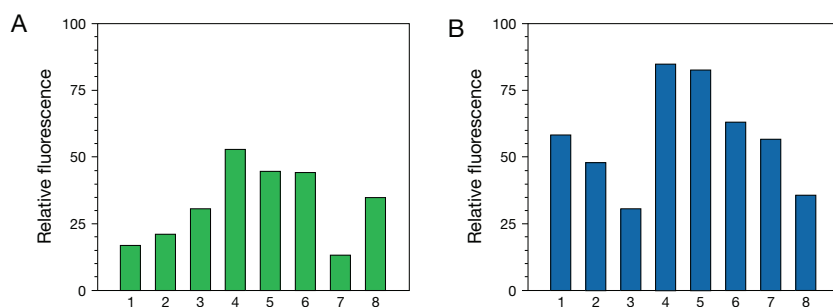

Figure 1.7.15 Histograms showing the fluorescence per fluorophore for A) fluorescein and B) Cascade Blue® conjugated to various proteins, relative to the fluorescence of the free dye in aqueous solution, represented by 100 on the y-axis. The proteins represented are: 1) avidin, 2) bovine serum albumin, 3) concanavalin A, 4) goat IgG, 5) ovalbumin, 6) protein A, 7) streptavidin and 8) wheat germ agglutinin.

Other Pyrenes

Conjugates of the pyrene succinimidyl esters (P130, P6114) have exceptionally long excited-state lifetimes (sometimes >100 nanoseconds), relatively short-wavelength emission and capacity for proximity-dependent excimer formation (Figure 1.7.17). These amine-reactive pyrene derivatives have primarily been used for labeling and detecting oligonucleotides,^{18,19} biogenic amines²⁰ and polyamines.²¹ Pyrene binds strongly to carbon nanotubes via pi-stacking interactions. This property makes 1-pyrenebutanoic acid succinimidyl ester (P130) a valuable reagent for functionalizing these remarkable nanomaterials for coupling to proteins.^{22,23}

The long fluorescence lifetime of pyrenebutyric acid (1-pyrenebutanoic acid) permits time-gating of the fluorescence, which is a useful technique for discriminating between the dye signal and sample autofluorescence,²⁴ and has been exploited for fluorescence immunoassays.²⁵ For preparing pyrene conjugates with long fluorescence lifetimes, we recommend the more water-soluble succinimidyl ester of *N*-(1-pyrenebutanoyl)cysteic acid (P6114, Figure 1.7.18). The amine-reactive 1-pyrenesulfonyl chloride (P24, Section 1.8) has been used to generate a fluorescent ATP sensor via modification of an ATP-binding ribonucleopeptide.²⁶

Figure 1.7.18 *N*-(1-pyrenebutanoyl)cysteic acid, succinimidyl ester, potassium salt (P6114).

Cascade Yellow™ and Other Pyridyloxazole Derivatives

Cascade Yellow™ Dye

Like the Alexa Fluor® 430 and Pacific Blue™ dyes described above, the Cascade Yellow™ dye exhibits an excitation maximum that falls between those of the UV light-excited dyes and the fluoresceins. This sulfonated pyridyloxazole (PyMPO) laser dye (Figure 1.7.19) exhibits an absorption maximum near 410 nm and an unusually high Stokes shift, with relatively strong emission at 550–570 nm^{27–29} (Figure 1.7.20). The large Stokes shift permits detection at a wavelength well beyond that of most sample autofluorescence, and allows multiple fluorophores to be excited at the same wavelengths and detected at different wavelengths. For example, protein conjugates of Cascade Yellow™ succinimidyl ester (C10164) can be simultaneously excited at 405 nm with Pacific Blue™ conjugates, and then separately detected at longer wavelengths (Figure 1.7.8). Cascade Yellow™ and Cascade Blue® antibody conjugates, along with several phycobiliprotein tandem conjugates, are utilized in an 11-color polychromatic flow cytometry technique.^{12,13}

Figure 1.7.19 Cascade Yellow™ succinimidyl ester (C10164).

PyMPO Dye

The pyridyloxazole derivatives—including the succinimidyl ester (PyMPO, SE; S6110; Figure 1.7.21) and the thiol-reactive maleimide (M6026, Section 2.2)—fill the spectral gap between UV light-excited dyes and the fluoresceins. These derivatives of the laser dye PyMPO exhibit absorption maxima near 415 nm and unusually high Stokes shifts, with emission at 560–580 nm.²⁸ Like the naphthalene-based dyes, the pyridyloxazole dyes exhibit environment-sensitive fluorescence spectra. PyMPO SE has been used to synthesize fluorescent gramicidin derivatives for following ion channel-gating processes.³⁰

Figure 1.7.20 Absorption and fluorescence emission spectra of Cascade Yellow™ goat anti-mouse IgG antibody in pH 8.0 buffer.

Figure 1.7.17 Excimer formation by pyrene in ethanol. Spectra are normalized to the 371.5 nm peak of the monomer. All spectra are essentially identical below 400 nm after normalization. Spectra are as follows: 1) 2 mM pyrene, purged with argon to remove oxygen; 2) 2 mM pyrene, air-equilibrated; 3) 0.5 mM pyrene (argon-purged); and 4) 2 μM pyrene (argon-purged). The monomer-to-excimer ratio (371.5 nm/470 nm) is dependent on both pyrene concentration and the excited-state lifetime, which is variable because of quenching by oxygen.

Figure 1.7.26 Bimane mercaptoacetic acid (carboxymethylthiobimane, B30250).

Naphthalenes, Including Dansyl Chloride

Aminonaphthalene-based probes tend to have emission spectra that are sensitive to the environment and to exhibit weak fluorescence in aqueous solution. Spectra of environment-sensitive probes respond to perturbations in the local environment (Table 1.13). For example, changes in solvation that occur because of ligand binding, protein assembly or protein denaturation can often evoke changes in the fluorescence properties of these probes. This property has made dansyl chloride (5-dimethylaminonaphthalene-1-sulfonyl chloride, D21) and other aminonaphthalene-based dyes important tools for protein structural studies.

Dansyl chloride is nonfluorescent until it reacts with amines. The resulting dansyl amides have environment-sensitive fluorescence quantum yields and emission maxima, along with large Stokes shifts. Despite the weak absorptivity ($EC \sim 4000 \text{ cm}^{-1}\text{M}^{-1}$ at 330–340 nm) and moderate fluorescence quantum yield of dansyl sulfonamides, dansyl chloride is widely used as a derivatization reagent for end-group analysis of proteins, amino acid analysis and HPLC detection (Section 1.8). The succinimidyl ester of dansylaminohexanoic acid (dansyl-X, SE; D6104; Figure 1.7.22) contains a seven-atom spacer ("X") that places the dansyl fluorophore further from its reaction site, potentially reducing the interaction of the fluorophore with the biomolecule to which it is conjugated and enhancing accessibility to antibody binding.^{31–33} A rabbit polyclonal antibody to the 1,5-dansyl fluorophore (A6398) that significantly enhances the dye's fluorescence is described in Section 7.4.

Conjugates of two isomers of dansyl chloride (2,5-dansyl chloride, D22; 2,6-dansyl chloride, D23) have smaller Stokes shifts and appreciably longer fluorescence lifetimes (up to ~30 nanoseconds) than conjugates of 1,5-dansyl chloride, making these isomers among the best available probes for fluorescence depolarization studies.³⁴ These dyes are particularly useful for preparing fluorescent drug or ligand analogs that are expected to bind to hydrophobic sites in proteins or membranes. The lipophilicity of these reagents may also facilitate the labeling of sites within the membrane-spanning portions of cellular proteins.

Dapoxyl® Dye

Dapoxyl® dye (Figure 1.7.23) is a particularly versatile derivatization reagent and precursor to environment-sensitive probes.³⁵ Like Cascade Yellow™ dye, Dapoxyl® dye exhibits an exceptionally large Stokes shift, with excitation/emission maxima of ~370/580 nm (Figure 1.7.24). Sulfonamides from Dapoxyl® sulfonyl chloride (D10160) have much higher extinction coefficients than those of dansyl chloride (~26,000 $\text{cm}^{-1}\text{M}^{-1}$ versus about 4000 $\text{cm}^{-1}\text{M}^{-1}$) and equal or greater quantum yields when dissolved in organic solvents; however, the fluorescence of Dapoxyl® derivatives is very sensitive to the dye environment, and fluorescence in water is very low, making them useful for sensing conformational changes,³⁶ denaturation and phosphorylation states³⁷ of proteins.

In addition to Dapoxyl® sulfonyl chloride, we offer the amine-reactive Dapoxyl® succinimidyl ester (D10161) and the carboxylic acid-reactive Dapoxyl® (2-aminoethyl)sulfonamide (D10460, Section 3.4). We have also exploited the environment-sensitive fluorescence of the Dapoxyl® dye (Figure 1.7.25) to develop a highly selective and photostable stain for the endoplasmic reticulum (ER-Tracker™ Blue-White DPX, E12353; Section 12.4).

Bimane Derivative

Bimane mercaptoacetic acid (carboxymethylthiobimane, B30250; Figure 1.7.26) is a blue-fluorescent dye with excitation/emission maxima of ~380/458 nm. It is useful as a reference standard for the fluorogenic monobromobimane and monochlorobimane reagents (Section 2.3) because it is an analog of the thioether product of their reaction with glutathione and other thiols.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- This sulfonated succinimidyl ester derivative is water soluble and may be dissolved in buffer at ~pH 8 for reaction with amines. Long-term storage in water is NOT recommended due to hydrolysis.
- The Alexa Fluor® 405 and Cascade Blue® dyes have a second absorption peak at about 376 nm with EC ~80% of the 395–400 nm peak.
- A30100 is an alternative packaging of A30000 but is otherwise identical.
- Unstable in water. Use immediately.
- Fluorescence emission spectrum shifts to shorter wavelengths in nonpolar solvents.
- D21 butylamine derivative has Abs = 337 nm (EC = 5300 cm⁻¹M⁻¹), Em = 492 nm in CHCl₃. Em and QY are highly solvent dependent: Em = 496 nm (QY = 0.45) in dioxane, 536 nm (QY = 0.28) in MeOH and 557 nm (QY = 0.03) in H₂O. (Biochemistry (1967) 6:3408) EC typically decreases upon conjugation to proteins (EC = 3400 cm⁻¹M⁻¹ at 340 nm). (Biochemistry (1986) 25:513) Fluorescence lifetimes (τ) of protein conjugates are typically 12–20 nanoseconds. (Arch Biochem Biophys (1969) 133:263, Arch Biochem Biophys (1968) 128:163)
- Do NOT dissolve in DMSO.
- D22 butylamine derivative: Abs = 375 nm (EC = 3100 cm⁻¹M⁻¹), Em = 470 nm in MeOH. D23 butylamine derivative: Abs = 375 nm (EC = 13,000 cm⁻¹M⁻¹), Em = 419 nm in CHCl₃.
- D1412 reaction product with 1-butylamine has Abs = 427 nm (EC = 48,000 cm⁻¹M⁻¹), Em = 478 nm in pH 9 buffer.
- D10160 fluorescence is very weak. Reaction product with butylamine has Abs = 373 nm (EC = 26,000 cm⁻¹M⁻¹), Em = 551 nm.
- D10161 butylamine derivative: Abs = 367 nm (EC = 25,000 cm⁻¹M⁻¹), Em = 574 nm in MeOH. QY of the derivative is approximately 15-fold higher than the unreacted reagent.
- Isothiocyanates are unstable in water and should not be stored in aqueous solution.
- D10166 butylamine derivative: Abs = 376 nm (EC = 25,000 cm⁻¹M⁻¹), Em = 469 nm in MeOH. QY of the derivative is approximately 6-fold higher than the unreacted reagent.
- H185 Abs = 339 nm (EC = 19,000 cm⁻¹M⁻¹), Em = 448 nm at pH 4.
- Spectra of the reaction product with butylamine.
- Pyrene derivatives exhibit structured spectra. The absorption maximum is usually about 340 nm with a subsidiary peak at about 325 nm. There are also strong absorption peaks below 300 nm. The emission maximum is usually about 376 nm with a subsidiary peak at 396 nm. Excimer emission at about 470 nm may be observed at high concentrations.

PRODUCT LIST 1.7 COUMARINS, PYRENES AND OTHER ULTRAVIOLET LIGHT EXCITABLE FLUOROPHORES

Cat. No.	Product	Quantity
A10168	Alexa Fluor® 350 carboxylic acid, succinimidyl ester	5 mg
A30000	Alexa Fluor® 405 carboxylic acid, succinimidyl ester	1 mg
A30100	Alexa Fluor® 405 carboxylic acid, succinimidyl ester	5 mg
A10169	Alexa Fluor® 430 carboxylic acid, succinimidyl ester	5 mg
A20180	Alexa Fluor® 350 Monoclonal Antibody Labeling Kit *5 labelings*	1 kit
A10170	Alexa Fluor® 350 Protein Labeling Kit *3 labelings*	1 kit
A10171	Alexa Fluor® 430 Protein Labeling Kit *3 labelings*	1 kit
A6118	6-((7-amino-4-methylcoumarin-3-acetyl)amino)hexanoic acid, succinimidyl ester (AMCA-X, SE)	10 mg
A10478	APEX® Pacific Blue™ Antibody Labeling Kit	1 kit
B30250	bimane mercaptoacetic acid (carboxymethylthiobimane)	5 mg
C2284	Cascade Blue® acetyl azide, trisodium salt	5 mg
C10164	Cascade Yellow™ succinimidyl ester	5 mg
D10161	Dapoxyl® carboxylic acid, succinimidyl ester	5 mg
D10160	Dapoxyl® sulfonyl chloride	10 mg
D21	5-dimethylaminonaphthalene-1-sulfonyl chloride (dansyl chloride)	1 g
D22	2-dimethylaminonaphthalene-5-sulfonyl chloride	100 mg
D23	2-dimethylaminonaphthalene-6-sulfonyl chloride	100 mg
D6104	6-((5-dimethylaminonaphthalene-1-sulfonyl)amino)hexanoic acid, succinimidyl ester (dansyl-X, SE)	25 mg
D1421	7-diethylaminocoumarin-3-carboxylic acid	100 mg
D1412	7-diethylaminocoumarin-3-carboxylic acid, succinimidyl ester	25 mg
D126	7-dimethylaminocoumarin-4-acetic acid (DMACA)	100 mg
D374	7-dimethylaminocoumarin-4-acetic acid, succinimidyl ester (DMACA, SE)	25 mg
D10166	7-dimethylamino-4-methylcoumarin-3-isothiocyanate (DACITC)	10 mg
H185	7-hydroxycoumarin-3-carboxylic acid *reference standard*	100 mg
H1193	7-hydroxycoumarin-3-carboxylic acid, succinimidyl ester	25 mg
H1428	7-hydroxy-4-methylcoumarin-3-acetic acid	100 mg
M10165	Marina Blue® succinimidyl ester	5 mg
M1420MP	7-methoxycoumarin-3-carboxylic acid	100 mg
M1410	7-methoxycoumarin-3-carboxylic acid, succinimidyl ester	25 mg
P30013	Pacific Blue™ Monoclonal Antibody Labeling Kit *5 labelings*	1 kit
P30012	Pacific Blue™ Protein Labeling Kit *3 labelings*	1 kit
P10163	Pacific Blue™ succinimidyl ester	5 mg
P30014	Pacific Orange™ Monoclonal Antibody Labeling Kit *5 labelings*	1 kit
P30016	Pacific Orange™ Protein Labeling Kit *3 labelings*	1 kit
P30253	Pacific Orange™ succinimidyl ester *triethylammonium salt*	1 mg
P130	1-pyrenebutanoic acid, succinimidyl ester	100 mg
P6114	N-(1-pyrenebutanoyl)cysteic acid, succinimidyl ester, potassium salt	5 mg
P24	1-pyrenesulfonyl chloride	100 mg
S6110	1-(3-(succinimidylloxycarbonyl)benzyl)-4-(5-(4-methoxyphenyl)oxazol-2-yl)pyridinium bromide (PyMPO, SE)	5 mg
Z25400	Zenon® Alexa Fluor® 350 Human IgG Labeling Kit *50 labelings*	1 kit
Z25000	Zenon® Alexa Fluor® 350 Mouse IgG ₁ Labeling Kit *50 labelings*	1 kit
Z25100	Zenon® Alexa Fluor® 350 Mouse IgG _{2a} Labeling Kit *50 labelings*	1 kit

1.8 Reagents for Analysis of Low Molecular Weight Amines

Not only are low molecular weight amines abundantly distributed in nature, but numerous drugs, synthetic probes and other molecules of interest also contain amino groups. The sensitive detection, identification and quantitation of amines are important applications of many of the reactive fluorophores in this section. Some of these reagents have also been used to indirectly detect carbohydrates, carboxylic acids, thiols and cyanide.

The preferred reagents for detecting and quantitating amines in solution or on amine-containing polymers are those that are nonfluorescent but form fluorescent conjugates stoichiometrically with amines. It is difficult to compare the sensitivity for amine detection of the different reagents because it depends heavily on the equipment and detection technology used. Many of the assays, however, are rapid, reliable and adaptable to a variety of different sample types and instrumentation.

Fluorescamine

Fluorescamine (F2332, F20261) is intrinsically nonfluorescent but reacts rapidly with primary aliphatic amines, including those in peptides and proteins, to yield a blue-green-fluorescent derivative^{1,2} (Figure 1.8.1). Modifications to the reaction protocol permit fluorescamine to be used to detect those amino acids containing secondary amines,³ such as proline. Excess reagent is rapidly converted to a non-fluorescent product by reaction with water,⁴ making fluorescamine useful for determining protein concentrations of solutions.^{5,6}

Fluorescamine can also be used to detect proteins in gels and to analyze low molecular weight amines by TLC, HPLC and capillary electrophoresis.^{7,8} An optimized procedure that employs fluorescamine for amino acid analysis in microplates has been published.⁹ Chiral separation of fluorescamine-labeled amino acids has been optimized using capillary electrophoresis in the presence of hydroxypropyl- β -cyclodextrin, a method designed for use in extraterrestrial exploration on Mars.¹⁰ Furthermore, a 200-fold increase in sensitivity and improved resolution in these measurements has been obtained by replacing fluorescamine with Pacific Blue™ succinimidyl ester¹¹ (P10163, Section 1.7).

Figure 1.8.1 Fluorogenic amine-derivatization reaction of fluorescamine (F2332, F20261).

Figure 1.8.2 Fluorogenic amine-derivatization reaction of *o*-phthalaldehyde (OPA, P2331MP).

Figure 1.8.3 Fluorogenic amine-derivatization reaction of naphthalene-2,3-dicarboxaldehyde (NDA, N1138).

Dialdehydes: OPA and NDA

Analyte Detection with OPA and NDA

The homologous aromatic dialdehydes *o*-phthalaldehyde¹² (OPA, P2331MP) and naphthalene-2,3-dicarboxaldehyde¹³ (NDA, N1138) are essentially nonfluorescent until reacted with a primary amine in the presence of a thiol such as 2-mercaptoethanol, 3-mercaptopropionic acid or the less obnoxious sulfite,¹⁴ or in the presence of excess cyanide, to yield a fluorescent isoindole (Figure 1.8.2, Figure 1.8.3). Improved detection sensitivity can be obtained by using SAMSA fluorescein (A685, Section 5.2) as the thiol reagent, thereby incorporating fluorescein as the R² substituent of the isoindole product¹⁵ (Figure 1.8.2). Modified protocols that use an excess of an amine and limiting amounts of other nucleophiles permit the determination of carboxylic acids¹⁶ and thiols,¹⁷ as well as of cyanide in blood, urine and other samples.^{18–21} Without an additional nucleophile, NDA forms fluorescent adducts with both hydrazine and methylated hydrazines²² (excitation/emission maxima ~403/500 nm).

Sensitivity of OPA and NDA

Amine adducts of NDA have longer-wavelength spectral characteristics and greater sensitivity than the amine adducts of OPA. The stability and detectability of the amine derivatives of NDA are also superior;^{23,24} the detection of glycine with NDA and cyanide is reported to be 50-fold more sensitive than with OPA and 2-mercaptoethanol.¹³ The limit for electrochemical detection of the NDA adduct of asparagine has been determined to be as low as 36 attomoles^{25,26} (36×10^{-18} moles). An optimized procedure that uses NDA for amino acid analysis in microplates has been published.⁹

Applications for OPA and NDA

OPA and NDA are used extensively for both pre- and post-column derivatization of amines (and thiols) separated by HPLC^{27,28} or by capillary electrophoresis.^{27,29} The amines in a single cell have been analyzed by capillary electrophoresis using a sequence of on-capillary lysis, derivatization with NDA and cyanide, and laser-excited detection.^{30,31}

ATTO-TAG™ Reagents

Sensitivity of ATTO-TAG™ CBQCA and ATTO-TAG™ FQ

ATTO-TAG™ CBQCA (A6222, A2333) and ATTO-TAG™ FQ (A10192, A2334) are designed to provide ultrasensitive detection of primary amines, including those in peptides, aminophospholipids and glycoproteins.^{32–35} These reagents combine high sensitivity, visible-wavelength excitation and freedom from background fluorescence, making them useful for research, as well as analytical, forensic and clinical³⁶ applications. Developed by Novotny and collaborators, the ATTO-TAG™ reagents are similar to OPA and NDA in that they rapidly react with amines in the presence of thiols or cyanide to form highly fluorescent isoindoles^{37–47} (Figure 1.8.4).

ATTO-TAG™ CBQCA reagent reacts specifically with amines to form charged conjugates that can be analyzed by electrophoresis techniques. Carbohydrates lacking amines can be detected following reductive amination with ammonia and NaCNBH₃.^{46,48,49} ATTO-TAG™ CBQCA conjugates are maximally excited at ~456 nm or by the 442 nm spectral line of the He-Cd laser, with peak emission at ~550 nm, whereas ATTO-TAG™ FQ conjugates are maximally excited at ~480 nm or by the 488 nm spectral line of the argon-ion laser, with peak emission at ~590 nm. Ultrasensitive detection of CBQCA-derivatized amino sugars, amino acids and low molecular weight peptides by capillary electrophoresis has been reported.^{35,50} In capillary electrophoresis, the sensitivity of amine detection of the laser-induced fluorescence is in the subattomole range (<10⁻¹⁸ moles) for ATTO-TAG™ CBQCA and subfemtomole range (<10⁻¹⁵ moles) for ATTO-TAG™ FQ.^{51,52} Detection sensitivity of reductively aminated glucose using ATTO-TAG™ CBQCA is reported to be 75 zeptomoles⁵³ (75 × 10⁻²¹ moles).

ATTO-TAG™ reagents can, of course, be used in HPLC and other modes of chromatography with either absorption or fluorescence detection. The principal limitation to obtaining ultrasensitive detection using the ATTO-TAG™ reagents and all other chemical derivatization reagents is that relatively high concentrations of the derivatizing reagent are required to obtain adequate kinetics and quantitative modification of the analyte.^{54,55} A very sensitive assay that uses ATTO-TAG™ CBQCA for rapid quantitation of protein amines in solution (C6667) is described in Section 9.2. Similarly, ATTO-TAG™ CBQCA has proven useful for *in situ* quantitation of proteins attached to microspheres.⁵⁶

ATTO-TAG™ Reagents and Kits

Because cyclodextrins have been reported to amplify the signal from ATTO-TAG™ CBQCA conjugates up to 10-fold,^{34,57} we have in-

cluded β-cyclodextrin in our ATTO-TAG™ Amine Derivatization Kits (A2333, A2334). These kits contain:

- 5 mg of ATTO-TAG™ CBQCA (in Kit A2333) or ATTO-TAG™ FQ (in Kit A2334)
- Potassium cyanide
- β-Cyclodextrin
- Protocol for amine modification

The ATTO-TAG™ CBQCA and ATTO-TAG™ FQ Amine Derivatization Kits supply sufficient reagents for derivatizing approximately 150 and 100 samples, respectively, depending on the amine concentration and sample volume.

7-Nitrobenz-2-Oxa-1,3-Diazole (NBD) Derivatives

NBD chloride (C20260, Figure 1.8.5) was first introduced in 1968 as a fluorogenic derivatization reagent for amines.⁵⁸ NBD fluoride (F486) usually yields the same products as NBD chloride but is much more reactive;⁵⁹ for example, the reaction of NBD fluoride with glycine is reported to be 500 times faster than the reaction of NBD chloride with glycine.⁶⁰ Reaction of NBD fluoride with alcohols leads to their utility for derivatizing and detecting lipopolysaccharides⁶¹ (LPS). Unlike OPA and fluorescamine, both NBD chloride and NBD fluoride react with secondary amines and are therefore capable of derivatizing proline and hydroxyproline.^{59,62} NBD chloride and NBD fluoride are extensively used as derivatization reagents for chromatographic analysis of amino acids⁶³ and other low molecular weight amines.³³

The absorption and fluorescence emission spectra, quantum yields and extinction coefficients of NBD conjugates are all markedly dependent on solvent;^{64,65} in particular, the fluorescence quantum yield in water of NBD adducts of amines can be very low (<0.01), particularly of secondary amines. NBD adducts of aromatic amines are essentially nonfluorescent, a property that we have utilized to prepare our QSY® 35 quenchers.

Fluorescence of lysine-modified NBD-labeled actin is sensitive to polymerization.⁶⁶ Inactivation of certain ATPases by NBD chloride apparently involves a tyrosine modification followed by intramolecular migration of the label to a lysine residue.^{67,68} NBD is also a functional analog of the dinitrophenyl hapten, and its fluorescence is quenched upon binding to anti-dinitrophenyl antibodies^{65,69} (Section 7.4).

NBD aminohexanoic acid (NBD-X, N316) and its succinimidyl ester (NBD-X, SE; S1167) are precursors to NBD-labeled phospholipids (Section 13.2), NBD C₆-ceramide (N1154, Section 12.4) and other probes.

Dansyl Chloride and Other Sulfonyl Chlorides

Many of the sulfonyl chlorides described in Section 1.7, including dansyl chloride (D21), 1-pyrenesulfonyl chloride (P24) and Dapoxyl® sulfonyl chloride (D10160), react with amines to yield blue- or blue-green-fluorescent sulfonamides and are particularly useful as chromatographic derivatization reagents. They react with both aliphatic and aromatic amines to yield very stable derivatives. In addition, they are

Figure 1.8.4 Fluorogenic amine-derivatization reaction of CBQCA (A6222, A2333).

generally good acceptors for fluorescence resonance energy transfer (FRET) from tryptophan, as well as good donors to longer-wavelength dyes such as QSY® dyes (Section 1.6) (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). Fluorescence of dansyl conjugates in aqueous solutions can be enhanced by adding cycloheptaamylose.⁷⁰

Although dansyl chloride is the most commonly used of these reagents, the stronger absorption of 1-pyrenesulfonamides and large Stokes shift of Dapoxyl® sulfonamides⁷¹ (Figure 1.8.6) should make these sulfonyl chlorides more sensitive reagents for amine analysis. Note that sulfonyl chlorides are unstable in dimethylsulfoxide (DMSO) and should never be used in that solvent.⁷²

Dansyl Chloride

Since its development by Weber in 1951,⁷³ dansyl chloride (D21, Section 1.7) has been used extensively to determine the N-terminal amino acid residue of proteins and to prepare fluorescent derivatives of drugs, amino acids, oligonucleotides and proteins for detection by numerous chromatographic methods.⁷⁴ Nonfluorescent dansyl chloride reacts with amines to form fluorescent dansyl amides that exhibit large Stokes shifts, along with environment-sensitive fluorescence quantum yields and emission maxima.

Pyrene Sulfonyl Chloride

The absorptivity (and therefore ultimate fluorescence output) of dansyl derivatives is weak compared with that of the more strongly UV light-absorbing fluorophores such as pyrene. Thus, 1-pyrenesulfonyl chloride (P24, Section 1.7) should have greater sensitivity for detection of amines. The fluorescence lifetime of pyrenesulfonamides can also be relatively long (up to ~30 nanoseconds), making them useful for fluorescence anisotropy measurements.⁷⁵ Fluorescence polarization measurements of DNA probes labeled with 1-pyrenesulfonyl chloride permit homogeneous detection of hybridization.⁷⁶

Dapoxyl® Sulfonyl Chloride

Sulfonamides derived from Dapoxyl® sulfonyl chloride (D10160, Section 1.7) have much higher extinction coefficients than those of dansyl chloride (~22,000 cm⁻¹M⁻¹ versus ~4000 cm⁻¹M⁻¹) and equal or greater quantum yields when dissolved in organic solvents; however, Dapoxyl® derivatives have very low fluorescence in water. The huge Stokes shifts (up to ~200 nm) and large extinction coefficients of Dapoxyl® derivatives in some solvents⁷¹ (Figure 1.8.6) make the reactive Dapoxyl® derivatives a good choice for derivatization reagents in chromatographic and electrophoretic analysis.⁷⁷

Figure 1.8.6 Absorption and fluorescence emission spectra of Dapoxyl® (2-aminoethyl)sulfonamide in methanol.

FITC and Other Isothiocyanates

Isothiocyanates for preparing bioconjugates have been described in several sections of this chapter. However, FITC (F143, F1906, F1907; Section 1.5) can also be used for derivatization of low molecular weight amines³³ and, like phenyl isothiocyanate, for microsequencing of peptides as their thiohydantoins.⁷⁸ A method for specific derivatization of the N-terminus of peptides by FITC has been described.⁷⁹ FITC-labeled amino acids and peptides have been separated by capillary electrophoresis with a detection limit of fewer than 1000 molecules.^{80,81}

Succinimidyl Esters and Carboxylic Acids

Succinimidyl esters have a high selectivity for reaction with aliphatic amines. Most of the succinimidyl ester reagents described elsewhere in this chapter can be used to derivatize low molecular weight amines for subsequent separation by chromatography or capillary electrophoresis. Alexa Fluor®, BODIPY®, Oregon Green® and fluorescein derivatives typically yield the greatest sensitivity, particularly when the conjugate is detected with laser excitation. Use of single isomers of these reactive dyes is essential for all high-resolution analyses. Analysis by capillary electrophoresis shows that carboxyfluorescein succinimidyl ester reacts faster and yields more stable amine conjugates than FITC or DTAF.⁸²

Figure 1.8.7 Normalized absorption spectra of the succinimidyl esters of the dabcyI (D2245, blue) and QSY* 35 (Q20133, red) dyes.

Figure 1.8.8 4-((4-(dimethylamino)phenyl)azo)benzoic acid, succinimidyl ester (dabcyI, SE; D2245).

Figure 1.8.10 QSY* 35 acetic acid, succinimidyl ester (Q20133).

The UV light-excitable coumarins described in Section 1.7 have good absorptivity at ~320–420 nm, with purple to bright blue emission at 400–500 nm. Aliphatic polyamines derivatized with 1-pyrenebutanoic acid succinimidyl ester (P130, Section 1.7) have been differentiated from pyrene-labeled monoamines by HPLC using their fluorescent excimer formation.⁸³

The Smallest Reactive Fluorophore

N-methylisatoic anhydride (M25) is a useful precursor for preparing esters or amides of the small *N*-methylanthranilic acid fluorophore. The small size of this fluorophore should reduce the likelihood that the label will interfere with the function of the biomolecule, an important advantage when designing site-selective probes. This amine-acylating reagent is often used to prepare fluorescent derivatives of biologically active peptides and toxins^{84–87} and, in combination with a quencher, to prepare fluorogenic endoprotease substrates.^{88,89}

Chromophoric Succinimidyl Esters: Fluorescence Quenchers

DabcyI has broad and intense visible absorption (Figure 1.8.7) but no fluorescence, making it useful as an acceptor in FRET applications (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). Biomolecules double-labeled with dabcyI and the appropriate fluorophore can be used to monitor proteolytic cleavage, conformational changes and other dynamic spatial movements. DabcyI succinimidyl ester (dabcyI, SE; D2245; Figure 1.8.8) is particularly useful in preparing quenched fluorogenic substrates for proteases, including our HIV protease (Figure 1.8.9) and renin substrates^{90–92} (H2930, R2931; Section 10.4), papain,^{93,94} Alzheimer disease-associated proteases⁹⁵ and others.^{96–99} Fluorogenic substrates using this quenching group have also been prepared for interleukin-1 β -converting enzyme (ICE),¹⁰⁰ a cysteine protease that is proposed to function in the onset of apoptosis.¹⁰¹ The dabcyI chromophore has been used as the quencher in donor-acceptor labeled oligonucleotides (molecular beacons);^{102–105} unfolding of these probes upon hybridization leads to recovery of the donor dye's fluorescence.

QSY* 35 acetic acid succinimidyl ester (Q20133, Figure 1.8.10) is an essentially nonfluorescent nitrobenzoxadiazole (NBD) derivative. Like the QSY* 7, QSY* 9 and QSY* 21 dyes (Section 1.6), the QSY* 35 dye has absorption at longer wavelengths than does the dabcyI dye (Figure 1.8.7), making it a very good acceptor from most blue-fluorescent dyes. A peptide containing the QSY* 35 quencher paired with the blue-fluorescent 7-hydroxy-4-methyl-3-acetylcoumarin fluorophore has proven useful in a fluorescence resonance energy transfer (FRET) assay for *Bacillus anthracis* lethal factor protease.¹⁰⁶ QSY* 35 iodoacetamide (Q20348, Section 2.2) and an Fmoc-protected QSY* 35 amino acid (Q21931, Section 9.5) are available for automated preparation of FRET-based protease substrates.

N-(*t*-BOC)-Aminoxyacetic Acid TFP Ester

The tetrafluorophenyl ester (TFP) of *N*-(*t*-BOC)-aminoxyacetic acid (B30300) is an amine-reactive protected hydroxylamine that is useful for synthesizing new aldehyde- and ketone-reactive probes in an organic solvent. Following coupling to aliphatic amines, the *t*-BOC group can be quantitatively removed with trifluoroacetic acid. The resultant hydroxylamine can then spontaneously react with aldehydes, the reducing ends of saccharides and oligosaccharides and abasic sites in oligonucleotides to form stable adducts (Section 3.3).

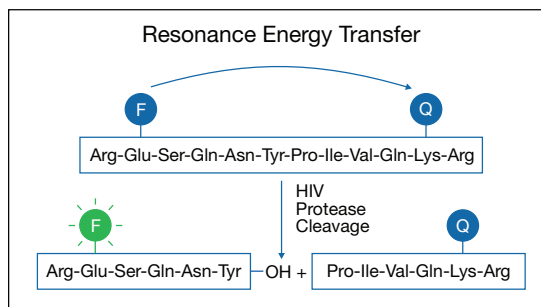

Figure 1.8.9 Principle of the fluorogenic response to protease cleavage exhibited by HIV protease substrate 1 (H2930). Quenching of the EDANS fluorophore (F) by distance-dependent resonance energy transfer to the dabcyI quencher (Q) is eliminated upon cleavage of the intervening peptide linker.

Notes

- Spectral data are for the reaction product with glycine in the presence of cyanide. Unreacted reagent in MeOH: Abs = 254 nm (EC = 46,000 cm⁻¹M⁻¹), nonfluorescent.
- ND = not determined.
- Solubility in methanol is improved by addition of base (e.g., 1–5% (v/v) 0.2 M KOH).
- Data represent the reactive dye component of this labeling kit.
- Spectral data are for the reaction product with glycine in the presence of cyanide. Unreacted reagent in MeOH: Abs = 282 nm (EC = 21,000 cm⁻¹M⁻¹), nonfluorescent.
- Spectra for primary aliphatic amine derivative of NBD chloride in MeOH: Abs = 465 nm (EC = 22,000 cm⁻¹M⁻¹), Em = 535 nm (QY = 0.3). Spectra for secondary aliphatic amine derivative in MeOH: Abs = 485 nm (EC = 25,000 cm⁻¹M⁻¹), Em = 540 nm (QY < 0.1). Aromatic amine derivatives are nonfluorescent. All NBD amine derivatives are almost nonfluorescent in water and have strongly solvent-dependent emission spectra. NBD fluoride yields the same derivatives as NBD chloride but is more reactive.
- Fluorescence of NBD and its derivatives in water is relatively weak. QY and τ increase and Em decreases in aprotic solvents and other nonpolar environments relative to water. (Biochemistry (1977) 16:5150, Photochem Photobiol (1991) 54:361)
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- D2245 is nonfluorescent both before and after reaction with amines. Reaction product with butylamine has Abs = 428 nm (EC = 32,000 cm⁻¹M⁻¹) in MeOH.
- Fluorescamine spectra are for the reaction product with butylamine. The fluorescence quantum yield and lifetime of the butylamine adduct in EtOH are 0.23 and 7.5 nanoseconds, respectively. (Arch Biochem Biophys (1974) 163:390) The unreacted reagent is nonfluorescent (Abs = 234 nm, EC = 28,000 cm⁻¹M⁻¹ in MeCN).
- The amide reaction product of M25 with butylamine has Abs = 353 nm (EC = 5900 cm⁻¹M⁻¹), Em = 426 nm in MeOH. Ester reaction products with alcohols have Abs = 350 nm (EC = 5700 cm⁻¹M⁻¹), Em = 446 nm in water (pH 8).
- Spectral data are for the reaction product with glycine in the presence of cyanide, measured in pH 7.0 buffer/MeCN (40:60). (Anal Chem (1987) 59:1102) Unreacted reagent in MeOH: Abs = 279 nm (EC = 5500 cm⁻¹M⁻¹), Em = 330 nm.
- Spectral data are for the reaction product of P2331MP with alanine and 2-mercaptoethanol. The spectra and stability of the adduct depend on the amine and thiol reactants. (Biochim Biophys Acta (1979) 576:440) Unreacted reagent in H₂O: Abs = 257 nm (EC = 1000 cm⁻¹M⁻¹).

PRODUCT LIST 1.8 REAGENTS FOR ANALYSIS OF LOW MOLECULAR WEIGHT AMINES

Cat. No.	Product	Quantity
A2333	ATTO-TAG™ CBQCA Amine-Derivatization Kit	1 kit
A6222	ATTO-TAG™ CBQCA derivatization reagent (CBQCA; 3-(4-carboxybenzoyl)quinoline-2-carboxaldehyde)	10 mg
A2334	ATTO-TAG™ FQ Amine-Derivatization Kit	1 kit
A10192	ATTO-TAG™ FQ derivatization reagent (FQ; 3-(2-furoyl)quinoline-2-carboxaldehyde)	10 mg
B30300	N-(t-BOC)-aminoxyacetic acid, tetrafluorophenyl ester	25 mg
C20260	4-chloro-7-nitrobenz-2-oxa-1,3-diazole (NBD chloride; 4-chloro-7-nitrobenzofurazan) *FluoroPure™ grade*	100 mg

2.1 Introduction to Thiol Modification and Detection

Common Applications for Thiol-Reactive Probes

Labeling Proteins and Nucleic Acids

Thiol-reactive dyes are principally used to label proteins for the detection of conformational changes, assembly of multisubunit complexes and ligand-binding processes¹ In the case of proteins and peptides, the primary targets of thiol-reactive probes are cysteine residues. In mammalian proteins, the occurrence frequency of cysteine targets (3.3%) is less than half that of lysine targets (7.2%), which are labeled by the amine-reactive reagents described in Chapter 1. Some proteins and many peptides have only a single cysteine residue, enabling site-specific labeling with thiol-reactive probes.^{2,3} In proteins with multiple cysteine residues, the multiplicity is often small enough that it is practicable to obtain single-cysteine variants by site-directed mutagenesis without significant disruption of the structure or function of the native protein. Site-specific modification is particularly important for labeling small proteins in applications where the activity or binding affinity of the conjugate is paramount;^{3,4} thiol-reactive labeling is the preferred approach over amine-reactive labeling in such cases.

The relatively low abundance of cysteine residues also makes it possible to obtain saturating modification with less risk of incurring the penalties of protein precipitation and fluorescence self-quenching interactions that make high-percentage amine-reactive modification largely impracticable.^{5,6} In proteins with multiple cysteine residues, however, the reactivity of an individual cysteine can be very dependent on both its local environment and the hydrophobicity of the reactive dye.⁷⁻¹⁰ Site-specific modification strategies involving site-directed cysteine mutagenesis, site-dependent variations in thiol reactivity and functional group protection/deprotection have been developed to double-label proteins with donor and acceptor dyes for fluorescence resonance energy transfer (FRET) applications^{2,11-16} (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). Thiol-reactive dyes can also be reacted with thiolated oligonucleotides for hybridization- or ligation-based nucleic acid detection applications¹⁷ and with thiouridine-modified tRNA for studying its association with protein synthesis machinery.^{18,19}

Derivatizing Low Molecular Weight Molecules

Several of the thiol-reactive probes described in this chapter are also useful for derivatizing low molecular weight thiols for various analytical assays that employ chromatographic and electrophoretic separation. An extensive review by Shimada and Mitamura describes the use of several of our thiol-reactive reagents for derivatizing thiol-containing compounds.²⁰

Quantitating Thiols

Thiols play a principal role in maintaining the appropriate oxidation–reduction state of proteins, cells and organisms. The susceptibility of thiols to oxidation, however, can lead to the formation of disulfides and higher oxidation products, often with loss of biological activity. Measuring the oxidation state of thiols within live cells is complicated by the high concentration of reduced glutathione in cells, which makes them difficult to assay with reagents that stoichiometrically react with the thiol. Nonetheless, many useful reagents and methods have been developed for the quantitative assay of thiols and disulfides.²¹

Reactivity of Thiol Groups

Reducing Disulfides with DTT or TCEP

In proteins, thiol groups (also called mercaptans or sulfhydryls) are present in cysteine residues. Thiols can also be generated by selectively reducing cystine disulfides with reagents such as dithiothreitol²² (DTT, D1532) or 2-mercaptoethanol (β -mercaptoethanol), each of which must then be removed by dialysis or gel filtration before reaction with the thiol-reactive probe.²¹

Unfortunately, removal of DTT or 2-mercaptoethanol is sometimes accompanied by air oxidation of the thiols back to the disulfides. Reformation of the disulfide bond can often be avoided by using the reducing agent tris-(2-carboxyethyl)phosphine^{23,24} (TCEP, T2556), which usually does not need to be removed prior to thiol modification because it does not contain thiols (Figure 2.1.1). However, there have been several reports that TCEP can react with haloacetamides or maleimides under certain conditions and that labeling in the presence of TCEP is inhibited.^{6,25} Carrying out thiol-reactive labeling on ammonium sulfate–precipitated proteins facilitates efficient and rapid removal of DTT after the preparatory reduction step and inhibits thiol reoxidation during the subsequent labeling reaction.³

TCEP is more stable at a higher pH and at higher temperatures²⁶ than is DTT and for a longer period of time in buffers without metal chelators such as EGTA; DTT is more stable than TCEP in solutions that contain metal chelators.²³ TCEP is also more stable in the presence of Ni²⁺ levels that commonly contaminate proteins eluted from Ni²⁺ affinity columns and that rapidly oxidize DTT.²³ Spin labels in TCEP are two to four times more stable than those in DTT, an advantage for electron paramagnetic resonance (EPR) spectroscopy.²³ In addition, TCEP is used to stabilize solutions of ascorbic acid.²⁷ TCEP is generally impermeable to cell membranes and to the hydrophobic protein core, permitting its use for the selective reduction of disulfides that have aqueous exposure. It has also been reported that TCEP can be used to deplete high-abundance

Figure 2.1.1 Reduction of a disulfide using TCEP (tris-(2-carboxyethyl)phosphine, hydrochloride; T2556). Unlike DTT (dithiothreitol, D1532), TCEP does not itself contain thiols, and therefore downstream thiol labeling reactions do not require preliminary removal of the reducing reagent.

plasma proteins (albumins, transferrin, etc.) prior to proteomic analysis because these proteins have a large number of disulfide bridges and are therefore particularly susceptible to reductive denaturation.²⁸

Thiol-Reactive Reagents

The primary thiol-reactive reagents, including iodoacetamides, maleimides, benzylic halides and bromomethylketones, react by S-alkylation of thiols to generate stable thioether products. Arylating reagents such as NBD halides react with thiols or amines by a similar substitution of the aromatic halide by the nucleophile. Because the thiolate anion is a better nucleophile than the neutral thiol, cysteine is more reactive above its pK_a²¹ (~8.3, depending on protein structural context). However, as in the case of amine modification by succinimidyl esters (Chapter 1), reagent stability also decreases with increasing pH (e.g., maleimide hydrolysis to unreactive maleamic acid), and therefore a compromise pH of 7.0–7.5 is typically used for protein modification reactions. It has been reported that iodoacetamide and maleimide adducts with intracellular proteins have different degrees of stability and toxicity. Analysis of the intracellular reactivity and toxicity of haloacetyl and maleimido thiol-reactive probes in HEK 293 cells indicates that maleimides are less stable and iodoacetamides are more toxic²⁹ (putatively because maleimide adducts degrade before they are able to trigger damage-signaling pathways).

Also available are the TS-Link™ series of reagents for reversible thiol modification (Section 2.2). The TS-Link™ reagents are water-soluble thiosulfates that react stoichiometrically with thiols to form mixed disulfides. Thiols also react with many of the amine-reactive reagents described in Chapter 1, including isothiocyanates and succinimidyl esters. However, the reaction products appear to be insufficiently stable to be useful for routine modification of thiols in proteins. Although the thiol–isothiocyanate product (a dithiocarbamate) can react with an adjacent amine to yield a thiourea, the dithiocarbamate is more likely to react with water, consuming the reactive reagent without forming a covalent adduct. In addition to insertion or deletion of cysteine residues by site-directed mutagenesis, several reagents have been developed for introducing thiols into proteins, nucleic acids and lipids. Because the selective introduction of thiols is particularly important for crosslinking two biomolecules, these reagents are discussed in Chapter 5.

Site-Specific Labeling with Thiol-Reactive Reagents

A method for the site-specific double-labeling of a protein containing at least one vicinal diol and another distal thiol has been reported.¹¹ In this labeling protocol, the vicinal diol is first protected with phenylarsine oxide (PAO) to allow labeling of the unprotected distal thiol with Oregon Green® 488 maleimide (O6034, Section 2.2). The blocked vicinal diol is then deprotected with dithiothreitol (DTT) and labeled with Alexa Fluor® 350 maleimide (A30505, Section 2.3). Target proteins

may need to be engineered to contain a vicinal diol and distal thiol in order to employ this labeling strategy.

In a similar double thiol-labeling method, instead of PAO protection/deprotection, the protein's tetracysteine tag was labeled using FLAsH-EDT₂ reagent (T34561, Section 2.2), and the Alexa Fluor® 568 maleimide (A20341, Section 2.2) was used to label a distal cysteine.³⁰ Fluorescence resonance energy transfer (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2) between the FLAsH label and Alexa Fluor® 568 dye was then used to detect ligand-induced conformational changes in the C-terminal domain of the β₂-adrenoreceptor in SF9 cells.

Iodoacetamides

Iodoacetamides readily react with all thiols, including those found in peptides, proteins and thiolated polynucleotides, to form thioethers (Figure 2.1.2); they are somewhat more reactive than bromoacetamides. When a protein's cysteine residues are blocked or absent, however, iodoacetamides can sometimes react with methionine residues.¹³ They may also react with histidine³¹ or tyrosine, but generally only if free thiols are absent. Although iodoacetamides can react with the free base form of amines, most aliphatic amines, except the α-amino group at a protein's N-terminus, are protonated and thus relatively unreactive below pH 8.³² In addition, iodoacetamides react with thiolated oligonucleotide primers, as well as with thiophosphates.³³

Iodoacetamides are intrinsically unstable in light, especially in solution; reactions should therefore be carried out under subdued light. Adding cysteine, glutathione or mercaptosuccinic acid to the reaction mixture will quench the reaction of thiol-reactive probes, forming highly water-soluble adducts that are easily removed by dialysis or gel filtration. Although the thioether bond formed when an iodoacetamide reacts with a protein thiol is very stable, the bioconjugate loses its fluorophore during amino acid hydrolysis, yielding S-carboxymethylcysteine.

Maleimides

Maleimides are excellent reagents for thiol-selective modification, quantitation and analysis. In this reaction, the thiol is added across the double bond of the maleimide to yield a thioether (Figure 2.1.3). Applications of these fluorescent and chromophoric analogs of N-ethylmaleimide (NEM) strongly overlap those of iodoacetamides, although maleimides apparently do not react with methionine, histidine or tyrosine. Reaction of maleimides with amines usually requires a higher pH than reaction of maleimides with thiols.

Hydrolysis of the maleimide to an unreactive product can compete significantly with thiol modification, particularly above

Alkyl halide or
Haloacetamide (X = I, Br, Cl)

Thioether

Figure 2.1.2 Reaction of a thiol with an alkyl halide.

Maleimide

Thioether

Figure 2.1.3 Reaction of a thiol with a maleimide.

pH 8. Furthermore, once formed, maleimide-derived thioethers can hydrolyze to an isomeric mixture of succinamic acid adducts, or they can undergo cyclization with adjacent amines to yield crosslinked products. This latter reaction is much less frequently encountered than the former.³⁴ Deliberate acceleration of the hydrolytic succinimide to succinamide acid ring-opening reaction by molybdate or chromate catalysis provides a strategy for decreasing the heterogeneity of bioconjugates derived from maleimide derivatization of thiols.³⁵

Reversible Thiol-Reactive Reagents

Several of our thiol-reactive probes can be used to form reversible bonds, including BODIPY® FL L-cystine (B20340), as well as the TS-Link™ BODIPY® thiosulfate and TS-Link™ DSB-X™ biotin C₅-thiosulfate reagents (Section 2.2, Section 4.2).

Symmetric disulfides such as BODIPY® FL L-cystine undergo a thiol–disulfide interchange reaction to yield a new asymmetric disulfide (Figure 2.1.4), a reaction that is freely reversible and thiol-specific. This disulfide linkage can be cleaved with reagents such as DTT or TCEP.

Thiosulfates (R–S–SO₃⁻), including our water-soluble TS-Link™ reagents, are similar to disulfides in that they stoichiometrically react with thiols to form disulfides (Figure 2.1.5). However, unlike the reaction of the BODIPY® FL cystine probe with a free thiol, no excess of the TS-Link™ reagent is required to drive the equilibrium.

Reagents for Quantitating Thiols

Measure-iT™ Thiol Assay Kit

The Measure-iT™ Thiol Assay Kit (M30550) provides an easy and accurate method for quantitating thiols. This thiol assay has a linear range of 0.05–5 μM thiol (Figure 2.1.6), making it up to 400 times more sensitive than colorimetric methods based on Ellman's reagent.

Each Measure-iT™ Thiol Assay Kit contains:

- Measure-iT™ thiol quantitation reagent (100X concentrate in 1,2-propanediol)
- Measure-iT™ thiol quantitation buffer (50 mM potassium phosphate buffer)
- Measure-iT™ thiol quantitation standard (reduced glutathione)
- Detailed protocols

Simply dilute the reagent 1:100, load 100 μL into the wells of a microplate, add 1–10 μL sample volumes, mix, then read the fluorescence. Maximum fluorescence signal is attained within 5 minutes and is stable for at least 1 hour. The assay is performed at room temperature, and common contaminants are well tolerated in the assay. The Measure-iT™ Thiol Assay Kit provides sufficient materials for 500 assays, based on a 100 μL assay volume in a 96-well microplate format; this thiol assay can also be adapted for use in cuvettes or 384-well microplates.

Figure 2.1.4 Reaction of a thiol with a symmetric disulfide.

Figure 2.1.5 Reaction of a TS-Link™ reagent with a thiol, followed by removal of the label with a reducing agent.

Figure 2.1.6 Linearity and sensitivity of the Measure-iT™ thiol assay. Triplicate 10 μL samples of glutathione were assayed using the Measure-iT™ Thiol Assay Kit (M30550). Fluorescence was measured using excitation/emission of 490/520 nm and plotted versus glutathione concentration. The variation (CV) of replicate samples was <2%.

PRODUCT LIST 2.1 INTRODUCTION TO THIOL MODIFICATION AND DETECTION

Cat. No.	Product	Quantity
D8451	5,5'-dithiobis-(2-nitrobenzoic acid) (DTNB; Ellman's reagent)	10 g
D1532	dithiothreitol (DTT)	1 g
M30550	Measure-iT™ Thiol Assay Kit *500 assays*	1 kit
T6060	Thiol and Sulfide Quantitation Kit *50–250 assays*	1 kit
T2556	tris-(2-carboxyethyl)phosphine, hydrochloride (TCEP)	1 g

2.2 Thiol-Reactive Probes Excited with Visible Light

Figure 2.2.1 Photobleaching resistance of the green-fluorescent Alexa Fluor® 488, Oregon Green® 488 and fluorescein dyes, as determined by laser-scanning cytometry. EL4 cells were labeled with biotin-conjugated anti-CD44 antibody and detected by Alexa Fluor® 488 (S11223, S32354), Oregon Green® 488 (S6368) or fluorescein (S869) streptavidin. The cells were then fixed in 1% formaldehyde, washed and wet-mounted. After mounting, cells were scanned 10 times on a laser-scanning cytometer; laser power levels were 25 mW for the 488 nm spectral line of the argon-ion laser. Scan durations were approximately 5 minutes apiece, and each repetition was started immediately after completion of the previous scan. Data are expressed as percentages derived from the mean fluorescence intensity (MFI) of each scan divided by the MFI of the first scan. Data contributed by Bill Telford, Experimental Transplantation and Immunology Branch, National Cancer Institute.

Figure 2.2.2 Photobleaching resistance of the red-fluorescent Alexa Fluor® 647, Alexa Fluor® 633, PBXL-3 and Cy®5 dyes and the allophycocyanin fluorescent protein, as determined by laser-scanning cytometry. EL4 cells were labeled with biotin-conjugated anti-CD44 antibody and detected by Alexa Fluor® 647 (S21374, S32357), Alexa Fluor® 633 (S21375), PBXL-3, Cy®5 or allophycocyanin (APC, S868) streptavidin. The cells were then fixed in 1% formaldehyde, washed and wet-mounted. After mounting, cells were scanned eight times on a laser-scanning cytometer; laser power levels were 18 mW for the 633 nm spectral line of the He-Ne laser. Scan durations were approximately 5 minutes apiece, and each repetition was started immediately after completion of the previous scan. Data are expressed as percentages derived from the mean fluorescence intensity (MFI) of each scan divided by the MFI of the first scan. Data contributed by Bill Telford, Experimental Transplantation and Immunology Branch, National Cancer Institute.

The thiol-reactive Alexa Fluor®, BODIPY®, fluorescein, Oregon Green®, tetramethylrhodamine and Texas Red® derivatives have strong absorptivity and high fluorescence quantum yields. This combination of attributes makes these compounds the preferred reagents for preparing protein and low molecular weight ligand conjugates to study the diffusion, structural properties and interactions of proteins and ligands using techniques such as:

- Fluorescence recovery after photobleaching (FRAP)
- Fluorescence polarization (FP) (Fluorescence Polarization (FP)—Note 1.4)
- Fluorescence correlation spectroscopy (FCS) (Fluorescence Correlation Spectroscopy (FCS)—Note 1.3) and other single-molecule detection techniques
- Fluorescence resonance energy transfer (FRET) (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2)

In this section and in Section 2.3, thiol-reactive reagents with similar spectra, rather than the same reactive group, are generally discussed together. The probes described in this section have visible absorption maxima beyond 410 nm; thiol-reactive probes with peak absorption below 410 nm are described in Section 2.3. Table 2.1 summarizes this section's thiol-reactive probes excited with visible light.

Alexa Fluor® Maleimides

Alexa Fluor® dyes set new standards for fluorescent dyes and the bioconjugates prepared from them (The Alexa Fluor® Dye Series—Note 1.1). Alexa Fluor® dyes exhibit several unique features:

- Strong absorption, with extinction coefficients greater than $65,000 \text{ cm}^{-1}\text{M}^{-1}$
- Excellent photostability (Figure 2.2.1, Figure 2.2.2), providing more time for observation and image capture than spectrally similar dyes allow (Figure 2.2.3)
- pH-insensitive fluorescence between pH 4 and pH 10
- Superior fluorescence output per protein conjugate, surpassing that of other spectrally similar fluorophore-labeled protein, including fluorescein, tetramethylrhodamine and Texas Red® conjugates, as well as Cy®3 and Cy®5 conjugates¹

Figure 2.2.3 Comparison of the photobleaching rates of the Alexa Fluor® 488 and Alexa Fluor® 546 dyes and the well-known fluorescein and Cy®3 fluorophores. The cytoskeleton of bovine pulmonary artery endothelial cells (BPAEC) was labeled with (top series) Alexa Fluor® 488 phalloidin (A12379) and mouse monoclonal anti- α -tubulin antibody (A11126) in combination with Alexa Fluor® 546 goat anti-mouse IgG antibody (A11003) or (bottom series) fluorescein phalloidin (F432) and the anti- α -tubulin antibody in combination with a commercially available Cy®3 goat anti-mouse IgG antibody. The pseudocolored images were taken at 30-second intervals (0, 30, 90 and 210 seconds of exposure from left to right). The images were acquired with bandpass filter sets appropriate for fluorescein and rhodamine.

For labeling thiol groups, we offer thiol-reactive Alexa Fluor® dyes that span the visible spectrum:

- Alexa Fluor® 350 C₅-maleimide (A30505, Section 2.3)
- Alexa Fluor® 488 C₅-maleimide (A10254, Figure 2.2.4)
- Alexa Fluor® 532 C₅-maleimide (A10255)
- Alexa Fluor® 546 C₅-maleimide (A10258)
- Alexa Fluor® 555 C₂ maleimide (A20346)
- Alexa Fluor® 568 C₅-maleimide (A20341)
- Alexa Fluor® 594 C₅-maleimide (A10256)
- Alexa Fluor® 633 C₅-maleimide (A20342)
- Alexa Fluor® 647 C₂-maleimide (A20347)
- Alexa Fluor® 660 C₂-maleimide (A20343)
- Alexa Fluor® 680 C₂-maleimide (A20344)
- Alexa Fluor® 750 C₅-maleimide (A30459)

* Absorption (Abs) and emission (Em) maxima, in nm. † Iodoacetate ester. ‡ Like the NBD probes, ABD-F (F6053) is a benz-2-oxa-1,3-diazole, except that it is sulfonated (i.e., an SBD probe) instead of nitrated (i.e., an NBD probe); its reaction product with dimethylaminoethanethiol has Abs/Em maxima of 376/510 nm. § Bifunctional crosslinker. 5 = 5-Isomer. 6 = 6-Isomer. M = Mixed isomers. C = BODIPY® FL L-cystine. T = TS-Link™ fluorescent thiosulfate. NA = Not applicable. More information on thiol-reactive dyes is available at www.invitrogen.com/handbook/labelingchemistry.

Figure 2.2.5 Normalized fluorescence emission spectra of goat anti-mouse IgG antibody conjugates of fluorescein (FL), tetramethylrhodamine (TMR) and the Texas Red® (TR) dyes, shown by dashed lines (---), as compared with goat anti-mouse IgG antibody conjugates of BODIPY® FL, BODIPY® TMR and BODIPY® TR dyes, respectively, shown by solid lines (—).

Figure 2.2.6 Comparison of the fluorophore orientation relative to the reactive moiety of two spectrally similar thiol-reactive BODIPY® dyes: A) BODIPY® 499/508 maleimide (D20350) and B) BODIPY® FL N-(2-aminoethyl)maleimide (B10250).

The Alexa Fluor® maleimides are particularly useful for labeling thiol-containing proteins on the surface of live cells, where their polarity permits the sensitive detection of exposed thiols.^{2–4} In proteomics applications, Alexa Fluor® protein conjugates can be electrophoretically separated and then detected without additional staining.^{5–7} As with their amine-reactive succinimidyl ester counterparts (Section 1.3), Alexa Fluor® 647 maleimide, Alexa Fluor® 750 maleimide and other long-wavelength reactive dyes are frequently used to make conjugates for *in vivo* imaging applications.^{8,9} In experiments using Alexa Fluor® 488 maleimide, immunodetection of labeled proteins can be accomplished using our anti-Alexa Fluor® 488 antibody (A11094, Section 7.4).

BODIPY® Derivatives

BODIPY® Iodoacetamides, Maleimides and Methyl Bromides

Like their amine-reactive BODIPY® counterparts (Section 1.4), BODIPY® iodoacetamides, BODIPY® maleimides and BODIPY® methyl bromides yield thiol adducts with several important properties:

- High extinction coefficients (EC >60,000 cm⁻¹M⁻¹)
- High fluorescence quantum yields, often approaching 1.0, even in water
- Narrow emission bandwidths (Figure 2.2.5)
- Good photostability¹⁰
- Spectra that are relatively insensitive to solvent polarity and pH of the medium¹¹
- Lack of ionic charge, which is especially useful when preparing membrane probes and cell-permeant reagents

BODIPY® dyes are chemically stable between about pH 3 and pH 10, although they are less stable to extremes of pH than are fluorescein and Alexa Fluor® derivatives. All of the thiol-reactive BODIPY® dyes are suitable for labeling cysteine residues in proteins and thiolated oligonucleotides and for detecting thiol conjugates separated by HPLC and capillary electrophoresis using ultrasensitive laser-scanning techniques.¹¹ BODIPY® FL iodoacetamide has been shown to be highly selective for cysteine labeling, producing little or no nonspecific labeling even at high dye:thiol ratios; in contrast, tetramethylrhodamine iodoacetamide exhibited nonspecific labeling as dye concentrations increased.¹² Furthermore, actin labeling with BODIPY® FL iodoacetamide (D6003) reportedly does not perturb actin polymerization.¹³ BODIPY® FL maleimide is a useful reagent for flow cytometric quantitation and confocal imaging of microparticles released upon agonist-elicited activation of human platelets.^{14,15} Labeling can be carried out after activation, avoiding concerns that pre-labeling might interfere with cellular functions involved in the activation process.

Our selection of thiol-reactive BODIPY® reagents includes:

- BODIPY® FL maleimide and BODIPY® FL iodoacetamide (B10250, Figure 2.2.6; D6003), which exhibit spectral characteristics very similar to fluorescein
- BODIPY® 507/545 iodoacetamide (D6004)
- BODIPY® TMR maleimide (B30466)
- BODIPY® 493/503 methyl bromide (B2103)
- BODIPY® 630/650 methyl bromide (B22802), with very long-wavelength spectra

Two additional symmetric maleimidylphenyl BODIPY® derivatives are available with excitation/emission maxima of ~499/508 nm (D20350, Figure 2.2.6) and ~577/618 nm (D20351).

BODIPY® FL L-Cystine

We have attached the BODIPY® FL fluorophore to the amino groups of the disulfide-linked amino acid cystine to create a reagent for reversible, *thiol-specific* labeling of proteins, thiolated oligonucleotides and cells.¹⁶ BODIPY® FL L-cystine (B20340) is virtually nonfluorescent due to interactions between the two fluorophores; however, thiol-specific exchange to form a mixed disulfide results in significant enhancement of the green fluorescence (Figure 2.2.7).

TS-Link™ BODIPY® Thiosulfate Reagents

The TS-Link™ BODIPY® reagents are water-soluble, fluorescent thiosulfates that react readily and selectively with free thiols to form disulfide bonds (Figure 2.2.8). In contrast to the thioether bonds formed by maleimides and iodoacetamides, the disulfide bond formed by the TS-Link™ reagents is reversible; the TS-Link™ BODIPY® fluorophore can easily be removed using a reducing agent such as dithiothreitol or tris-(2-carboxyethyl)phosphine (DTT, D1532; TCEP, T2556; Section 2.1), leaving the molecule of interest unchanged for downstream processing. These TS-Link™ reagents yield the same disulfide products as methanethiosulfonates (MTS reagents), but they are much more polar and water soluble and may therefore selectively react with residues on the surface of a protein or live cell.¹⁷

We currently offer:

- TS-Link™ BODIPY® FL C₂-thiosulfate (T30453)
- TS-Link™ BODIPY® TMR C₅-thiosulfate (T30454)
- TS-Link™ BODIPY® TR C₅-thiosulfate (T30455)
- TS-Link™ BODIPY® 630/650 C₅-thiosulfate (T30456)

We also offer TS-Link™ DSB-X™ biotin C₅-thiosulfate (TS-Link™ desthiobiotin-X C₅-thiosulfate, T30754), which is described in Section 4.2.

Fluorescein Derivatives, Including Thiol-Reactive Oregon Green® Dyes

Fluorescein Iodoacetamide, Maleimide and Methyl Bromide

The excellent water solubility of the fluorescein iodoacetamide single isomers (I30451, I30452) and fluorescein-5-maleimide (F150, Figure 2.2.9) at pH 7 makes it easy to prepare green-fluorescent thiol conjugates of biomolecules. Fluorescein maleimide and 5-iodoacetamidofluorescein have been the most extensively used visible wavelength-excitabile, thiol-reactive dyes for modifying proteins, nucleic acids and other biomolecules. Following conjugation to thiols, fluorescein-5-maleimide (and other fluoresceins) can be radioiodinated.¹⁸

When compared with these iodoacetamide and maleimide derivatives, 5-(bromomethyl)fluorescein (B1355, Figure 2.2.10) reacts more slowly with thiols of peptides, proteins and thiolated nucleic acids but forms stronger thioether bonds that are expected to remain stable under the conditions required for complete amino acid analysis. With the possible exception of our Alexa Fluor® maleimides and the thiol-reactive BODIPY® dyes described above, 5-(bromomethyl)fluorescein has the highest intrinsic detectability of all thiol-reactive probes, particularly for capillary electrophoresis instrumentation that uses the 488 nm spectral line of the argon-ion laser.¹⁹

Figure 2.2.8 Reaction of a TS-Link™ reagent (R¹) with a thiol (R²), followed by removal of the label with a reducing agent.

Figure 2.2.9 Fluorescein-5-maleimide (F150).

Figure 2.2.10 5-(bromomethyl)fluorescein (B1355).

Figure 2.2.7 Reaction of intramolecularly quenched BODIPY® FL L-cystine (B20340) with a thiol, yielding two fluorescent products—a mixed disulfide labeled with the BODIPY® FL dye and a BODIPY® FL cysteine derivative.

Oregon Green® 488 Iodoacetamide and Maleimide

The Oregon Green® 488 dye (2',7'-difluorofluorescein, D6145; Section 1.5) has absorption and emission spectra that are a perfect match to those of fluorescein. In addition to Oregon Green® 488 isothiocyanate, carboxylic acid and succinimidyl ester derivatives (Section 1.5), we have synthesized the isomeric mixture of Oregon Green® 488 iodoacetamide (O6010) and the single-isomer Oregon Green® 488 maleimide (O6034, Figure 2.2.11). These thiol-reactive probes yield conjugates that have several important advantages when directly compared with fluorescein conjugates, including:

- Greater photostability (Figure 2.2.12)
- A lower pK_a (pK_a of 4.8 for 2',7'-difluorofluorescein versus 6.4 for fluorescein) (Figure 2.2.13)
- Higher fluorescence and less quenching at comparable degrees of substitution (Figure 2.2.14)
- Utility as fluorescence anisotropy probes for measuring protein-protein and protein-nucleic acid interactions²⁰ (Fluorescence Polarization (FP)—Note 1.4)

Eosin Maleimide

As compared with the corresponding fluorescein derivative, eosin maleimide (E118, Figure 2.2.15) is less fluorescent but much more phosphorescent and a better photosensitizer.²¹ With eosin's high quantum yield of 0.57 for singlet oxygen generation,^{22–24} eosin conjugates can be used as effective photooxidizers of diaminobenzidine (DAB) in high-resolution electron microscopy studies²⁵ (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2).

Eosin (excitation/emission maxima ~519/540 nm) derivatives efficiently absorb the fluorescence from fluorescein and other fluorophores such as the BODIPY® FL, Alexa Fluor® 488, Oregon Green® 488, dansyl

and coumarin dyes, making them good acceptors in FRET techniques²⁶ (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2).

Although usually selectively reactive with thiols, eosin maleimide reportedly also reacts with a specific lysine residue of the band-3 protein in human erythrocytes, inhibiting anion exchange in these cells.^{27,28} A flow cytometry assay for hereditary spherocytosis (HS), characterized by band-3 protein-deficient erythrocytes, has been developed using this selective binding by eosin maleimide.^{29–31} In this assay, HS erythrocytes are identified as the population exhibiting low eosin fluorescence.

Rhodamine Derivatives, Including Thiol-Reactive Texas Red® Dyes

Tetramethylrhodamine Iodoacetamide and Maleimide

Tetramethylrhodamine iodoacetamide (TMRIA) and tetramethylrhodamine maleimide yield photostable, pH-insensitive, red-orange-fluorescent thiol conjugates.^{32,33} These iodoacetamide and maleimide derivatives, however, are difficult to prepare in pure form and different batches of our mixed-isomer products have contained variable mixtures of the 5- and 6-isomers. Moreover, certain cytoskeletal proteins

Figure 2.2.11 Oregon Green® 488 maleimide (O6034).

Figure 2.2.15 Eosin-5-maleimide (E118).

Figure 2.2.12 Comparison of photostability of green-fluorescent antibody conjugates. The following fluorescent goat anti-mouse IgG antibody conjugates were used to detect mouse anti-human IgG antibody labeling of human anti-nuclear antibodies in HEP-2 cells on prefixed test slides (INOVA Diagnostics Corp.): Oregon Green® 514 (O6383, ■), Alexa Fluor® 488 (A11001, ○), BODIPY® FL (B2752, △), Oregon Green® 488 (O6380, □) or fluorescein (F2761, ●). Samples were continuously illuminated and viewed on a fluorescence microscope using a fluorescein longpass filter set; images were acquired every 5 seconds. For each conjugate, three data sets, representing different fields of view, were averaged and then normalized to the same initial fluorescence intensity value to facilitate comparison.

Figure 2.2.13 Comparison of pH-dependent fluorescence of the Oregon Green® 488 (●), carboxyfluorescein (○) and Alexa Fluor® 488 (□) fluorophores. Fluorescence intensities were measured for equal concentrations of the three dyes using excitation/emission at 490/520 nm.

Figure 2.2.14 Comparison of relative fluorescence as a function of the number of fluorophores attached per protein for goat anti-mouse IgG antibody conjugates prepared using Oregon Green® 514 carboxylic acid succinimidyl ester (O6139, ■), Oregon Green® 488 carboxylic acid succinimidyl ester (O6147, ●), fluorescein-5-EX succinimidyl ester (F6130, ○) and fluorescein isothiocyanate (FITC, F143, F1906, F1907, □). Conjugate fluorescence is determined by measuring the fluorescence quantum yield of the conjugated dye relative to that of the free dye and multiplying by the number of fluorophores per protein.

preferentially react with individual isomers, leading to complications in the interpretation of labeling results.^{34–37} Consequently, we now prepare the 5-isomer of TMRIA (T6006, Figure 2.2.16) and the 5-isomer (T6027, Figure 2.2.17) and 6-isomer (T6028, Figure 2.2.18) of tetramethylrhodamine maleimide. A fluorogenic ADP biosensor has been described that exploits nucleotide-modulated self-quenching of two TMRIA labels that have been site-specifically attached to *Escherichia coli* ParM nucleotide-binding protein.³⁸ Tetramethylrhodamine-5-maleimide is often used for voltage-clamp fluorometry,³⁹ wherein it is attached to cysteine residues in the voltage-sensor domains of ion channels, generating fluorescence signals that are responsive to structural rearrangements associated with channel gating.^{40,41} In this context, the dye is sometimes referred to as TMRM, but it should not be confused with tetramethylrhodamine methyl ester (T668, Section 12.2), a structurally similar but functionally quite different dye that is identified by the same acronym.

Rhodamine-Based Crosslinking Reagent

The thiol-reactive, homobifunctional crosslinker bis-((*N*-iodoacetyl)piperazinyl)sulfonerhodamine (B10621, Figure 2.2.19) is derived from a relatively rigid rhodamine dye. It is similar to a thiol-reactive rhodamine-based crosslinking reagent used to label regulatory light-chains of chicken gizzard myosin for fluorescence polarization experiments.⁴² Researchers have attached bis-((*N*-iodoacetyl)piperazinyl)sulfonerhodamine to the kinesin motor domain and determined the orientation of kinesin bound to microtubules in the presence of a non-hydrolyzable ATP analog by fluorescence polarization microscopy.^{43,44} Images of single molecules of chicken calmodulin crosslinked

between two engineered cysteines by bis-((*N*-iodoacetyl)piperazinyl)sulfonerhodamine have been used to generate comparisons of experimental and theoretical super-resolution point-spread functions⁴⁵ (PSF). Dibromobimane (D1379, Section 2.3) is a shorter-wavelength alternative for applications requiring a fluorescent homobifunctional thiol crosslinker.

Rhodamine Red™ Maleimide

We offer a maleimide derivative of our Rhodamine Red™ fluorophore (R6029), which is spectrally similar to Lissamine rhodamine B (Figure 2.2.20). The spectral properties of Rhodamine Red™ maleimide have been exploited to improve the light-harvesting efficiency of chlorophyll by site-specific labeling of cysteine residues in the recombinantly expressed apoprotein in order to fill in the "green gap" in the absorption spectrum.⁴⁶ Rhodamine Red™ C₂-maleimide is a mixture of two isomeric sulfonamides (Figure 2.2.21).

Texas Red® Bromoacetamide and Maleimide

Conjugates of the bromoacetamide and maleimide derivatives of our Texas Red® fluorophore (T6009, T6008) have very little spectral overlap with fluorescein or Alexa Fluor® 488 conjugates (Figure 2.2.20) and are therefore useful as second labels in multicolor applications or as energy transfer acceptors from green-fluorescent dyes.^{47,48} Bromoacetamides are only slightly less reactive with thiols than are iodoacetamides. The Texas Red® bromoacetamide (Figure 2.2.22) and maleimide (Figure 2.2.23) derivatives are mixtures of the corresponding two isomeric sulfonamides.

Figure 2.2.29 Lucifer yellow iodoacetamide, dipotassium salt (L1338).

PyMPO Maleimide

PyMPO maleimide (M6026, Figure 2.2.24) is an environment-sensitive thiol-reactive dye with a fluorescence excitation peak near 415 nm and an unusually long Stokes shift (fluorescence emission peak at ~560–580 nm). Its most widespread application is for labeling cysteine residues in the voltage-sensor domains of ion channels, where its fluorescence is exquisitely sensitive to structural rearrangements associated with channel gating.^{40,49} This technique is commonly referred to as voltage-clamp fluorometry.³⁹

Benzoxadiazole Derivatives, Including NBD Probes

NBD Chloride and NBD Fluoride

NBD chloride (C20260, Figure 2.2.25) and the more reactive NBD fluoride (F486) are common reagents for amine modification (Section 1.8). They also react with thiols^{50–52} and cysteine in several proteins^{53–57} to yield thioethers. NBD conjugates of thiols usually have much shorter-wavelength absorption and weaker fluorescence than do NBD conjugates of amines.⁵² Selective modification of cysteines in the presence of reactive lysines and tyrosines is promoted by carrying out the reaction at pH < 7;^{58,59} however, NBD conjugates of thiols are often unstable, resulting in time-dependent label migration to adjacent lysine residues.^{52,59}

ABD-F

Thiol conjugates of 7-fluorobenz-2-oxa-1,3-diazole-4-sulfonamide^{60,61} (ABD-F, F6053; Figure 2.2.26) are much more stable in aqueous solution than are the thiol conjugates prepared from NBD chloride or NBD fluoride.⁶⁰ ABD-F is nonfluorescent until reacted with thiols and therefore can be used to quantitate thiols in solution,⁶² as well as thiols separated by HPLC⁶³ or TLC.⁶⁴ ABD-F also reportedly reacts slowly with the hydroxy group of some tyrosine residues as well as α -amino groups in some proteins, forming products that are nonfluorescent but can be detected by absorbance at 385 nm.⁶⁵ ABD-F labeling is blocked by zinc binding to protein thiols and can therefore be used as an inverse proportionality indicator of bound Zn^{2+} .^{66,67} In contrast, the fluorescent zinc indicators described in Section 19.7 primarily detect free Zn^{2+} ions. ABD-cysteine conjugates are very stable to acid hydrolysis, but labeling is partially reversed in basic solution containing DTT^{68,69} (D1532; Section 2.1).

IANBD Ester and IANBD Amide

When conjugating the NBD fluorophore to thiols located in hydrophobic sites of proteins, we recommend using the NBD iodoacetate ester (IANBD ester, I9; Figure 2.2.27) or, preferably, the more hydrolytically stable NBD iodoacetamide (IANBD amide, D2004; Figure 2.2.28). These reactive reagents exhibit appreciable fluorescence only after reaction with thiols that are buried or unsolvated, and this fluorescence is highly sensitive to changes in protein conformation and assembly of molecular complexes.^{70,71}

Lucifer Yellow Iodoacetamide

Lucifer yellow CH is a well-known polar tracer for neurons (Section 14.3). Its iodoacetamide derivative (L1338, Figure 2.2.29) similarly has high water solubility and visible absorption and emission spectra similar to those of lucifer yellow CH (Figure 2.2.30). As with the polar Alexa Fluor® maleimides and the stilbene iodoacetamide and maleimide (A484, A485; Section 2.3), a principal application of lucifer yellow iodoacetamide is the labeling of exposed thiols of proteins in solution, as well as in the outer membrane of live cells.⁷² Lucifer yellow iodoacetamide has also been used as a fluorescence energy acceptor from aequorin in bioluminescence resonance energy transfer (BRET) assays.⁷³

TC-FIAsH™ and TC-ReAsH™ Detection of Tetracysteine-Tagged Proteins

TC-FIAsH™ and TC-ReAsH™ Detection Technology

TC-FIAsH™ and TC-ReAsH™ detection technology, based on the tetracysteine tag first described by Griffin, Adams and Tsien in 1998,^{74,75} takes advantage of the high-affinity interaction of a biarsenical ligand (FIAsH-EDT₂ or ReAsH-EDT₂) with the thiols in a tetracysteine (TC) expression tag fused to the protein of interest. The FIAsH-EDT₂ ligand is essentially fluorescein that has been modified to contain two arsenic atoms at a set distance from each other, whereas the ReAsH-EDT₂ ligand is a similarly modified resorufin (Figure 2.2.31). Virtually nonfluorescent in the ethanedithiol (EDT)-bound state, these reagents become highly fluorescent when bound to the tetracysteine tag Cys-Cys-Xxx-Yyy-Cys-Cys, where Xxx-Yyy is typically Pro-Gly⁷⁶ (Figure 2.2.32). Modified tags with additional flanking sequences produce higher-affinity binding of the biarsenical ligand, resulting in improved signal-to-background characteristics.^{77,78} Background due to off-target endogenous thiols can be diminished by washing with competitor dithiols such as 2,3-dimercaptopropanol (BAL). Although tetracysteine tag labeling is best suited to reducing intracellular environments, protocols involving co-administration of trialkylphosphine or dithiothreitol (DTT, D1532; Section 2.1) reducing agents have been devised for applications in oxidizing environments, including cell surfaces.^{79,80} Photosensitized oxidation of diaminobenzidine (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2) by ReAsH enables correlated fluorescence and electron microscopy of tetracysteine-tagged proteins.^{80–82}

Figure 2.2.30 Absorption and fluorescence emission spectra of lucifer yellow CH in water.

Figure 2.2.31 The structures of A) FIAsH-EDT₂ ligand and B) ReAsH-EDT₂ ligand, which are biarsenical labeling reagents provided in the TC-FIAsH™ II and TC-ReAsH™ II In-Cell Tetracysteine Tag Detection Kits (T34561, T34562), respectively.

The six-amino acid tetracysteine tag is less likely to disrupt native protein structure and function than larger tags such as Green Fluorescent Protein⁸³ (GFP, 238 amino acids). Although the majority of TC-FIAsH™ and TC-ReAsH™ applications have been in mammalian cells (Figure 2.2.33), the reagents and associated methods are also particularly useful for nondisruptive labeling of viral coat proteins^{84–88} and successful adaptations for labeling proteins in yeast,⁸³ bacteria,^{89,90} *Dictyostelium discoideum*⁹¹ and plants⁹² have been described.

TC-FIAsH™ and TC-ReAsH™ Tetracysteine Tag Detection Kits

Transfecting the host cell line with an expression construct comprising the protein of interest fused to a tetracysteine tag (CCPGCC) is the first step into TC-FIAsH™ TC-ReAsH™ detection. The tagged protein is then detected by the addition of FIAsH-EDT₂ reagent or ReAsH-EDT₂ reagent, which generates green or red fluorescence, respectively, upon binding the tetracysteine motif. For detection of tetracysteine-tagged proteins expressed in cells, we offer the TC-FIAsH™ II and TC-ReAsH™ II In-Cell Tetracysteine Tag Detection Kits (T34561, T34562), which provide:

- FIAsH-EDT₂ or ReAsH-EDT₂ reagent (in Kit T34561 or T34562), respectively
- BAL wash buffer
- Detailed protocols

Figure 2.2.32 Binding of the nonfluorescent FIAsH-EDT₂ ligand to a recombinantly expressed tetracysteine sequence yields a highly fluorescent complex.

Figure 2.2.33 CHO-k1 cells expressing a tetracysteine-tagged version of β -tubulin labeled with FIAsH-EDT₂ reagent, provided in the TC-FIAsH™ II In-Cell Tetracysteine Tag Detection Kit (T34561). Upon treatment with vinblastine, a compound known to perturb cytoskeletal structure, tubulin drastically rearranges from A) a reticular structure to B) rod-shaped structures.

Figure 2.2.35 QSY* 7 C₅-maleimide (Q10257).

Figure 2.2.36 Normalized absorption spectra of the QSY* 35 (blue), QSY* 7 (red) and QSY* 21 (orange) dyes. The QSY* 7 and QSY* 9 dyes have essentially identical spectra.

Figure 2.2.37 4-dimethylaminophenylazophenyl-4'-maleimide (DABMI, D1521).

We also offer these TC-FlAsH™ and TC-ReAsH™ detection reagents bundled with Gateway expression vectors for use in cloning the tetracysteine-tagged protein fusion. The TC-FlAsH™ II TC-ReAsH™ II In-Cell Tetracysteine Tag Detection Kit (with mammalian TC-Tag Gateway expression vectors) (T34563) provides:

- FlAsH-EDT₂ and ReAsH-EDT₂ reagents
- BAL wash buffer
- pcDNA 6.2/cTC-Tag-DEST
- pcDNA 6.2/nTC-Tag-DEST
- pcDNA 6.2/nTC-Tag-p64 control plasmid
- Detailed protocols

In addition to these kits for in-cell detection, we offer the TC-FlAsH™ Expression Analysis Detection Kits (A10067, A10068; Section 9.4), which are designed for detecting tetracysteine-tagged proteins in polyacrylamide gels (Figure 2.2.34).

Chromophoric Maleimides and Iodoacetamides

QSY* Maleimides and Iodoacetamide

QSY* 7 C₅-maleimide⁹³ (Q10257, Figure 2.2.35) and QSY* 9 C₅-maleimide (Q30457) are nonfluorescent, thiol-reactive diarylrhodamines with absorption spectra similar to those of our QSY* 7 and QSY* 9 succinimidyl esters (Q10193, Q20131; Section 1.6; Figure 2.2.36), respectively. Although the QSY* 7 and QSY* 9 chromophores are spectrally similar, QSY* 9 dye exhibits enhanced water solubility. QSY* 35 iodoacetamide (Q20348) is a nonfluorescent thiol-reactive analog of the amine-reactive nitrobenzoxadiazole (NBD) dye.

The principal applications of these thiol-reactive QSY* derivatives are as nonfluorescent acceptor dyes in fluorescence resonance energy transfer (FRET) assays^{93–95} (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). The use of nonfluorescent acceptor dyes avoids the background fluorescence that often results from direct (i.e., nonsensitized) excitation of fluorescent acceptor dyes. The broad and strong absorption of QSY* 7 and QSY* 9 dyes (absorption maximum ~560 nm, EC ~90,000 cm⁻¹M⁻¹) yields extraordinarily efficient quenching of donors that have blue, green, orange or red fluorescence. QSY* 35 derivatives absorb light maximally near 470 nm (Figure 2.2.36), making their conjugates excellent FRET acceptors from UV light-excited donor dyes.

DABMI

DABMI (D1521, Figure 2.2.37) is the thiol-reactive analog of dabcyI succinimidyl ester (D2245, Section 1.8) and has similar properties and applications. Its principal application is as a nonfluorescent acceptor dye in fluorescence resonance energy transfer (FRET) assays^{96–98} (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). The donor dyes in these assays typically include IAEDANS (I14) and other dyes described in Section 2.3. DABMI is also a useful derivatization reagent for MALDI-MS fragmentation analysis of cysteine-containing peptides.⁹⁹

Figure 2.2.34 Protein gel staining using TC-FlAsH™ Expression Analysis Detection Kit (A10068). **A)** Tetracysteine-tagged proteins are labeled with FlAsH-EDT₂ reagent and fluoresce green. **B)** Total proteins are labeled with the Red total-protein stain provided in the kit and fluoresce red. **C)** An overlay of the two images reveals relative amounts of protein.

NANOGOLD® Monomaleimide

In collaboration with Nanoprobes, Inc. (www.nanoprobes.com), we offer thiol-reactive NANOGOLD® monomaleimide (N20345). NANOGOLD® particles are small metal cluster complexes of gold particles for research applications in light or electron microscopy.^{100,101} These cluster complexes are discrete chemical compounds, not gold colloids. NANOGOLD® monomaleimide (N20345) permits attachment of these very small (1.4 nm) yet uniformly sized gold particles to accessible thiol groups in biomolecules (Figure 2.2.38, Figure 2.2.39). NANOGOLD® monomaleimide, which is supplied as a set of five vials of a powder lyophilized from pH 7.5 HEPES buffer, is simply resuspended with the thiol-containing protein in deionized water at room temperature or below to form the conjugate, after which any excess NANOGOLD® monomaleimide is removed by gel filtration.^{102,103}

In addition to its many uses for light and electron microscopy, NANOGOLD® monomaleimide has been shown to be an extremely efficient quencher for dyes in molecular beacons—probes that can be used for homogeneous fluorescence *in situ* hybridization assays.¹⁰⁴ NANOGOLD® conjugates of antibodies and streptavidin are described in Section 7.2 and Section 7.6, respectively, along with reagents and methods for silver enhancement to amplify electron microscopy detection.¹⁰⁴

Figure 2.2.38 Reaction of NANOGOLD® monomaleimide (N20345) with a thiol. Image courtesy of Nanoprobes, Inc.

Notes

- Aqueous stock solutions should be used within 24 hours; long-term storage is NOT recommended.
- The fluorescence lifetime (τ) of the Alexa Fluor® 488 dye in pH 7.4 buffer at 20°C is 4.1 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
- Abs and Em of the Alexa Fluor® 488 dye are red-shifted by as much as 16 nm and 25 nm respectively on microarrays relative to aqueous solution values. The magnitude of the spectral shift depends on the array substrate material. (Biotechniques (2005) 38:127)
- The fluorescence lifetime (τ) of the Alexa Fluor® 594 dye in pH 7.4 buffer at 20°C is 3.9 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
- The fluorescence lifetime (τ) of the Alexa Fluor® 568 dye in pH 7.4 buffer at 20°C is 3.6 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
- The fluorescence lifetime (τ) of the Alexa Fluor® 660 dye in pH 7.5 buffer at 20°C is 1.2 nanoseconds. Data provided by Pierre-Alain Muller, Max Planck Institute for Biophysical Chemistry, Göttingen.
- The fluorescence lifetime (τ) of the Alexa Fluor® 680 dye in pH 7.5 buffer at 20°C is 1.2 nanoseconds. Data provided by Pierre-Alain Muller, Max Planck Institute for Biophysical Chemistry, Göttingen.
- The fluorescence lifetime (τ) of the Alexa Fluor® 647 dye in H₂O at 20°C is 1.0 nanoseconds and 1.5 nanoseconds in EtOH. (Bioconjug Chem (2003) 14:195)
- Absorption and fluorescence of fluorescein derivatives are pH dependent. Extinction coefficients and fluorescence quantum yields decrease markedly at pH <7.
- B2103 spectra are for the unreacted reagent. The thiol adduct has Abs = 493 nm, Em = 503 nm in MeOH.
- The absorption and fluorescence spectra of BODIPY® derivatives are relatively insensitive to the solvent.
- Iodoacetamides in solution undergo rapid photodecomposition to unreactive products. Minimize exposure to light prior to reaction.
- Fluorescence emission of B20340 is relatively weak until the disulfide linkage between its two BODIPY® FL fluorophores is reductively cleaved.
- B22802 spectral data are for the unreacted reagent. The thiol adduct has Abs = 629 nm, Em = 647 nm in dichloromethane (CH₂Cl₂).
- Spectra of 2-mercaptoethanol adduct of NBD chloride in MeOH: Abs = 425 nm (EC = 13,000 cm⁻¹M⁻¹), Em = 520 nm. NBD fluoride yields the same derivatives as NBD chloride but is more reactive.
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- Spectral data of the 2-mercaptoethanol adduct.
- Spectral data are for the unreacted reagent and are essentially unchanged upon reaction with thiols.
- Eosin and erythrosin derivatives also exhibit phosphorescence with an emission maximum at ~680 nm. The phosphorescence lifetime is ~1 millisecond for eosin and 0.5 milliseconds for erythrosin. (Biochem J (1979) 183:561, Spectroscopy (1990) 5:20) Fluorescence lifetimes (τ) are 1.4 nanoseconds (QY = 0.2) for eosin and 0.1 nanoseconds (QY = 0.02) for erythrosin. (J Am Chem Soc (1977) 99:4306)
- QY increases on reaction with thiols; Abs, EC and Em are essentially unchanged. (Anal Biochem (2001) 295:101)
- F6053 reaction product with dimethylaminoethanethiol has Abs = 376 nm (EC ~8000 cm⁻¹M⁻¹), Em ~510 nm in MeOH.
- Fluorescence emission spectrum shifts to shorter wavelengths in nonpolar solvents.
- Absorption and fluorescence of Oregon Green® 488 derivatives are pH dependent only in moderately acidic solutions (pH <5).

DATA TABLE 2.2 THIOL-REACTIVE PROBES EXCITED WITH VISIBLE LIGHT—continued

24. The fluorescence lifetime (τ) of the Alexa Fluor® 750 dye in H₂O at 22°C is 0.7 nanoseconds. Data provided by ISS Inc. (Champaign, IL).
25. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
26. Data for T34561 represents FIAsh complexed with the tetracysteine peptide FLNCCPGCCMEP. (Nat Biotechnol (2005) 23:1308, Nat Protoc (2008) 3:1527) The FIAsh-EDT₂ reagent is essentially nonfluorescent and has Abs = 496 nm (EC = 69,500 cm⁻¹M⁻¹) in 0.1 M NaOH. (Nat Protoc (2008) 3:1527)
27. Data for T34562 represents ReAsH complexed with the tetracysteine peptide FLNCCPGCCMEP. (Nat Biotechnol (2005) 23:1308, Nat Protoc (2008) 3:1527) The ReAsH-EDT₂ reagent is essentially nonfluorescent and has Abs = 579 nm (EC = 63,000 cm⁻¹M⁻¹) in 0.1 M NaOH. (Nat Protoc (2008) 3:1527)

PRODUCT LIST 2.2 THIOL-REACTIVE PROBES EXCITED WITH VISIBLE LIGHT

Cat. No.	Product	Quantity
A10254	Alexa Fluor® 488 C ₅ -maleimide	1 mg

2.3 Thiol-Reactive Probes Excited with Ultraviolet Light

Figure 2.3.1 Alexa Fluor® 350 C₅-maleimide (A30505).

Figure 2.3.2 Fluorescence excitation and emission spectra of Alexa Fluor® 350 goat anti-mouse IgG antibody in pH 8.0 buffer.

Figure 2.3.3 Absorption and fluorescence emission spectra of 7-amino-4-methylcoumarin in pH 7.0 buffer.

Figure 2.3.4 Pacific Blue™ C₅-maleimide (P30506).

The thiol-reactive dyes described in this section have their longest-wavelength absorption peaks at less than 410 nm (Table 2.2). Typically, these dyes exhibit blue fluorescence and have much weaker absorption than the dyes described in Section 2.2, with extinction coefficients often below 20,000 cm⁻¹M⁻¹.

The strong environmental dependence of the emission spectra and quantum yields of several of the dyes—especially the coumarin, benzoxadiazole (NBD probes and ABD-F, Section 2.2), aminonaphthalene (e.g., dansyl) and Dapoxyl® fluorophores—makes some of these thiol-reactive probes useful for investigating protein structure and assembly, following protein transport through membranes and studying ligand binding to receptors.¹

Coumarin Derivatives

Alexa Fluor® 350 Maleimide

Alexa Fluor® 350 C₅-maleimide (A30505), a thiol-reactive, sulfonated coumarin derivative (Figure 2.3.1), produces protein conjugates that are optimally excited at 346 nm and have bright blue fluorescence emission (Figure 2.3.2) at wavelengths slightly shorter than AMCA or AMCA-X conjugates (Figure 2.3.3) (emission maximum ~442 nm versus 448 nm). The shorter emission maximum of Alexa Fluor® 350 conjugates reduces their spectral overlap with the emission of fluorescein and Oregon Green® 488 dyes.² Like our other Alexa Fluor® dyes, Alexa Fluor® 350 C₅-maleimide offers unrivaled brightness and pH-independent fluorescence, as well as water solubility and a low degree of quenching upon conjugation (Section 1.3).

Pacific Blue™ Maleimide

The Pacific Blue™ dye, which is based on the 6,8-difluoro-7-hydroxycoumarin fluorophore (Figure 2.3.4), exhibits bright blue fluorescence, with excitation/emission maxima of ~410/455 nm. Significantly, the pK_a value of this 6,8-difluoro-7-hydroxycoumarin derivative is 2–3 log units lower than that of the corresponding 7-hydroxycoumarin. Thus, the thiol-reactive

Table 2.2 Molecular Probes® thiol-reactive dyes excited with ultraviolet light.

* Approximate absorption (Abs) and emission (Em) maxima, in nm, for the reagent (if fluorescent) or the fluorescent thiol adduct. † Environment-sensitive fluorophore. ‡ Very weakly fluorescent until reacted with thiols. NA = Not applicable. More information on thiol-reactive dyes is available at www.invitrogen.com/handbook/labelingchemistry.

Pacific Blue™ C₅-maleimide (P30506) yields conjugates that are strongly fluorescent, even at neutral pH. In addition, Pacific Blue™ conjugates are efficiently excited by the 405 nm spectral line of the violet diode laser developed for fluorescence microscopy and flow cytometry.³

Other Coumarin Maleimides and Iodoacetamides

We offer several blue-fluorescent thiol-reactive dialkylcoumarins (Table 2.2), including 7-diethylamino-3-(4'-maleimidylphenyl)-4-methylcoumarin (CPM, D346; Figure 2.3.5) and *N*-(7-dimethylamino-4-methylcoumarin-3-yl)maleimide (DACM, D10251) and the corresponding iodoacetamides DCIA (D404) and DACIA (D10252). The dialkylcoumarin fluorophore is an excellent fluorescence resonance energy acceptor from tryptophan and a good donor to fluorescein, NBD, Alexa Fluor® 488 dye, Green Fluorescent Protein (GFP) and the nonfluorescent QSY® 7, QSY® 9 and QSY® 35 quenchers, making these thiol-reactive coumarins especially valuable for studying protein structure and for detecting protein-membrane interactions.^{4–6} Fluorescence emission of the dialkylcoumarin conjugates is moderately sensitive to environment.

Unlike MDCC (described below), which is intrinsically fluorescent, the maleimides CPM and DACM are essentially nonfluorescent until they react with thiols, permitting thiol quantitation without a separation step.^{7,8} The environment-sensitive fluorescence of CPM is also a useful indicator of protein folding in thermal-shift assays of ligand- and mutagenesis-dependent protein stability⁹ (Monitoring Protein-Folding Processes with Environment-Sensitive Dyes—Note 9.1).

We also offer 7-diethylamino-3-(((2-maleimidyl)ethyl)amino)carbonyl)coumarin (MDCC, D10253; Figure 2.3.6). When conjugated to a mutant phosphate-binding protein, MDCC has proven useful for direct, real-time measurement of inorganic phosphate release during enzymatic reactions.^{10,11} Similarly, environment-sensitive fluorescence of MDCC site-specifically attached to *Escherichia coli* ParM nucleotide-binding protein provides the basis for a fluorogenic ADP biosensor.¹²

Figure 2.3.5 7-diethylamino-3-(4'-maleimidylphenyl)-4-methylcoumarin (CPM, D346).

Figure 2.3.6 7-diethylamino-3-(((2-maleimidyl)ethyl)amino)carbonyl)coumarin (MDCC, D10253).

Figure 2.3.7 *N*-(1-pyrene)maleimide (P28).

Figure 2.3.8 Excimer formation by pyrene in ethanol. Spectra are normalized to the 371.5 nm peak of the monomer. All spectra are essentially identical below 400 nm after normalization. Spectra are as follows: 1) 2 mM pyrene, purged with argon to remove oxygen; 2) 2 mM pyrene, air-equilibrated; 3) 0.5 mM pyrene (argon-purged); and 4) 2 μM pyrene (argon-purged). The monomer-to-excimer ratio (371.5 nm/470 nm) is dependent on both pyrene concentration and the excited-state lifetime, which is variable because of quenching by oxygen.

Figure 2.3.9 *N*-(1-pyrene)iodoacetamide (P29).

Figure 2.3.10 *N*-(1-pyrenemethyl)iodoacetamide (PMIA amide, P2007MP).

Pacific Orange™ Maleimide

The thiol-reactive Pacific Orange™ C₅-maleimide (P30507) yields conjugates with excitation/emission maxima of ~400/551 nm, making it ideal for use with violet diode laser-equipped flow cytometers and fluorescence microscopes. Moreover, Pacific Blue™ conjugates (described above with the other coumarins) and Pacific Orange™ conjugates are both excited with the 405 nm spectral line of the violet diode laser and emit at 455 and 551 nm, respectively, facilitating two-color analysis using 405 nm excitation and multiparameter analysis using the other flow cytometer channels.³

Pyrene Derivatives

Pyrene Maleimide

Not only is *N*-(1-pyrene)maleimide (pyrene maleimide, P28; Figure 2.3.7) essentially nonfluorescent until it has reacted with thiols, but once excited, pyrene-thiol conjugates can interact to form excited-state dimers (excimers) that emit at longer wavelengths than the excited monomeric fluorophore. Pyrene maleimide conjugates often have very long fluorescence lifetimes (>100 nanoseconds), giving proximal pyrene rings within 6–10 Å of each other ample time to form the spectrally altered excimer (Figure 2.3.8). The excimer-forming capacity of pyrene maleimide can be exploited for detection of conformational changes¹³ and subunit assembly¹⁴ of proteins and for analysis of protease activity.¹⁵

Pyrene Iodoacetamides

Fluorescence of the actin monomer labeled with pyrene iodoacetamide (P29, Figure 2.3.9) has been demonstrated to change upon polymerization, making this probe a widely utilized tool for following the kinetics

Figure 2.3.11 6-acryloyl-2-dimethylaminonaphthalene (acrylodan, A433).

Figure 2.3.12 6-bromoacetyl-2-dimethylaminonaphthalene (badan, B6057).

Figure 2.3.13 Fluorescence emission spectra of the 2-mercaptoethanol adduct of badan (B6057) in: 1) toluene, 2) chloroform, 3) acetonitrile, 4) ethanol, 5) methanol and 6) water. Each solution contains the same concentration of the adduct. Excitation of all samples is at 380 nm.

Figure 2.3.14 Ribbon representation of the ADIFAB free fatty acid indicator (A3880). In the left-hand image, the fatty acid binding site of intestinal fatty acid-binding protein (yellow) is occupied by a covalently attached acrylodan fluorophore (blue). In the right-hand image, a fatty acid molecule (gray) binds to the protein, displacing the fluorophore (green) and producing a shift of its fluorescence emission spectrum. Image contributed by Alan Kleinfeld, FFA Sciences LLC, San Diego.

Figure 2.3.15 2-(4'-(iodoacetamido)anilino)naphthalene-6-sulfonic acid, sodium salt (IAANS, I7).

of actin polymerization.^{16–19} Conjugates of *N*-(1-pyrenemethyl)iodoacetamide (P2007MP, Figure 2.3.10) have the longest excited-state fluorescence lifetimes (>100 nanoseconds) of all reported thiol-reactive probes. Excimer formation can also be a useful indicator of protein folding.²⁰

Naphthalene Derivatives

Acrylodan and Badan

As compared with iodoacetamides or maleimides, acrylodan (A433, Figure 2.3.11) and 6-bromoacetyl-2-dimethylaminonaphthalene (badan, B6057, Figure 2.3.12) generally react with thiols more slowly but they form very strong thioether bonds that are expected to remain stable under conditions required for complete amino acid analysis. The fluorescence emission peak and intensity of these adducts (Figure 2.3.13) are particularly sensitive to conformational changes or ligand binding, making these dyes some of the most useful thiol-reactive probes for protein structure studies.^{21–23} For example, the acrylodan conjugate of an intestinal fatty acid-binding protein, ADIFAB (A3880, Section 17.4), is a sensor for free fatty acids²⁴ (Figure 2.3.14).

IAANS and MIANS

To develop appreciable fluorescence, both the reactive anilino-naphthalenesulfonate iodoacetamide (IAANS, I7; Figure 2.3.15) and maleimide (MIANS, also called Mal-ANS; M8, Figure 2.3.16) must be reacted with thiols that are located in hydrophobic sites. Often, however, buried unsolvated thiol residues are exceptionally reactive, allowing these sites to be selectively modified by these reagents. The environment-sensitive fluorescence properties of the protein conjugates of MIANS and IAANS are similar to those of the structurally related probes 1,8-ANS and 2,6-TNS (A47, T53; Section 13.5). The fluorescence intensity, and to a lesser extent, the emission wavelengths of the conjugates, tend to be very sensitive to substrate binding and folding and unfolding of the protein, as well as the association of the labeled protein with other proteins, membranes or nucleic acids.^{25,26}

IAEDANS

The fluorescence of IAEDANS (I14, Figure 2.3.17) is quite dependent upon environment,²⁷ although less so than that of IAANS and MIANS conjugates. Its conjugates frequently respond to ligand binding by undergoing spectral shifts and changes in fluorescence intensity that are determined by the degree of aqueous solvation. Advantages of this reagent include high water solubility above pH 4 and a relatively long fluorescence lifetime (sometimes >20 nanoseconds, although commonly 10–15 nanoseconds), making the conjugates useful for fluorescence polarization assays^{28,29} (Fluorescence Polarization (FP)—Note 1.4). The emission spectrum of IAEDANS overlaps well with the absorption of fluorescein, Alexa Fluor® 488 and Oregon Green® 488 dyes, as well as that of Green Fluorescent Protein (GFP). IAEDANS is an excellent reagent for fluorescence resonance energy transfer (FRET) measurements^{30–32} (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). IAEDANS usually reacts with thiols; however, it has been reported to react with a lysine residue in tropomyosin.³³

Bimanes for Thiol Derivatization

Monobromobimane and Monochlorobimane

Monobromobimane (M1378, M20381; Figure 2.3.18), which is essentially nonfluorescent until conjugated, readily reacts with low molecular weight thiols,³⁴ including glutathione.³⁵ This reagent, originally described by Kosower and colleagues,^{36,37} is also useful for detecting the distribution

Figure 2.3.16 2-(4'-(maleimidyl)anilino)naphthalene-6-sulfonic acid, sodium salt (MIANS, M8).

Figure 2.3.17 5-(((2-iodoacetyl)amino)ethyl)amino)naphthalene-1-sulfonic acid (1,5-IAEDANS), I14.

of protein thiols in cells before and after chemical reduction of disulfides.³⁸ Monobromobimane is reportedly susceptible to inactivation by the disulfide reducing agent TCEP³⁹ (T2556, Section 2.1). Both monobromobimane and the more thiol-selective monochlorobimane (M1381MP) have been extensively used for detecting glutathione in live cells^{40,41} (Section 15.6).

Dibromobimane

Dibromobimane (D1379, Figure 2.3.19) is an interesting homobifunctional crosslinking reagent for proteins^{42–44} because it is unlikely to fluoresce until *both* of its alkylating groups have reacted. It has been used to crosslink thiols in myosin,⁴⁵ *Escherichia coli* lactose permease⁴⁶ and P-glycoprotein.⁴⁷ Despite its short length, dibromobimane is also an effective intermolecular crosslinker in some cases.⁴⁸

Bimane Iodoacetamide and Maleimide

Bimane iodoacetamide (B30500, Figure 2.3.20) and bimane C₃-maleimide (B30501, Figure 2.3.21) are blue-fluorescent thiol-reactive fluorophores with excitation/emission maxima of ~375/456 nm. The small size of the bimane fluorophore reduces the likelihood that the label will interfere with the function of the biomolecule, an important advantage for site-selective probes.

Polar Reagents for Determining Thiol Accessibility

Like IAEDANS (I14), the iodoacetamide and maleimide derivatives of stilbene (A484, A485) have high water solubility and are readily conjugated to thiols. Their combination of high polarity and membrane impermeability makes these polysulfonated dyes useful for determining whether thiol-containing proteins and polypeptide chains are exposed at the extracellular or cytoplasmic membrane surface.

The sulfonated stilbene iodoacetamide (A484, Figure 2.3.22) was used to label single-cysteine mutants of staphylococcal α -hemolysin in order to determine structural changes that occur during oligomerization and pore formation⁴⁹ and of the lipid-binding region of *E. coli* pyruvate oxidase in order to detect conformational changes upon substrate binding.⁵⁰ Similarly, single-cysteine mutants of *Escherichia coli* Na⁺-glutamate transporter GHS have been probed with the sulfonated stilbene maleimide (A485, Figure 2.3.23) to systematically study the topology of this membrane protein.⁵¹

1,10-Phenanthroline Iodoacetamide for Preparing Metal-Binding Conjugates

Conjugation of *N*-(1,10-phenanthrolin-5-yl)iodoacetamide (P6879, Figure 2.3.24) to thiol-containing ligands confers the metal-binding properties of this important complexing agent on the ligand. For example, the covalent copper–phenanthroline complex of oligonucleotides or nucleic acid–binding molecules in combination with hydrogen peroxide acts as a chemical nuclease to selectively cleave DNA or RNA.^{52,53}

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Fluorescence of unconjugated A433 is weak, increasing markedly upon reaction with thiols. Em (QY) for the 2-mercaptoethanol adduct are: 540 nm (0.18) in H₂O, 513 nm (0.57) in MeOH, 502 nm (0.79) in EtOH, 468 nm (0.78) in MeCN, 435 nm (0.83) in dioxane. (*J Biol Chem* (1983) 258:7541)
- Spectral data of the 2-mercaptoethanol adduct.
- Iodoacetamides in solution undergo rapid photodecomposition to unreactive products. Minimize exposure to light prior to reaction.
- Aqueous stock solutions should be used within 24 hours; long-term storage is NOT recommended.
- Em for 2-mercaptoethanol adduct of B6057: 550 nm in H₂O (pH 7), 523 nm in MeOH, 514 nm in EtOH, 502 nm in MeCN, 469 nm in CHCl₃, 457 nm in dioxane, 445 nm in toluene. Abs is relatively independent of solvent.
- Spectral data are for the 2-mercaptoethanol adduct. The unreacted reagent is nonfluorescent, Abs = 384 nm (EC = 32,000 cm⁻¹M⁻¹) in MeOH.
- Bimanes are almost nonfluorescent until reacted with thiols. For monobromobimane conjugated to glutathione, Abs = 394 nm, Em = 490 nm (QY ~0.1–0.3) in pH 8 buffer. (*Methods Enzymol* (1987) 143:76, *Methods Enzymol* (1995) 251:133)
- Spectral data are for the 2-mercaptoethanol adduct. The unreacted reagent is nonfluorescent, Abs = 381 nm (EC = 27,000 cm⁻¹M⁻¹) in MeOH.
- QY increases on reaction with thiols; Abs, EC and Em are unchanged. (*J Chem Soc Perkin Trans I* (1994) 2975)
- The 2-mercaptoethanol adduct of I14 has essentially similar spectral characteristics in aqueous solution. (*Biochemistry* (1973) 12:4154) Fluorescence lifetime (τ) = 21 nsec when conjugated to myosin subfragment-1. (*Biochemistry* (1973) 12:2250)
- Spectral data are for the 2-mercaptoethanol adduct. The unreacted reagent is nonfluorescent, Abs = 443 nm (EC = 13,000 cm⁻¹M⁻¹) in MeOH.
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- Fluorescence of unreacted P28 is weak. Em data represent the 2-mercaptoethanol adduct.
- Pyrene derivatives exhibit structured spectra. The absorption maximum is usually about 340 nm with a subsidiary peak at about 325 nm. There are also strong absorption peaks below 300 nm. The emission maximum is usually about 376 nm with a subsidiary peak at 396 nm. Excimer emission at about 470 nm may be observed at high concentrations.
- The fluorescence quantum yield of Pacific Blue™ dye in 50 mM potassium phosphate, 150 mM NaCl, pH 7.2, at 22°C is 0.78.

PRODUCT LIST 2.3 THIOL-REACTIVE PROBES EXCITED WITH ULTRAVIOLET LIGHT

Cat. No.	Product	Quantity
A484	4-acetamido-4'-((iodoacetyl)amino)stilbene-2,2'-disulfonic acid, disodium salt	25 mg
A485	4-acetamido-4'-maleimidylstilbene-2,2'-disulfonic acid, disodium salt	25 mg
A433	6-acryloyl-2-dimethylaminonaphthalene (acrylodan)	25 mg

3.1 Click Chemistry

Principles of Bioorthogonal Labeling and Click Chemistry

The amine- and thiol-reactive labeling chemistries described in Chapter 1 and Chapter 2 are generally used in one of two ways: (1) labeling of purified proteins or other biopolymers yielding conjugates that are subsequently applied to cell or tissue specimens, or (2) non-selective *in situ* labeling of total cellular thiol or amine content. *In situ* labeling of specific molecular populations—such as proteins and nucleic acids that have been newly synthesized in some experimental time window of interest—is not feasible due to the ubiquitous distribution of amines and thiols in cells, as well as in the media in which they are maintained. Click-iT® labeling technology overcomes this obstacle

by employing bioorthogonal reactive chemistry, in which the reaction partners have no endogenous representation in biological molecules, cells, tissues or model organisms.¹⁻³ In addition to reaction selectivity, *in situ* labeling methods should allow reactivity under mild conditions and in predominantly aqueous solvent conditions.

Although several known chemistries fulfill the requirements described above,^{1,3} Click-iT® labeling technology is founded upon one of the most successful and versatile bioorthogonal labeling reactions currently available—the copper-catalyzed azide-alkyne cycloaddition^{4,5} (Figure 3.1.1). Application of this reaction to *in situ* labeling of cells

Figure 3.1.1 Click-iT® copper-catalyzed azide-alkyne cycloaddition chemistry applied to detection of **A)** nucleic acids, **B)** proteins, **C)** carbohydrates and **D)** lipids. The reaction partners are **A)** 5-ethynyl-2'-deoxyuridine (EdU) and Alexa Fluor® 488 azide, **B)** L-homopropargylglycine (HPG) and Alexa Fluor® 488 azide, **C)** N-azidoacetylgalactosamine and Alexa Fluor® 488 alkyne and **D)** 15-azidopentadecanoic acid and Alexa Fluor® 488 alkyne (D). In each case, the left-hand partner is a metabolic precursor that can be incorporated into proteins and nucleic acids via *de novo* synthesis or post-translational modification pathways.

is a two-step process. First, one reaction partner—either an azide or alkyne linked to a “building block” such as a nucleotide, nucleoside, amino acid, monosaccharide or fatty acid—is biosynthetically incorporated. Subsequently, the other reaction partner—the complementary alkyne or azide linked to a fluorescent dye, biotin or other detection reagent—is “clicked” into place in the presence of catalytic copper (I). One reaction partner must be an azide derivative and the other an alkyne derivative, but either functional moiety can serve as the biosynthetically incorporated molecule or the detection molecule⁶ (e.g., L-azidohomoalanine (AHA) + Alexa Fluor® 488 alkyne is the inverse of the reaction scheme shown in Figure 3.1.1B).

Another important aspect of the azide and alkyne reaction partners is their small size (Figure 3.1.2). Expression tags such as Green Fluorescent Protein (GFP) provide the ultimate in labeling specificity because their linkage to proteins of interest is genetically prescribed. Once the GFP transgene has been inserted into a cell (BacMam Gene Delivery

and Expression Technology—Note 11.1), *in situ* labeling is obtained without any outside intervention using the cellular transcription and translation machinery. However, the finite size of GFP (~27,000 daltons) sometimes causes functional perturbations and has spurred the development of alternative, smaller-sized expression tags such as the TC-FLAsH™ tetracycline tag and biarsenical ligand system (T34561, T34562, T34563; Section 2.2). Furthermore, nucleic acids, lipids, glycans and post-translational protein modifications can only be detected indirectly by genetically encoded protein reporters. The small size of alkyne and azide tags allows the biosynthetic building blocks to which they are attached to be processed by enzymes, such as nucleotide polymerases and aminoacyl tRNA synthetases, that have poor tolerance for substrates with larger modifications such as fluorescent organic dyes.⁷

The 1,2,3-triazole linkage between the azide and alkyne reaction partners (Figure 3.1.1) is extremely stable. It is not susceptible to hydrolysis, oxidation or reduction, and it survives ionization in mass

Figure 3.1.2 Relative size of detection molecules commonly used in cellular analysis. Because the azide and alkyne moieties can be used interchangeably to optimize labeling configurations, R₁ can be either the biomolecule of interest or the detection reagent. For biotin and Alexa Fluor® 488, R₂ represents the biomolecule of interest.

Table 3.1 Molecular Probes® azide and alkyne derivatives.

Compound or Fluorophore	Azide or Alkyne	Cat. No.	Application
Azide- or Alkyne-Modified Biomolecules for Metabolic or Enzymatic Labeling			
Click-iT® AHA (L-azidohomoalanine)	azide	C10102	Monitor nascent protein synthesis or inhibition
Click-iT® HPG (L-homopropargylglycine)	alkyne	C10186	
Click-iT® farnesyl alcohol, azide	azide	C10248	Identification of isoprenylated proteins

spectrometry (MS) analysis. The reaction is also regioselective, yielding exclusively 1,4-disubstituted-1,2,3-triazole linkages (Figure 3.1.1). The copper (I) catalyst is both an essential feature of the reaction and its most problematic aspect in terms of applications.^{1,3,8} Without the copper (I) catalyst, which accelerates the rate of the reaction by a factor of $>10^6$, the reaction is impractically slow. For convenience, copper (I) is usually prepared *in situ* by reduction of extraneously added copper (II) using ascorbate or TCEP (T2556, Section 2.1). Insufficient reductive capacity can result in attenuation of *in situ* reactions in highly oxidizing environments.⁹ Copper is cytotoxic, due at least in part to its capacity for sensitizing oxidative damage to proteins and nucleic acids, and limiting applications of the azide-alkyne cycloaddition reaction in live cells. Copper/ascorbate treatment also causes extinction of R-phycoerythrin (R-PE) and GFP fluorescence.¹⁰ An excellent analysis of these considerations, together with a list of practical recommendations for their management with respect to bioconjugation applications of copper-catalyzed azide-alkyne cycloaddition chemistry, has been published by Finn and co-workers.⁸ Our Click-iT[®] product portfolio, consisting of individual azide and alkyne labeling reagents and application-specific kits, is described in detail below.

Click-iT[®] Azide and Alkyne Labeling Reagents

Although *in situ* labeling of biomolecules for cytochemical and proteomic analysis is perhaps the most notable application of Click-iT[®] technology, it is by no means the only one. This specific and direct labeling methodology can also be applied to bioconjugate preparation,⁸ surface and particle functionalization and molecular ligations. Our Click-iT[®] azide and alkyne labeling reagents support these applications and also provide foundational tools for developing new *in situ* labeling applications (Table 3.1).

Azide- and Alkyne-Derivatized Dyes and Biotinylation Reagents

We offer a rich selection of azide- and alkyne-derivatized fluorescent dyes for coupling to complementary azide- and alkyne-functionalized biomolecules:

- Alexa Fluor[®] 488 azide (A10266, Figure 3.1.1) and alkyne (A10267, Figure 3.1.1)
- Alexa Fluor[®] 555 azide (A20012) and alkyne (A20013)
- Alexa Fluor[®] 594 azide (A10270) and alkyne (A10275)
- Alexa Fluor[®] 647 azide (A10277) and alkyne (A10278)
- Oregon Green[®] 488 azide (O10180) and alkyne (O10181)
- Tetramethylrhodamine (TAMRA) azide (T10182) and alkyne (T10183)
- Biotin azide (B10184, Figure 3.1.3) and alkyne (B10185, Figure 3.1.4)

Antibodies to Oregon Green[®] 488, tetramethylrhodamine and Alexa Fluor[®] 488 dyes (Section 7.4) and Tyramide Signal Amplification (TSA[™]) Kits (Section 6.2) are available to provide signal amplification if necessary.¹¹ The biotin azide and alkyne reagents facilitate western blotting applications and streptavidin enrichment in combination with our streptavidin or CaptAvidin[™] agarose^{12–14} (S951, C21386; Section 7.6).

Azide- and Alkyne-Modified Nucleosides and Amino Acids

We offer the following azide- and alkyne-modified nucleosides and amino acids for Click-iT[®] labeling protocols:

- 5-ethynyl uridine (EU, E10345)
- 5-ethynyl-2'-deoxyuridine (EdU; A10044, E10187, E10415; Figure 3.1.1A)
- Click-iT[®] AHA (L-azidohomoalanine for nascent protein synthesis, C10102)
- Click-iT[®] HPG (L-homopropargylglycine for nascent protein synthesis, C10186; Figure 3.1.1B)

The alkyne-modified nucleosides EdU and EU form the basis of our Click-iT[®] cell proliferation and nascent RNA assays described below. The individual packaging of these reagents provide the larger quantities required for *in vivo* labeling applications.^{6,15} AHA and HPG are methionine surrogates providing nonradioactive alternatives to ³⁵S-methionine for pulse-chase detection of protein synthesis and degradation.^{16–19}

Azide- and Alkyne-Modified Monosaccharides, Fatty Acids and Isoprenoids

The Click-iT® metabolic glycoprotein labeling reagents provide biosynthetic precursors for detecting and characterizing post-translational glycosylation of proteins:^{14,20–22}

- Click-iT® GalNAz metabolic glycoprotein labeling reagent (tetraacetylated *N*-azidoacetylgalactosamine for labeling *O*-linked glycoproteins, C33365; Figure 3.1.1C, Figure 3.1.5)
- Click-iT® ManNAz metabolic glycoprotein labeling reagent (tetraacetylated *N*-azidoacetylmannosamine for labeling sialic acid–modified glycoproteins, C33366; Figure 3.1.6)
- Click-iT® GlcNAz metabolic glycoprotein labeling reagent (tetraacetylated *N*-azidoacetylglucosamine for labeling *O*-linked *N*-acetylglucosamine (*O*-GlcNAc)-modified glycoproteins, C33367; Figure 3.1.7)
- Click-iT® fucose alkyne (tetraacylfucose alkyne, C10264; Figure 3.1.8)

Cultured cells are simply incubated with the modified sugars for 2–3 days or until cells reach the appropriate density. The acetyl groups improve cell permeability of the modified sugars and are removed by nonspecific intracellular esterases (Figure 3.1.8). The resulting azide- or alkyne-modified sugar is then metabolically incorporated through the permissive nature of the oligosaccharide biosynthesis pathway, yielding functionalized glycoproteins that can be chemoselectively coupled to complementary alkyne- or azide-functionalized fluorophores and biotinylation reagents for detection or affinity capture. We also offer the the Click-iT® *O*-GlcNAc Enzymatic Labeling System for *in vitro* enzyme-mediated *N*-azidoacetylgalactosamine labeling of *O*-GlcNAc–modified glycoproteins^{26,27} (C33368, Section 9.4) and Click-iT® Protein Analysis Detection Kits (C33370, C33371, C33372; Section 9.4) for detection of azide-functionalized glycoproteins in 1D or 2D electrophoresis gels or western blots.

Similarly, our azide-functionalized isoprenoids and fatty acids enable detection of post-translational lipidation of proteins by in-gel fluorescence scanning, fluorescence microscopy and flow cytometry.^{23–25} We offer the following azide-modified fatty acids and isoprenoids:

- Click-iT® farnesyl alcohol, azide (C10248, Figure 3.1.9)
- Click-iT® geranylgeranyl alcohol, azide (C10249, Figure 3.1.10)
- Click-iT® palmitic acid, azide (15-azidopentadecanoic acid, C10265; Figure 3.1.1D)
- Click-iT® myristic acid, azide (12-azidododecanoic acid, C10268)

Heterobifunctional Reagents

Our collection of heterobifunctional reagents provide a means for adapting the amine- and thiol-reactive labeling chemistries described in Chapters 1 and 2 with the azide–alkyne Click-iT® labeling protocols:

- Azide succinimidyl ester (A10280, Figure 3.1.11)
- Alkyne succinimidyl ester (A10279, Figure 3.1.12)
- Azide iodoacetamide (I10188, Figure 3.1.13)
- Alkyne iodoacetamide (I10189, Figure 3.1.14)

Figure 3.1.6 Metabolic incorporation of tetraacetylated azido sugars.

The succinimidyl ester reagents can be used for azide or alkyne functionalization of amine-containing molecules and molecular assemblies including terminally or internally modified oligonucleotides and nanoparticles.^{8,28}

Click-iT® Reaction Buffers

For added convenience, we offer Click-iT® Reaction Buffer Kits for protein or cell samples labeled with an azide- or alkyne-tagged biomolecule. The Click-iT® Cell Reaction Buffer Kit (C10269) includes sufficient reagents to perform 50 reactions based on a 0.5 mL reaction volume for subsequent analyses by flow cytometry, fluorescence microscopy or high-content screening (HCS). The Click-iT® Protein Reaction Buffer Kit (C10276) includes everything required for click coupling to functionalized proteins for subsequent standard protein biochemical analyses (e.g., western blots or mass spectrometry).

Click-iT® Tools for Cell Proliferation Analysis

The Click-iT® EdU cell proliferation assay provides a superior alternative to bromodeoxyuridine (BrdU) or ³H-thymidine incorporation methods for measuring new DNA synthesis.^{29,30} The alkyne nucleoside analog EdU (5-ethynyl-2'-deoxyuridine; A10044, E10187, E10415) is incorporated into DNA during the synthesis phase (S phase) of the cell cycle and is subsequently detected by copper (I)-catalyzed click coupling to an azide-derivatized fluorophore⁶ (Figure 3.1.2). The small size of the click-coupled fluorophore compared to that of antibodies required for immunodetection of BrdU (Figure 3.31) enables efficient penetration of complex samples without the need for harsh cell treatment, simplifying the assay considerably. The Click-iT® EdU assay protocol is compatible with both adherent cells and cell suspensions. From start to finish, the EdU detection assay is complete in as little as 90 minutes, as compared with the antibody-based BrdU method, which takes 6–24 hours to complete. In addition, the Click-iT® EdU cell proliferation assay can be multiplexed with surface and intracellular marker detection using Alexa Fluor® dye-labeled secondary antibodies^{15,31–33} (Section 7.2) (Figure 3.1.15). Although the majority of applications are in cultured mammalian cells, Click-iT® EdU reagents and methods have also been successfully applied to a wide range of model organisms including:

- *Escherichia coli*³⁴
- *Caenorhabditis elegans*³²
- *Drosophila*³⁵
- Zebrafish³⁶
- Mouse¹⁵
- Plants^{37,38} (alfalfa, *Arabidopsis*, grape, maize, rice and tobacco)

Figure 3.1.15 Multicolor imaging with the Click-iT® EdU Imaging Kits. Muntjac cells were treated with 10 μM EdU for 45 minutes. Cells were then fixed and permeabilized, and EdU that had been incorporated into newly synthesized DNA was detected by the far-red-fluorescent Click-iT® EdU Alexa Fluor® 647 HCS Assay Kit (C10356, C10357). Tubulin was labeled with an anti-tubulin antibody and visualized with an Alexa Fluor® 350 goat anti-mouse IgG antibody (A21049). The Golgi complex was stained with the green-fluorescent Alexa Fluor® 488 conjugate of lectin HPA from *Helix pomatia* (edible snail) (L11271), and peroxisomes were labeled with an anti-peroxisome antibody and visualized with an orange-fluorescent Alexa Fluor® 555 donkey anti-rabbit IgG antibody (A31572).

Click-iT® EdU Flow Cytometry Assay Kits

The Click-iT® EdU Flow Cytometry Assay Kits provide all the reagents needed to perform 50 assays using 0.5 mL reaction buffer per assay, including the nucleoside analog EdU and all components for fixation, permeabilization and labeling whole blood samples, adherent cells or suspension cells.^{30,39}

- Click-iT® EdU Alexa Fluor® 488 Flow Cytometry Assay Kit (C35002)
- Click-iT® EdU Alexa Fluor® 647 Flow Cytometry Assay Kit (A10202)
- Click-iT® EdU Pacific Blue™ Flow Cytometry Assay Kit (A10034)

Additionally, two cell-cycle stains compatible with the fluorescence excitation and emission characteristics of the fluorescent azide detection reagents are included.

Click-iT® EdU Imaging Kits

The Click-iT® EdU Imaging Kits contain all of the components needed to label and detect incorporated EdU on 50 coverslips using 0.5 mL reaction buffer per test, as well as the blue-fluorescent Hoechst 33342 nuclear stain for identification of cells irrespective of EdU incorporation status:

- Click-iT® EdU Alexa Fluor® 488 Imaging Kit (C10337)
- Click-iT® EdU Alexa Fluor® 555 Imaging Kit (C10338)
- Click-iT® EdU Alexa Fluor® 594 Imaging Kit (C10339)
- Click-iT® EdU Alexa Fluor® 647 Imaging Kit (C10340)

Click-iT® EdU HCS Assay Kits

The Click-iT® EdU HCS Assay Kits contain all of the materials needed to label and detect incorporated EdU in adherent cells in 96-well microplates and 100 µL reaction buffer per assay:

- Click-iT® EdU Alexa Fluor® 488 HCS Assay Kit (2-plate size, C10350; 10-plate size, C10351)
- Click-iT® EdU Alexa Fluor® 555 HCS Assay Kit (2-plate size, C10352; 10-plate size, C10353)
- Click-iT® EdU Alexa Fluor® 594 HCS Assay Kit (2-plate size, C10354; 10-plate size, C10355)
- Click-iT® EdU Alexa Fluor® 647 HCS Assay Kit (2-plate size, C10356; 10-plate size, C10357; Figure 3.1.15)

For cell registration or DNA profiling, these kits also include the blue-fluorescent HCS NuclearMask™ Blue stain.

Click-iT® EdU Microplate Assay Kit

The Click-iT® EdU Microplate Assay Kit provides a simple and rapid workflow with fewer wash steps resulting in a substantial time-savings advantage over traditional BrdU colorimetric or fluorescent cell proliferation assays. This assay uses Oregon Green® 488 azide for click coupling to synthetically incorporated EdU. The signal is amplified using immunodetection of the Oregon Green® 488 fluorophore by a rabbit anti-Oregon Green® horseradish peroxidase (HRP) conjugate followed by fluorogenic or chromogenic detection with our Amplex® UltraRed HRP substrate. The Click-iT® EdU microplate assay has been successfully tested in HeLa, A549, U2OS and A541 cells with a variety of reagents that modulate DNA synthesis, including the DNA synthesis inhibitor aphidicolin and the mitotic inhibitor paclitaxel. The Click-iT® EdU Microplate Assay Kit (C10214) contains sufficient reagents for performing 400 individual assays in a 96-well plate format.

Click-iT® TUNEL Assay

The terminal deoxynucleotidyl transferase-dUTP nick end labeling (TUNEL) assay—based on the incorporation of modified dUTPs by terminal deoxynucleotidyl transferase (TdT) at the 3'-OH ends of fragmented DNA—is probably the most widely used *in situ* test for studying apoptotic DNA fragmentation. For a sensitive and reliable TUNEL imaging assay, it is vital that the modified nucleotide is an efficient substrate for TdT. The minimally modified EdUTP

nucleotide (Figure 3.1.16) used in the Click-iT® TUNEL imaging assay is rapidly incorporated by TdT, allowing samples to be rapidly fixed in order to preserve late-stage apoptotic cells, thereby lessening the possibility of false-negative results due to cell detachment and subsequent loss. The enzymatically incorporated nucleotide is detected by copper (I)-catalyzed click coupling to an azide-derivatized fluorophore. Compared with assays that use one-step incorporation of dye-modified nucleotides, the fast and sensitive Click-iT® TUNEL imaging assay can detect a higher percentage of apoptotic cells under identical conditions in 2 hours or less.

The Click-iT® TUNEL Imaging Assay Kits are available with a choice of azide-derivatized Alexa Fluor® dyes, providing flexibility for combination with other apoptosis detection reagents (Section 15.5):

- Click-iT® TUNEL Alexa Fluor® 488 Imaging Assay (C10245)
- Click-iT® TUNEL Alexa Fluor® 594 Imaging Assay (C10246)
- Click-iT® TUNEL Alexa Fluor® 647 Imaging Assay (C10247)

The Click-iT® TUNEL assay has been tested in HeLa, A549 and CHO K1 cells with a variety of reagents that induce apoptosis, including staurosporine, and multiplexed with antibody-based detection of other apoptosis biomarkers such as cleaved poly(ADP-ribose) polymerase (PARP), cleaved caspase-3 and phosphohistone 2B. It has also proven effective for detection of apoptosis induced by siRNA knockdown of the DEC2 transcription factor in human MCF-7 breast cancer cells.⁴⁰

Figure 3.1.18 Click-iT® AHA (L-azidohomoalanine, C10102).

Click-iT® Tools for Detecting RNA and Protein Synthesis

Click-iT® RNA Kits

Click-iT® RNA Imaging and Click-iT® RNA HCS Assay Kits provide everything needed to detect newly synthesized RNA in adherent cells.:

- Click-iT® RNA Alexa Fluor® 488 Imaging Kit (C10329)
- Click-iT® RNA Alexa Fluor® 594 Imaging Kit (C10330)
- Click-iT® RNA Alexa Fluor® 488 HCS Assay (C10327)
- Click-iT® RNA Alexa Fluor® 594 HCS Assay (C10328)

Click-iT® RNA assays are ideal for imaging global RNA synthesis in multiplex analyses using traditional fluorescence microscopy or high-content screening (HCS). The Click-iT® RNA assays employ the alkyne-modified nucleoside EU (5-ethynyl uridine, E10345; Figure 3.1.17), which is supplied to cells and incorporated into nascent RNA.⁴¹ The small size of the alkyne tag enables efficient incorporation by RNA polymerases without any apparent changes to the RNA levels of several housekeeping genes. Detection of incorporated EU is accomplished by copper (I)-catalyzed click coupling to an azide-derivatized fluorophore. The multiplexing capability of the assays makes them ideal for toxicological profiling or interrogation of disease models using high-content imaging platforms.

The Click-iT® RNA HCS Assay Kits (C10329, C10330) contain sufficient reagents to label and detect newly synthesized RNA in whole cells using two 96-well microplates and 50 µL reaction volumes per well. These kits also supply the blue-fluorescent HCS NuclearMask™ blue stain as a nuclear counterstain for cell demarcation or for DNA profiling. The Click-iT® RNA Imaging Kits (C10327, C10328) contain sufficient reagents to label and detect newly synthesized RNA in whole cells using 25 coverslips and 500 µL reaction volume per well. These kits also supply the blue-fluorescent Hoechst 33342 dye as a nuclear counterstain or for DNA profiling.

The Click-iT® Nascent RNA Capture Kit (C10365) enables RNA synthesized during a time window defined by administration of EU to be selectively biotinylated via click coupling of EU to biotin azide. Biotinylated RNA is then captured using streptavidin-functionalized magnetic beads for reverse transcription and subsequent analysis by DNA sequencing, PCR or microarray hybridization.

Click-iT® Nascent Protein Synthesis Detection Kit

Detecting newly synthesized protein is key for researchers studying protein biosynthesis, trafficking and degradation. Click-iT® AHA (L-azidohomoalanine, Figure 3.1.18) incorporation provides a fast, sensitive and nonradioactive alternative to the traditional radioactive ³⁵S-methionine

technique for the detection of nascent protein.^{19,42} *L*-azidohomoalanine, an analog of *L*-methionine, is supplied to cultured cells and is biosynthetically incorporated into proteins. The incorporated amino acid is then detected by copper (I)-catalyzed click coupling to an alkyne-derivatized fluorophore. This two-step labeling and detection method provides detection sensitivity comparable with that obtained using the radioactive ³⁵S-methionine method and is compatible with downstream LC-MS/MS and MALDI-MS analysis. Click-iT[®] AHA is available as a stand-alone reagent (C10102) or in the Click-iT[®] AHA Alexa

Fluor[®] 488 Protein Synthesis HCS Assay Kit (C10289), which contains Alexa Fluor[®] 488 alkyne for detection. Click-iT[®] AHA has proven to be a successful substitute for methionine in many cell types, including COS-7, 3T3-L1, HeLa, HEK 293 and Jurkat cells. Cellular incorporation of Click-iT[®] AHA should be carried out in methionine-free media, as methionine is the preferred substrate for methionyl tRNA transferase, and supplemented media (i.e., methionine-free DMEM) should be used in place of HBSS to achieve greater Click-iT[®] AHA incorporation at lower concentrations.

For definitions of the contents of this data table, see "Using *The Molecular Probes[®] Handbook*" in the introductory pages.

Notes

- E10187 and E10415 are an alternative packaging of A10044 but are otherwise identical.
- C10264 is deacetylated *in vivo* yielding the 6-ethynyl analog of fucose (MW = 174.15).
- C33365, C33366 and C33367 are deacetylated *in vivo* yielding *N*-azidoacetylgalactosamine, *N*-azidoacetylmannosamine and *N*-azidoacetylglucosamine (all MW = 262.22), respectively.
- Iodoacetamides in solution undergo rapid photodecomposition to unreactive products. Minimize exposure to light prior to reaction.
- Absorption and fluorescence of Oregon Green[®] 488 dyes are pH dependent only in moderately acidic solutions (pH <5).
- Abs and Em for tetramethylrhodamine dyes in pH 8 buffer are red-shifted approximately 8 nm compared to MeOH, with EC lower by ~10%.

PRODUCT LIST 3.1 CLICK CHEMISTRY

Cat. No.	Product	Quantity
A10267	Alexa Fluor® 488 alkyne (Alexa Fluor® 488 5-carboxamido-(propargyl), bis(triethylammonium salt)) *5-isomer*	0.5 mg
A20013	Alexa Fluor® 555 alkyne, triethylammonium salt	0.5 mg

3.2 Reagents for Modifying Alcohols

Alcohols in Proteins: Serine, Threonine and Tyrosine Residues

Although alcohols (including phenols such as tyrosine and the hydroxyl groups in serine, threonine, sterols and carbohydrates) are abundant in biomolecules, their chemical reactivity in aqueous solution is extremely low. Few reagents are selective for alcohols in aqueous solution, especially in the presence of more reactive nucleophiles such as thiols and amines. It is therefore difficult to selectively modify serine, threonine and tyrosine residues in proteins except when they exhibit unusual reactivity, such as by residing at an enzyme's active site.

Serine and Threonine Residues

Nonacylated N-terminal serine and threonine residues in peptides and proteins can be oxidized with periodate to yield aldehydes^{1,2} (Figure 3.2.1) that can be subsequently modified with a variety of hydrazine, hydroxylamine or amine derivatives (Section 3.3, Table 3.2). In addition, peptides containing serine, threonine or tyrosine residues separated from a histidine residue by a single amino acid can be selectively acylated by the succinimidyl ester or sulfosuccinimidyl ester of biotin-X³ (B1582, B6353; Section 4.2; Figure 3.2.2). This property may also permit selective modification of these sequences (Ser-x-His, Thr-x-His and Tyr-x-His, where “x” refers to any amino acid) in peptides and proteins with fluorescent succinimidyl esters (Chapter 1). O-acylation versus N-acylation can be detected by treatment with hydroxylamine, which cleaves esters but usually not amides.⁴

Figure 3.2.3 4-Chloro-7-nitrobenz-2-oxa-1,3-diazole (NBD chloride; 4-chloro-7-nitrobenzofurazan, C20260).

Figure 3.2.1 Sodium periodate oxidation of an N-terminal serine residue to an aldehyde, with the release of formaldehyde. The aldehyde thus formed from the protein can be subsequently modified with a variety of hydrazine, hydroxylamine or amine derivatives.

Figure 3.2.2 Nucleophilic attack of serine on the carbonyl group (C=O) of biotin-X, SSE (B6353) results in the stable O-acylated derivative. In addition to histidine-x-serine, this stable intermediate can be formed in the presence of linear sequences of histidine-x-tyrosine and histidine-x-threonine, where “x” refers to any amino acid.

Tyrosine Residues

Modification of tyrosine residues is sometimes a side reaction when proteins are reacted with sulfonyl chlorides, iodoacetamides or other reactive dyes described in Chapter 1 and Chapter 2. For example, NBD chloride (C20260, Section 1.8, Figure 3.2.3) reacts with an active-site tyrosine in *Escherichia coli* F₁-ATPase, causing strong inhibition.⁵

Tyrosine residues in some proteins can be selectively modified by initial nitration of the *ortho* position of its phenol using tetranitromethane, and then reduction of the *o*-nitrotyrosine with sodium dithionite (Na₂S₂O₄) to form an *o*-aminotyrosine (Figure 3.2.4). Although much less reactive than aliphatic amines, the aromatic amine of *o*-aminotyrosine can react with most amine-reactive reagents (Chapter 1) between pH 5 and pH 7.⁶ To obtain selective derivatization in complex samples, it is of course critical to block all aliphatic primary amines, typically by acetylation with acetic anhydride, prior to reduction of nitrotyrosine. Nitration of tyrosine residues by nitric oxide occurs naturally in cells through peroxynitrite radical intermediates (Section 18.3, Table 18.1), yielding derivatives that can be reduced to *o*-aminotyrosine and subsequently detected using amine-reactive reagents.^{6,7} Tyrosine residues of peptides and proteins can be selectively coupled to aniline derivatives in the presence of formaldehyde.⁸ Chemoselective derivatization of tyrosine has also been accomplished using a fluorescent diazodicarboxamide reagent prepared from carboxy-X-rhodamine (ROX) succinimidyl ester⁹ (C1309, Section 1.6).

Another method for modifying tyrosine groups in peptides is to convert the phenol group in tyrosine residues to a salicylaldehyde derivative, and then to react the salicylaldehyde with 1,2-diamino-4,5-dimethoxybenzene (DI463, Section 3.3) to form a fluorescent benzimidazole.^{10–12}

The tyramide signal amplification (TSA™) technology (Section 6.2), which was developed by NEN (now a part of PerkinElmer Corporation) and licensed for in-cell and in-tissue applications, permits significant amplification of the detectability of targets by a horseradish peroxidase-mediated scheme. In the TSA™ method, the labeled tyramide becomes covalently linked to tyrosine residues in or near the target. We have introduced an extensive selection of TSA™ Kits that utilize an Alexa Fluor® tyramide, Oregon Green® 488 tyramide or biotin-XX tyramide as the amplification reagents (Section 6.2).

Figure 3.2.4 Reaction scheme for the conversion of tyrosine to *o*-aminotyrosine. Tyrosine undergoes nitration by reaction with tetranitromethane, followed by reduction with sodium dithionite, to yield an *o*-aminotyrosine.

Alcohols in Carbohydrates

As with derivatization of alcohols in proteins, it is difficult to selectively modify most carbohydrates in aqueous solution because of their low reactivity and the competing hydrolysis of the reactive reagents. However, several reagents are available for derivatizing reducing sugars (which contain a low equilibrium concentration of the reactive aldehyde function), as well as for modifying aldehydes and ketones obtained by periodate oxidation of various carbohydrates. To pursue this labeling approach, see Section 3.3 for a description of aldehyde- and ketone-reactive reagents.

Dichlorotriazines

Dichlorotriazines readily modify amines in proteins, and they are among the few reactive groups that are reported to react directly with polysaccharides and other alcohols in aqueous solution, provided that the pH is >9 and that other nucleophiles are absent. We offer the 5-isomer of fluorescein dichlorotriazine (5-DTAF, D16), with absorption/emission maxima of ~492/516 nm, as well as Texas Red® C₂-dichlorotriazine (T30200, Figure 3.2.5), with absorption/emission maxima of ~588/601 nm. 5-DTAF has been used to label a wide range of hydroxylated biopolymers including collagen,¹³ cellulose,¹⁴ cyclodextrins¹⁵ and soluble beta-glucan,¹⁶ as well as functionalized carbon nanotubes.¹⁷

Figure 3.2.5 Texas Red® C₂-dichlorotriazine (T30200).

N-Methylisatoic Anhydride

In the absence of other reactive functional groups, *N*-methylisatoic anhydride (M25) will convert ribonucleotides and certain other carbohydrates^{18,19} to fluorescent esters with excitation/emission maxima of ~350/446 nm in mildly basic aqueous solution.^{20–24} The compactness and moderate environmental sensitivity of this fluorophore, which is a synthetic precursor to blue-fluorescent *N*-methylanthraniloyl (MANT) amides and esters,²³ may be advantageous for preparing site-selective probes. Low molecular weight alcohols are better derivatized by this reagent in aprotic organic solvents^{25–27} (Figure 3.2.6).

Figure 3.2.6 Reaction of *N*-methylisatoic anhydride (M25) with an alcohol to produce a blue-fluorescent (~350/446 nm) *N*-methylanthraniloyl (MANT) ester.

Figure 3.2.7 *m*-Dansylaminophenylboronic acid (D2281).

Figure 3.2.8 Reaction of *m*-dansylaminophenylboronic acid (D2281) with a vicinal diol to form a reversible fluorescent cyclic complex.

Dansyl Aminophenylboronic Acid

m-Dansylaminophenylboronic acid (D2281, Figure 3.2.7) reacts with vicinal diols (hydroxyl groups on adjacent carbon atoms) and certain amino alcohols²⁸ to form cyclic complexes²⁹ (Figure 3.2.8) that have a fluorescence intensity and peak emission dependent on the environment of the dansyl fluorophore. This interesting reagent binds reversibly to cell-wall carbohydrates,³⁰ as well as to glycosylated (but not deglycosylated) human serum albumin.³¹ Dansylaminophenylboronic acid is also used as an HPLC derivatization reagent for vicinal diols³² and as a detection reagent for glycolipids analyzed by thin-layer chromatography.³³

Alcohol Modification in Organic Solvents

Two functional groups—acyl azides and acyl nitriles—react directly with aliphatic amines to yield the same products as do the corresponding succinimidyl esters. When reacted in organic solvents, however, these reagents can also form derivatives of alcohols and phenols, making them extremely useful for sensitive analysis of alcohols by HPLC or capillary electrophoresis.

Isocyanates Prepared from Acyl Azides

Alcohols are much easier to modify in anhydrous organic solvents than in aqueous solution. Perhaps the most effective reagents are isocyanates, which are much more reactive with alcohols (and amines) than are isothiocyanates but are not sufficiently stable to permit their sale. Fortunately, isocyanates can often be prepared by Curtius rearrangement of acyl azides (Figure 3.2.9). When an acyl azide and alcohol are heated together in an organic solvent such as toluene, dioxane or DMF at 80°C, the acyl azide will rearrange to form an isocyanate that then reacts with the alcohol to form a stable urethane. As little as 50 femtograms of the urethane conjugates prepared from coumarin derivatives 7-methoxycoumarin-3-carbonyl azide (M1445) and 7-diethylaminocoumarin-3-carbonyl azide (D1446) can be detected using an HPLC fluorescence detector.^{34,35} Alcohol conjugates (urethanes) prepared from the single-isomer carbonyl azides of fluorescein diacetate (F6218) and tetramethylrhodamine (T6219) may provide even higher sensitivity, particularly with instruments that employ the argon-ion laser. Following rearrangement and alcohol conjugation, the acetates of the fluorescein derivative can be removed by hydrolysis at pH 9–10. The diacetate of fluorescein-5-carbonyl azide has been used to synthesize a fluorogenic substrate for the anandamide transmembrane carrier.³⁶ Tetramethylrhodamine-5-carbonyl azide has been successfully conjugated to the hydrophobic poly(ϵ -caprolactone) (PCL) block of a diblock copolymer micelle in order to follow its cellular internalization^{37,38} and has also been used to prepare riboflavin conjugates for the same purpose.^{39,40}

Acyl Nitriles

9-Anthrolylnitrile (A1440) reacts with alcohols, such as steroids and acylglycerols, in organic solvents to yield carboxylate esters that are useful for HPLC.^{41,42} To optimize solid-phase organic synthesis, 9-anthrolylnitrile has been used to quantitate the absolute amount of resin-bound hydroxyl groups directly on solid support.⁴³ In addition, 9-anthrolylnitrile has been reported to be useful for the selective labeling of certain serine and threonine residues in myosin.^{44–48} The lipophilicity of 9-anthrolylnitrile may make it useful for modifying hydroxyl groups of proteins and hydroxylated fatty acids that are buried within cell membranes.

Figure 3.2.9 Derivatization of an alcohol using the diacetate of fluorescein-5-carbonyl azide (F6218). This process consists of three steps: 1) rearrangement of the acyl azide to an isocyanate, 2) reaction of the isocyanate with an alcohol to form a urethane and 3) deprotection of the nonfluorescent urethane derivative using hydroxylamine.

DATA TABLE 3.2 REAGENTS FOR MODIFYING ALCOHOLS

Cat. No.	MW	Storage	Soluble	Abs	EC	Em	Solvent	Notes
A1440	231.25	F,D,L	DMF, MeCN	361	7500	470	MeOH	1
D16	495.28	F,D,L	pH >6, DMF	492	83,000	516	pH 9	2, 3
D1446	286.29	F,D,L	DMF, MeCN	436	57,000	478	MeOH	
D2281	370.23	D,L	DMF, DMSO	337	4600	517	MeOH	4
F6218	485.41	FF,D	DMF, MeCN	<300		none		
M25	177.16	D	DMF, DMSO	316	3500	386	MeOH	5
M1445	245.19	FF,D,L	DMF, MeCN	360	25,000	415	MeOH	
T6219	455.47	FF,D,L	DMF, MeCN	545	90,000	578	MeOH	
T30200	796.74	F,D,L	DMF, DMSO	583	87,000	604	MeOH	

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- The absorption spectrum of A1440 has subsidiary peaks at 380 nm and 344 nm. Emission spectrum is unstructured. Ester derivatives formed by reaction with alcohols have essentially similar spectra.
- Unstable in water. Use immediately.
- Absorption and fluorescence of fluorescein derivatives are pH dependent. Extinction coefficients and fluorescence quantum yields decrease markedly at pH <7.
- Fluorescence of D2281 when bound to proteins is typically blue shifted (Em ~490 nm).
- The amide reaction product of M25 with butylamine has Abs = 353 nm (EC = 5900 cm⁻¹M⁻¹), Em = 426 nm in MeOH. Ester reaction products with alcohols have Abs = 350 nm (EC = 5700 cm⁻¹M⁻¹), Em = 446 nm in water (pH 8).

PRODUCT LIST 3.2 REAGENTS FOR MODIFYING ALCOHOLS

Cat. No.	Product	Quantity
A1440	9-anthrolynitrile	25 mg
D2281	<i>m</i> -dansylaminophenylboronic acid	100 mg
D16	5-(4,6-dichlorotriazinyl)aminofluorescein (5-DTAF) *single isomer*	100 mg
D1446	7-diethylaminocoumarin-3-carbonyl azide	25 mg
F6218	fluorescein-5-carbonyl azide, diacetate	10 mg
M1445	7-methoxycoumarin-3-carbonyl azide	25 mg
M25	<i>N</i> -methylisatoic anhydride *high purity*	1 g
T6219	tetramethylrhodamine-5-carbonyl azide	5 mg
T30200	Texas Red® C ₂ -dichlorotriazine	5 mg

3.3 Reagents for Modifying Aldehydes and Ketones

Aldehydes and ketones are present in a number of low molecular weight molecules such as drugs, steroid hormones, reducing sugars and metabolic intermediates (e.g., pyruvate and α -ketoglutarate). Except for polysaccharides containing free reducing sugars, however, biopolymers generally lack aldehyde and ketone groups. Even those aldehydes and ketones that are found in the open-ring form of simple carbohydrates are usually in equilibrium with the closed-ring form of the sugar.

The infrequent occurrence of aldehydes and ketones in biomolecules has stimulated the development of techniques to selectively introduce these functional groups, thus providing unique sites for chemical modification and greatly extending the applications of the probes found in this section. Fluorescent modification of aldehyde or carboxylic acid groups in carbohydrates is also frequently utilized for their analysis by HPLC, capillary electrophoresis¹ and other methods.

Introducing Aldehydes and Ketones into Biomolecules

Periodate Oxidation

The most common method for introducing aldehydes and ketones into polysaccharides and glycoproteins (including antibodies) is by periodate-mediated oxidation of vicinal diols. These introduced aldehydes and ketones can then be modified with fluorescent or biotinylated hydrazine, hydroxylamine or amine derivatives to label the polysaccharide or glycoprotein. For example, some of the hydrazine derivatives described in this section have been used to detect periodate-oxidized glycoproteins in gels.² The Pro-Q® Emerald 300 and Pro-Q® Emerald 488 Glycoprotein Gel and Blot Stain Kits (P21855, P21857, M33307;

Figure 3.3.1 Sodium periodate oxidation of an N-terminal serine residue to an aldehyde, with the release of formaldehyde. The aldehyde thus formed from the protein can be subsequently modified with a variety of hydrazine, hydroxylamine or amine derivatives.

Figure 3.3.2 Oxidation of the terminal galactose residue of a glycoprotein, glycolipid or polysaccharide results in the generation of an aldehyde, which can react with hydrazines, hydroxylamines or primary amine-containing compounds.

Section 9.4) are based on periodate oxidation of glycoproteins and subsequent labeling with a Pro-Q® Emerald dye.³

Periodate oxidation of the 3'-terminal ribose provides one of the few methods of selectively modifying RNA; periodate-oxidized ribonucleotides can subsequently be converted to fluorescent nucleic acid probes by reaction with fluorescent hydrazines, hydroxylamines and amines.⁴⁻⁶ Alkenes from unsaturated fatty acids and ceramides can also be converted to glycols by osmium tetroxide and then oxidized by periodate to aldehydes, and periodate will oxidize certain β -aminoethanol derivatives such as the hydroxylysine residues in collagen, as well as methionine (to its sulfoxide) and certain thiols (usually to disulfides). These other reactions, however, usually occur at a slower rate than oxidation of vicinal diols.

In addition to vicinal diols, N-terminal serine and threonine residues of peptides and proteins can be selectively oxidized by periodate to aldehyde groups⁷⁻⁹ (Figure 3.3.1). Moreover, because antibodies are glycosylated at sites distant from the antigen-binding region, modification of periodate-oxidized antibodies by hydrazines¹⁰ and hydroxylamines usually does not inactivate the antibody, as sometimes occurs with amine-reactive labeling.

Galactose Oxidase-Mediated Oxidation and Other Methods

Galactose oxidase oxidizes terminal galactose residues to aldehydes, particularly in glycoproteins.¹¹⁻¹⁵ The introduction of galactose residues can be especially advantageous for structural studies because it provides a means of selectively labeling specific sites on biomolecules. For example, 2-keto-galactose has been specifically inserted into the Fc glycans of therapeutic antibodies, including Herceptin and Avastin, enabling site-specific labeling with Alexa Fluor® 488 hydroxylamine^{16,17} (A30629). Galactose oxidase-modified lipopolysaccharides (LPS) have been modified with Alexa Fluor® 488 hydrazide (A10436) to probe for LPS-binding sites on cells.¹⁸ Because galactose oxidase-mediated oxidation liberates a molecule of hydrogen peroxide for each molecule of aldehyde that is formed (Figure 3.3.2), horseradish peroxidase-catalyzed oxidation of the Amplex® Red reagent to red-fluorescent resorufin by hydrogen peroxide provides a ready means by which the number of aldehyde residues introduced into a biomolecule, including on a cell surface, can be quantitated. The Amplex® Red Galactose/Galactose Oxidase Assay Kit (A22179, Section 10.5) provides the reagents and a general protocol for this assay of introduced aldehyde residues. Other methods for aldehyde and ketone introduction include selective N-terminal transamination in the presence of pyridoxal-5'-phosphate,¹⁹ ligation of a ketone analog of biotin to proteins with a biotin acceptor peptide (BAP) fusion tag by biotin ligase (BirA)²⁰ and co-translational modification of recombinantly tagged proteins by formylglycine-generating enzyme²¹ (FGE).

Figure 3.3.3 N-(t-BOC)-aminoxyacetic acid, tetrafluorophenyl ester (B30300).

Coupling Hydrazines and Amines to Amine-Containing Biomolecules without Introducing Aldehydes and Ketones

Common tissue fixatives such as formaldehyde and glutaraldehyde can be used to couple hydrazine and amine derivatives to proteins and other amine-containing polymers. For example, lucifer yellow CH (L453) can be conjugated to surrounding biomolecules by common aldehyde-based fixatives in order to preserve the dye's staining pattern during subsequent tissue manipulations.²²

Introducing a Hydroxylamine into a Biomolecule

The tetrafluorophenyl (TFP) ester of *N*-(*t*-BOC)-aminoxyacetic acid (B30300, Figure 3.3.3) is an amine-reactive protected hydroxylamine that is useful for synthesizing new aldehyde- and ketone-reactive probes in an organic solvent. Following coupling to aliphatic amines, the *t*-BOC group can be quantitatively removed with trifluoroacetic acid. The resultant hydroxylamine probe can then spontaneously react with aldehydes, the reducing ends of saccharides and oligosaccharides, and abasic sites in oligonucleotides to form stable adducts.

Hydrazines and Hydroxylamines

Reactivity of Hydrazine and Hydroxylamine Derivatives

Although certain aromatic amines such as 8-aminonaphthalene-1,3,6-trisulfonic acid (ANTS, A350), 2-aminoacridone (A6289) and 8-aminopyrene-1,3,6-trisulfonic acid (APTS, A6257; Figure 3.3.4) have been extensively utilized to modify reducing sugars for analysis and sequencing, the most reactive reagents for forming stable conjugates of aldehydes and ketones are usually hydrazine derivatives, including hydrazides, semicarbazides and carbohydrazides (Figure 3.3.5), as well as hydroxylamine derivatives. Hydrazine derivatives react with ketones to yield relatively stable hydrazones (Figure 3.3.6), and with aldehydes to yield hydrazones that are somewhat less stable, though they may be formed faster. Hydroxylamine derivatives (aminoxy compounds) react with aldehydes and ketones to yield oximes. Oximes are superior to hydrazones with respect to hydrolytic stability.²³ Both hydrazones and oximes can be reduced with sodium borohydride (NaBH₄) to further increase the stability of the linkage. Rates and yields of aldehyde reactions with hydrazine and hydroxylamine derivatives are substantially enhanced by aniline catalysis.²⁴ This chemistry is sufficiently mild and efficient to be applicable for labeling periodate-oxidized sialylated glycoproteins on the surface of live cells.²⁵

Fluorescent Hydrazine and Hydroxylamine Derivatives Excited with Visible Light

We offer a large number of fluorescent hydrazine and hydroxylamine derivatives for reaction with aldehydes or ketones (Table 3.2). Because they are more photostable than the fluorescein derivatives, the Alexa Fluor®, BODIPY® and Texas Red® hydrazides should be among the most sensitive reagents for detecting aldehydes and ketones in laser-excited chromatographic methods.²⁶ However, with the exception of the Alexa Fluor® 555 and Alexa Fluor® 647 hydrazides and the Alexa Fluor® 647 hydroxylamine, the Alexa Fluor® reagents are mixed isomers and may resolve into multiple peaks when analyzed with high-resolution separation techniques. Fluorescent hydrazides and hydroxylamines are extensively used for labeling glycans via derivatization of aldehydes generated after periodate oxidation or via coupling to the reducing terminus.^{27,28} Alexa Fluor® 488 hydroxylamine (A30629, Figure 3.3.7) is particularly useful for detecting aldehyde groups at abasic DNA lesions,^{29,30} similar to the biotinylated hydroxylamine ARP described later in this section.

Fluorescent Hydrazine and Hydroxylamine Derivatives Excited with UV Light

Dansyl hydrazine (D100) has been by far the most widely used UV light-excitable hydrazine probe for derivatizing aldehydes and ketones for chromatographic analysis and mass spectrometry.^{31,32} A unique application that has been reported for dansyl hydrazine, but that is likely a general reaction of hydrazine derivatives, is the detection of *N*-acetylated or *N*-formylated proteins through transfer of the acyl group to the fluorescent hydrazide.^{33,34} Although dansyl hydrazine has been widely used as a UV light-excitable derivatization reagent, our 7-diethylaminocoumarin

and pyrene hydrazides (D355, P101) have much higher absorptivity and fluorescence, which should make their conjugates more detectable than those of dansyl hydrazine.

Figure 3.3.8 Absorption and fluorescence emission spectra of lucifer yellow CH in water.

Polar Fluorescent Hydrazides and Hydroxylamines

Lucifer yellow CH (L453) is most commonly used as an aldehyde-fixable neuronal tracer with visible absorption and emission (Figure 3.3.8). This membrane-impermeant hydrazide also reacts with periodate-oxidized cell-surface glycoproteins,^{35,36} oxidized ribonucleotides³⁷ and gangliosides.³⁸ Cascade Blue[®] hydrazide (C687) exhibits high absorptivity ($EC > 28,000 \text{ cm}^{-1} \text{ M}^{-1}$), fluorescence quantum yield (0.54) and water solubility³⁹ (~1%). Like Cascade Blue[®] hydrazide, Alexa Fluor[®] 350 hydrazide (A10439) and Alexa Fluor[®] 350 hydroxylamine (A30627) also have high water solubility and bright blue fluorescence. These sulfonated pyrene and coumarin derivatives have applications similar to those of lucifer yellow CH, including as aldehyde-fixable polar tracers;⁴⁰ see Section 14.3 for a more complete discussion of this application.

Cell membrane-impermeant aldehyde- and ketone-reactive reagents are also important probes for assessing the topology of peptide and protein exposure on the surface of live cells. Periodate- or galactose oxidase-mediated oxidation of cell-surface glycoproteins and polysaccharides can be used to selectively introduce aldehyde residues on the cell surface, and these aldehydes can then be reacted with a membrane-impermeant hydrazide. The high polarity of our Alexa Fluor[®] hydrazides (A10436, A10437, A10438, A10439, A20501MP, A20502, A30634), Alexa Fluor[®] hydroxylamines

* Hydrazine, hydroxylamine and aromatic amine derivatives are discussed in Section 3.3, and aliphatic amine derivatives are discussed in Section 3.4, except for D1552, which appears in Section 12.3. † Aromatic amines used extensively for modifying aldehydes and ketones. ‡ Biotin and desthiobiotin (DSB-X™ biotin) derivatives are listed in Section 4.2. § ARP is the abbreviation for *N*-(aminoxyacetyl)-*N'*-(*D*-biotinoyl)hydrazine. ** B30300 requires t-BOC deprotection by trifluoroacetic acid to generate free hydroxylamine. More information on reactive dyes is available at www.invitrogen.com/handbook/labelingchemistry.

(A30627, A30629, A30632), lucifer yellow CH (L453) and Cascade Blue[®] hydrazide (C687) make them the preferred labeling reagents.

NBD Methylhydrazine

NBD methylhydrazine (*N*-methyl-4-hydrazino-7-nitrobenzofurazan, M20490) has been used to monitor aldehydes and ketones in tobacco smoke⁴¹ and automobile exhaust⁴² and also to measure nitrite in water⁴³ (Section 21.2). NBD methylhydrazine reacts with carbonyl compounds in acidic media, forming the corresponding hydrazones (Figure 3.3.9). Following separation by HPLC, the hydrazones can be detected either by spectrophotometry (using wavelengths corresponding to the absorption maxima of the relevant hydrazone) or by fluorescence spectroscopy using excitation/emission at ~470/560 nm.

Biotin Hydrazides and Biotin Hydroxylamine

In addition to the fluorescent hydrazine and hydroxylamine derivatives, we offer several nonfluorescent biotin and DSB-X[™] biotin hydrazides (B1603, B2600, D20653; Section 4.2) and the biotin hydroxylamine derivative ARP (A10550, Section 4.2), each of which can be detected using fluorescent dye- or enzyme-labeled avidin or streptavidin (Section 7.6, Table 7.9). DSB-X[™] biotin hydrazide, which has moderate affinity for avidin and streptavidin that is rapidly reversed by low concentrations of free biotin, can be used to produce a DSB-X[™] biotin-labeled molecule that reversibly binds avidin or streptavidin affinity matrices (Section 7.6).

We recommend the biotin hydroxylamine derivative ARP (aldehyde-reactive probe, A10550; Figure 3.3.10) as our most efficient reagent for incorporating biotins into aldehyde- or ketone-containing cell surfaces. ARP has been used extensively to modify the exposed aldehyde group at abasic lesions in DNA^{44,45} (Figure 3.3.11). A quick and sensitive microplate assay for abasic sites can be performed using ARP.⁴⁶ In addition, ARP is membrane permeant, permitting detection

Figure 3.3.9 Reaction scheme illustrating the principle of ketone and aldehyde detection by NBD methylhydrazine (M20490).

Figure 3.3.10 *N*-(aminooxyacetyl)-*N'*-(*D*-biotinoyl) hydrazine, trifluoroacetic acid salt (ARP, A10550).

of abasic sites in live cells.^{47,48} Once the aldehyde groups in abasic sites are modified by ARP and the cells are fixed and permeabilized, the resulting biotinylated DNA can be detected with fluorescent dye-, Qdot[®] nanocrystal- or enzyme-conjugated streptavidin conjugates (Section 7.6, Table 7.9). Likewise, ARP can be used to detect and capture 4-hydroxynonenal (HNE)-modified proteins.⁴⁹ ARP has also been used to immobilize IgG antibodies on streptavidin-coated monolayer surfaces with their binding sites oriented toward the solution phase.⁵⁰ An alternative to ARP for detection of protein carbonyls is dinitrophenylhydrazine derivatization followed by immunolabeling with our Alexa Fluor[®] 488 dye-labeled anti-dinitrophenyl antibody⁵¹ (A11097, Section 7.4).

Figure 3.3.11 Aldehyde-reactive probe (ARP) used to detect DNA damage. The biotin hydroxylamine ARP (A10550) reacts with aldehyde groups formed when reactive oxygen species depurinate DNA. This reaction forms a covalent bond linking the DNA to biotin. The biotin can then be detected using fluorophore- or enzyme-linked streptavidin.

Aliphatic and Aromatic Amines

Primary aliphatic and aromatic amines (Table 3.2) can be coupled reversibly to aldehydes and ketones to form hydrolytically unstable Schiff bases¹¹ (Figure 3.3.12). The reversibility of this modification makes reagents that contain amines less desirable unless the Schiff base is reduced by sodium borohydride^{52,53} or sodium cyanoborohydride.⁵⁴ Chemical reduction also retains the amine's original charge. Sequencing of carbohydrate polymers using fluorescent derivatives has usually relied on derivatization of the reducing end of the polymer with a fluorescent amine.⁵⁵ Certain aromatic amines have been extensively utilized for coupling to aldehydes, ketones, monosaccharides and the reducing end of carbohydrate polymers:

- 2-Aminoacridone (A6289) forms conjugates that can be separated by HPLC^{56,57} or, as their borate complexes, by polyacrylamide gel electrophoresis,^{55,58,59} capillary electrophoresis^{60–62} and micellar electrokinetic capillary chromatography^{63,64} (MECC). Starting with as little as 25 µg of a glycoprotein, researchers have efficiently released and purified the carbohydrates, and then derivatized them with 2-aminoacridone for subsequent structural analysis.⁶⁵ 2-Aminoacridone derivatives of oligosaccharides have

been directly analyzed by MALDI-TOF mass spectrometry.⁶⁶ 2-Aminoacridone is also used to prepare fluorogenic substrates for proteases.⁶⁷

- 7-Amino-4-methylcoumarin (A191), which is a common base of protease substrates (Section 10.4), can be used for the reductive derivatization of oligosaccharides.^{68,69}
- 8-Aminopyrene-1,3,6-trisulfonic acid (APTS, A6257) has been extensively used to derivatize carbohydrates prior to separation by gel or capillary electrophoresis.^{70,71} Among the amines we offer, APTS is the aromatic amine that has the most favorable combination of strong absorbance, high quantum yield and ionic charge.
- ANTS (A350) has a high ionic charge, permitting electrophoretic separation of its products with complex oligosaccharides.⁷²

The aromatic diamine 1,2-diamino-4,5-dimethoxybenzene (DDB, D1463), which forms heterocyclic compounds with certain aldehydes and ketones, has been used to selectively detect aromatic aldehydes in the presence of aliphatic aldehydes, including carbohydrates.⁷³ DDB has proven to be a useful reagent for HPLC analysis of the cytotoxic metabolic by-product methylglyoxal in blood samples from diabetic patients.⁷⁴

Alternatively, aldehydes and ketones can be transformed into primary aliphatic amines by reductive amination with ammonia, ethylenediamine or other nonfluorescent diamines.⁷⁵ This chemistry is particularly useful because the products can then be coupled with any of the amine-reactive reagents described in Chapter 1 such as the succinimidyl esters of TAMRA dye⁷⁶ (C1171, C6121, C6122; Section 1.6). Derivatization by succinimidyl esters has been extensively utilized for tagging oligosaccharides that are to be separated by capillary zone electrophoresis with laser-induced fluorescence detection.^{76–79}

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. Spectra of this compound are in methanol containing a trace of KOH.
2. Maximum solubility in water is ~8% for A10437 and A10438.
3. Aqueous stock solutions should be used within 24 hours; long-term storage is NOT recommended.
4. The fluorescence lifetime (τ) of the Alexa Fluor® 488 dye in pH 7.4 buffer at 20°C is 4.1 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
5. Abs and Em of the Alexa Fluor® 488 dye are red-shifted by as much as 16 nm and 25 nm respectively on microarrays relative to aqueous solution values. The magnitude of the spectral shift depends on the array substrate material. (*Biotechniques* (2005) 38:127)
6. Absorption and fluorescence of fluorescein derivatives are pH dependent. Extinction coefficients and fluorescence quantum yields decrease markedly at pH <7.
7. The Alexa Fluor® 405 and Cascade Blue® dyes have a second absorption peak at about 376 nm with EC ~80% of the 395–400 nm peak.
8. Maximum solubility in water is ~1% for C687, ~1% for C3221 and ~8% for C3239.
9. The absorption and fluorescence spectra of BODIPY® derivatives are relatively insensitive to the solvent.
10. Fluorescence of D7918 is weak. Reaction with α -ketoaldehydes yields fluorescent benzoquinoxaline derivatives (Abs = 365 nm, Em = 540 nm in H₂O at pH 8). (*J Chromatogr B Biomed Sci Appl* (1999) 729:237)
11. The fluorescence quantum yield of lucifer yellow CH in H₂O is 0.21. (*J Am Chem Soc* (1981) 103:7615)
12. Maximum solubility in water is ~8% for L453, ~6% for L682 and ~1% for L1177.
13. NBD methylhydrazine reacts with aldehydes and ketones in the presence of strong acid, yielding weakly fluorescent hydrazone products. (*Anal Chem* (1999) 71:1893) Abs = 493 nm, Em = 552 nm in MeOH for reaction product with acetone.
14. Pyrene derivatives exhibit structured spectra. The absorption maximum is usually about 340 nm with a subsidiary peak at about 325 nm. There are also strong absorption peaks below 300 nm. The emission maximum is usually about 376 nm with a subsidiary peak at 396 nm. Excimer emission at about 470 nm may be observed at high concentrations.

PRODUCT LIST 3.3 REAGENTS FOR MODIFYING ALDEHYDES AND KETONES

Cat. No.	Product	Quantity
A30627	Alexa Fluor® 350 C ₅ -aminoxyacetamide, trifluoroacetate salt (Alexa Fluor® 350 hydroxylamine)	1 mg
A30629	Alexa Fluor® 488 C ₅ -aminoxyacetamide, bis(triethylammonium) salt (Alexa Fluor® 488 hydroxylamine)	1 mg
A30632	Alexa Fluor® 647 C ₅ -aminoxyacetamide, bis(triethylammonium) salt (Alexa Fluor® 647 hydroxylamine)	1 mg
A10439	Alexa Fluor® 350 hydrazide, sodium salt	5 mg
A10436	Alexa Fluor® 488 hydrazide, sodium salt	1 mg
A20501MP	Alexa Fluor® 555 hydrazide, tris(triethylammonium) salt	1 mg
A10437	Alexa Fluor® 568 hydrazide, sodium salt	1 mg
A10438	Alexa Fluor® 594 hydrazide, sodium salt	1 mg
A30634	Alexa Fluor® 633 hydrazide, bis(triethylammonium) salt	1 mg
A20502	Alexa Fluor® 647 hydrazide, tris(triethylammonium) salt	1 mg
A6289	2-aminoacridone, hydrochloride	25 mg
A191	7-amino-4-methylcoumarin *reference standard*	100 mg
A350	8-aminonaphthalene-1,3,6-trisulfonic acid, disodium salt (ANTS)	1 g
A6257	8-aminopyrene-1,3,6-trisulfonic acid, trisodium salt (APTS)	10 mg
B30300	<i>N</i> -(<i>t</i> -BOC)-aminoxyacetic acid, tetrafluorophenyl ester	25 mg
C356	5-(((2-(carbohydrazino)methyl)thio)acetyl)aminofluorescein	25 mg
C687	Cascade Blue® hydrazide, trisodium salt	10 mg
D1463	1,2-diamino-4,5-dimethoxybenzene, dihydrochloride (DDB)	100 mg
D7918	2,3-diaminonaphthalene	100 mg
D355	7-diethylaminocoumarin-3-carboxylic acid, hydrazide (DCCH)	25 mg
D2371	4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza- <i>s</i> -indacene-3-propionic acid, hydrazide (BODIPY® FL hydrazide)	5 mg
D100	5-dimethylaminonaphthalene-1-sulfonyl hydrazine (dansyl hydrazine)	100 mg
F121	fluorescein-5-thiosemicarbazide	100 mg
L453	lucifer yellow CH, lithium salt	25 mg
M20490	<i>N</i> -methyl-4-hydrazino-7-nitrobenzofurazan (NBD methylhydrazine)	25 mg
P101	1-pyrenebutanoic acid, hydrazide	100 mg
T6256	Texas Red® hydrazide *>90% single isomer*	5 mg

3.4 Derivatization Reagents for Carboxylic Acids and Carboxamides

Carboxylic acids can be converted to esters, amides, acyl hydrazides or hydroxamic acids, all of which are discussed in this section. Alternatively, the half-protected *tert*-butyloxycarbonyl (*t*-BOC) propylendiamine derivative (M6248) is useful for converting organic solvent-soluble carboxylic acids into aliphatic amines. Following coupling of the half-protected aliphatic diamine to an activated carboxylic acid, the *t*-BOC group can be quantitatively removed with trifluoroacetic acid (Figure 3.4.1). The resultant aliphatic amine can then be modified with any of the amine-reactive reagents described in Chapter 1 or coupled to solid-phase matrices for affinity chromatography.

Coupling Hydrazines, Hydroxylamines and Amines to Carboxylic Acids

Modification in Aqueous Solutions

The carboxylic acids of water-soluble biopolymers such as proteins can be coupled to hydrazines, hydroxylamines and amines (Table 3.2) in aqueous solution using water-soluble carbodiimides such as 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDAC, E2247). Including *N*-hydroxysuccinimide (H2249) in the reaction mixture has been shown to improve the coupling efficiency of EDAC-mediated protein-carboxylic acid conjugations^{1,2} (Figure 3.4.2). To reduce intra- and inter-protein coupling to lysine residues,³ which is a common side reaction, carbodiimide-mediated coupling should be performed in a concentrated protein solution at a low pH, using a large excess of the

nucleophile. EDAC-mediated coupling has been used to functionalize Qdot® 605 ITK™ carboxyl quantum dots (Q21301MP, Section 6.6) with the GABA receptor agonist muscimol.⁴ EDAC has been shown to be impermeable to membranes of live cells, which permits its use to distinguish between cytoplasmic and luminal sites of reaction.⁵

Fluoresceinyl glycine amide (5-(aminoacetamido)fluorescein, A1363) and various hydrazines and hydroxylamines may be the best probes for this application because they are more likely to remain reactive at a lower pH than are aliphatic amines such as the cadaverines.⁶ Fluoresceinyl glycine amide has been coupled to the carboxylic acid of a cyclosporin derivative by EDAC.⁷

ANTS (8-aminonaphthalene-1,3,6-trisulfonic acid, A350; Section 3.3) has a high ionic charge, which permits electrophoretic separation of its products with complex oligosaccharides.⁸ Several of the fluorescent hydrazine and hydroxylamine derivatives described in Section 3.3 should have similar utility for carbodiimide-mediated derivatization of carboxylic acids.

Modification in Organic Solvents

Peptide synthesis research has led to the development of numerous methods for coupling carboxylic acids to amines in organic solution. One such method involves the conversion of carboxylic acids to succinimidyl esters or mixed anhydrides. Dicyclohexylcarbodiimide and diisopropylcarbodiimide are widely used to promote amide formation in organic solution. Another recommended derivatization method for coupling organic solvent-soluble carboxylic acids, including

Figure 3.4.1 Conversion of a carboxylic acid group into an aliphatic amine. The activated carboxylic acid is derivatized with a half-protected aliphatic diamine (mono-*N*-(*t*-BOC)-propylendiamine, M6248), usually in an organic solvent, followed by removal of the *t*-BOC-protecting group with trifluoroacetic acid.

Figure 3.4.2 Stabilization of an unstable *O*-acylisourea intermediate by *N*-hydroxysuccinimide in a carbodiimide-mediated (EDAC, E2247) modification of a carboxylic acid with a primary amine.

peptides, to aliphatic amines without racemization is the combination of 2,2'-dipyridyldisulfide and triphenylphosphine.^{9,10} Unlike fluorescent aliphatic amines, fluorescent aromatic amines such as those derived from 7-amino-4-methylcoumarin (A191) and 2-aminoacridone (A6289, Section 3.3) exhibit a shift in their absorption and emission (if any) to much shorter wavelengths upon forming carboxamides. This property makes these aromatic amines preferred reagents for preparing peptidase substrates (Section 10.4). Aromatic amines can generally be coupled to acid halides and anhydrides, with organic solvents usually required for efficient reaction.

Hydrazine, Hydroxylamine and Aliphatic Amine Derivatives

We provide a wide selection of carboxylic acid-reactive reagents (Table 3.2), including several different Dapoxyl®, Alexa Fluor®, BODIPY®, fluorescein, Oregon Green®, rhodamine, Texas Red® and QSY® hydrazine derivatives, hydroxylamine derivatives and amine derivatives, all of which are particularly useful for synthesizing drug analogs and as probes for fluorescence polarization immunoassays^{11–13} (Fluorescence Polarization (FP)—Note 1.4). These probes all require a coupling agent such as a carbodiimide to react with carboxylic acids; they do not spontaneously react with carboxylic acids in solution. They do, however, react spontaneously with the common amine-reactive functional groups described in Section 1.1, including succinimidyl esters and isothiocyanates. Some of the more important probes and their applications include:

- Alexa Fluor® hydrazides (A10436, A10437, A10438, A10439, A30634, A20501MP, A20502; Section 3.3), Alexa Fluor® hydroxylamines (A30627, A30629, A30632; Section 3.3) and Alexa Fluor® cadaverines (A30674, A30675, A30676, A30677, A30678, A30679, A30680), our brightest and most photostable carboxylic acid-reactive probes
- BODIPY® aliphatic amines (D2390, D6251), for preparing pH-insensitive probes, such as BODIPY® FL etoposide,¹⁴ from carboxylic acid derivatives
- Isomeric aminomethylfluoresceins (A1351, A1353), which are readily coupled to activated carboxylic acids¹⁵
- Dapoxyl® (2-aminoethyl)sulfonamide (D10460) for preparing conjugates with strong UV absorption and a Stokes shift of ~200 nm (Figure 3.4.3)
- Dansyl ethylenediamine (D112), dansyl cadaverine (D113), Dapoxyl® (2-aminoethyl)sulfonamide (D10460) and Lissamine rhodamine B ethylenediamine (L2424), for carboxylic acid derivatization¹⁶ and glutamine transamidation reactions¹⁷ (Figure 3.4.4)
- Bimane amine (B30633), a small blue-fluorescent dye for carboxylic acid derivatization
- EDANS (A91), for preparing radioactive IAEDANS,^{13,18} energy transfer-quenched substrates for endopeptidases¹⁹ (Section 10.4) and an ATP substrate analog for DNA-dependent RNA polymerase²⁰
- QSY® 7 amine (Q10464, Figure 3.4.5), which is an essentially non-fluorescent dye with strong visible absorption for preparing highly efficient quenchers for bioassays based on fluorescence resonance energy transfer (FRET) (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2)
- Hydrazine (Section 3.3) and amine derivatives of lucifer yellow (A1339), Alexa Fluor® 405 (A30675) and Cascade Blue® (C621) dyes, which are precursors of highly fluorescent, water-soluble probes
- Hydrazine and amine derivatives of biotin and desthiobiotin (Section 4.2), which are versatile intermediates for synthesizing biotin- and desthiobiotin-containing probes^{21,22}

Figure 3.4.3 Absorption and fluorescence emission spectra of Dapoxyl® (2-aminoethyl)sulfonamide in methanol.

Figure 3.4.5 QSY® 7 amine, hydrochloride (Q10464).

Figure 3.4.4 Transglutaminase-mediated labeling of a protein using dansyl cadaverine (D113).

Enzyme-Catalyzed Transamidation

A transglutaminase-catalyzed transamidation reaction of glutamine residues in some proteins and peptides enables their selective modification by amine-containing probes^{23,24} (Figure 3.4.4). This unique method for selective protein modification requires formation of a complex consisting of the glutamine residue, the aliphatic amine probe and the enzyme. It has been found that a short aliphatic spacer in the amine probe enhances the reaction. The cadaverine ($-\text{NH}(\text{CH}_2)_5\text{NH}-$) spacer is usually optimal. Although dansyl cadaverine (D113) has been probably the most widely used reagent,^{25–27} Alexa Fluor® cadaverines²⁴ (A30674, A30675, A30676, A30677, A30678, A30679, A30680), Oregon Green® 488 cadaverine (O10465), fluorescein cadaverine^{28–33} (A10466), tetramethylrhodamine cadaverine³⁴ (A1318), Texas Red® cadaverine (T2425) and BODIPY® TR cadaverine (D6251) are among the most fluorescent transglutaminase substrates available. The intrinsic transglutaminase activity in sea urchin eggs has been used to covalently incorporate dansyl cadaverine during embryonic development.³⁵ Two biotin cadaverines (A1594, B1596; Section 4.2) are also available for transglutaminase-mediated reactions.^{36–38} Amine-terminated peptides and fluorescent and biotin hydrazides, including Cascade Blue® hydrazide, have been successfully incorporated into protein fragments by transamidation during enzyme-catalyzed proteolysis.³⁹

Transamidation of cell-surface glutamine residues by the combination of a transglutaminase enzyme and a fluorescent or biotinylated aliphatic amine can form stable amides.²⁷ Impermeability of the enzyme restricts this reaction to a limited number of proteins on the cell surface. This technique was used to selectively label erythrocyte band 3 protein with dansyl cadaverine (D113) and proteins of the extracellular matrix with fluorescein cadaverine^{31,32} (A10466). Following protease treatment, the dansylated peptides were isolated using an anti-dansyl affinity column.⁴⁰

Figure 3.4.7 BODIPY® 493/503 methyl bromide (8-bromomethyl-4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-s-indacene, B2103).

Esterification of Carboxylic Acids with Fluorescent Diazoalkanes

Biologically important molecules, especially the nonchromophoric fatty acids, bile acids and prostaglandins, are typically esterified by carboxylic acid-reactive reagents in organic solvents. Esterification of carboxylic acids in aqueous solution is usually not possible, and esters tend to be unstable in water. Fluorescent derivatization reagents for biomedical chromatography have been extensively discussed in reviews.^{41,42}

HPLC derivatization reagents for carboxylic acids include two fluorescent analogs of the common esterification reagent diazomethane. Diazoalkanes react without the addition of catalysts and may be useful for direct carboxylic acid modification of proteins and synthetic polymers. Fluorescent diazoalkanes also react with phosphates⁴³ and potentially with lipid-associated carboxylic acids in membrane-bound proteins or with free fatty acids.

The fluorescent diazomethyl derivative 9-anthryldiazomethane (ADAM, A1400) has been commonly used to derivatize biomolecules. Unfortunately, ADAM is not very stable and may decompose during storage. 1-Pyrenyldiazomethane^{44–47} (PDAM, P1405) is recommended as a replacement for ADAM because it has much better chemical stability. Moreover, the detection limit for PDAM conjugates is reported to be about 20–30 femtomoles, which is five times better than reported for detection of ADAM conjugates.⁴⁵ In addition, fatty acids derivatized with these reagents have been used to measure phospholipase A₂ activity⁴⁸ (Section 17.4). It has been reported that photolysis of pyrenemethyl esters liberates the free carboxylic acid,⁴⁷ making PDAM a potential protecting group for carboxylic acids.

Figure 3.4.8 2-(2,3-Naphthalimino)ethyl trifluoromethanesulfonate (N2461).

Fluorescent Alkyl Halides

The low nucleophilicity of carboxylic acids requires that they be converted to anions (typically cesium or quaternary ammonium are used as counterions) before they can be esterified with alkyl halides in organic solvents. Conjugates of 6-bromoacetyl-2-dimethylaminonaphthalene (badan, B6057) have a high Stokes shift, as well as spectral properties that are very sensitive

to their environment. 5-(Bromomethyl)fluorescein (B1355, Figure 3.4.6) and BODIPY® 493/503 methyl bromide (B2103, Figure 3.4.7) have the strongest absorptivity and fluorescence of the currently available carboxylic acid-derivatization reagents.⁴⁹ An analytical method for estimating the degree of EDAC crosslinking of collagen has been developed based on derivatization of residual carboxyl groups by 5-bromomethylfluorescein.⁵⁰

All of the alkyl halides in this section also react with thiol groups, including those in proteins.^{51,52} Although more commonly used as thiol-reactive reagents, the monobromobimanes (M1378, M20381; Section 2.3) have been reported to react with carboxylic acids in organic solvents.⁵³ The coumarin iodoacetamide DCIA (D404, Section 2.3) has also been used to derivatize carboxylic acids;⁵⁴ other iodoacetamides described in Chapter 2 will probably react similarly.

Figure 3.4.9 4-Sulfo-2,3,5,6-tetrafluorophenol (STP, S10490) can be used to prepare water-soluble activated esters from various carboxylic acids.

Fluorescent Trifluoromethanesulfonate

2-(2,3-Naphthalimino)ethyl trifluoromethanesulfonate (N2461, Figure 3.4.8) reacts rapidly with the anions of carboxylic acids in acetonitrile to give adducts that are reported to be detectable by absorption at 259 nm down to 100 femtomoles and by fluorescence at 394 nm down to 4 femtomoles.⁵⁵ This naphthalimide sulfonate ester will likely react with other nucleophiles too, including thiols, amines, phenols (e.g., tyrosine) and probably histidine. 2-(2,3-Naphthalimino)ethyl trifluoromethanesulfonate has been used for the sensitive reverse-phase HPLC detection of eicosanoids in brain tissue.⁵⁶

4-Sulfo-2,3,5,6-Tetrafluorophenol (STP) and *N*-Hydroxysulfosuccinimide (NHSS)

4-Sulfo-2,3,5,6-tetrafluorophenol (STP, S10490) and *N*-hydroxysulfosuccinimide (NHSS, H2249) can be used to prepare water-soluble activated esters from various carboxylic acids (Figure 3.4.9). Coupling typically involves a carbodiimide such as EDAC (E2247) and is performed in an organic solvent. We have found that the resulting STP esters are much easier to purify and more stable than activated esters prepared from *N*-hydroxysulfosuccinimide.⁵⁷ NHSS esters of biotin and other derivatives considerably increase the aqueous solubility of the reagents.⁵⁸ We offer a variety of amine-reactive STP esters, which are discussed in Chapter 1.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. A191 in aqueous solution (pH 7.0): Abs = 342 nm (EC = 16,000 cm⁻¹M⁻¹), Em = 441 nm.
2. Absorption and fluorescence of fluorescein derivatives are pH dependent. Extinction coefficients and fluorescence quantum yields decrease markedly at pH <7.
3. The Alexa Fluor® 405 and Cascade Blue® dyes have a second absorption peak at about 376 nm with EC ~80% of the 395–400 nm peak.
4. The fluorescence lifetime (τ) of the Alexa Fluor® 488 dye in pH 7.4 buffer at 20°C is 4.1 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
5. Abs and Em of the Alexa Fluor® 488 dye are red-shifted by as much as 16 nm and 25 nm respectively on microarrays relative to aqueous solution values. The magnitude of the spectral shift depends on the array substrate material. (*Biotechniques* (2005) 38:127)
6. The absorption and fluorescence spectra of BODIPY® derivatives are relatively insensitive to the solvent.
7. Fluorescence emission spectrum shifts to shorter wavelengths in nonpolar solvents.
8. Absorption and fluorescence of Oregon Green® 488 derivatives are pH dependent only in moderately acidic solutions (pH <5).

PRODUCT LIST 3.4 DERIVATIZATION REAGENTS FOR CARBOXYLIC ACIDS AND CARBOXAMIDES

Cat. No.	Product	Quantity
A30674	Alexa Fluor® 350 cadaverine	1 mg
A30675	Alexa Fluor® 405 cadaverine, trisodium salt ⁴	1 mg
A30676	Alexa Fluor® 488 cadaverine, sodium salt	1 mg
A30677	Alexa Fluor® 555 cadaverine, disodium salt	1 mg
A30680	Alexa Fluor® 568 cadaverine, diammonium salt	1 mg
A30678	Alexa Fluor® 594 cadaverine	1 mg
A30679	Alexa Fluor® 647 cadaverine, disodium salt	1 mg
A1363	5-(aminoacetamido)fluorescein (fluoresceinyl glycine amide)	10 mg
A1339	<i>N</i> -(2-aminoethyl)-4-amino-3,6-disulfo-1,8-naphthalimide, dipotassium salt (lucifer yellow ethylenediamine)	25 mg
A91	5-((2-aminoethyl)amino)naphthalene-1-sulfonic acid, sodium salt (EDANS)	1 g
A191	7-amino-4-methylcoumarin *reference standard*	100 mg
A1351	4'-(aminomethyl)fluorescein, hydrochloride	25 mg
A1353	5-(aminomethyl)fluorescein, hydrochloride	10 mg
A1318	5-(and-6)-((<i>N</i> -(5-aminopentyl)amino)carbonyl)tetramethylrhodamine (tetramethylrhodamine cadaverine) *mixed isomers*	10 mg
A1340	<i>N</i> -(5-aminopentyl)-4-amino-3,6-disulfo-1,8-naphthalimide, dipotassium salt (lucifer yellow cadaverine)	25 mg
A10466	5-((5-aminopentyl)thioureidyl)fluorescein, dihydrobromide salt (fluorescein cadaverine)	25 mg
A1400	9-anthryldiazomethane (ADAM)	25 mg
B30633	bimane amine	5 mg
B2103	BODIPY® 493/503 methyl bromide (8-bromomethyl-4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-s-indacene)	5 mg
B6057	6-bromoacetyl-2-dimethylaminonaphthalene (badan)	10 mg
B1355	5-(bromomethyl)fluorescein	10 mg
C621	Cascade Blue® ethylenediamine, trisodium salt	10 mg
D10460	Dapoxyl® (2-aminoethyl)sulfonamide	10 mg
D2390	4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-propionyl ethylenediamine, hydrochloride (BODIPY® FL EDA)	5 mg
D6251	5-(((4-(4,4-difluoro-5-(2-thienyl)-4-bora-3a,4a-diaza-s-indacene-3-yl)phenoxy)acetyl)amino)pentylamine, hydrochloride (BODIPY® TR cadaverine)	5 mg
D112	5-dimethylaminonaphthalene-1-(<i>N</i> -(2-aminoethyl)sulfonamide (dansyl ethylenediamine)	100 mg
D113	5-dimethylaminonaphthalene-1-(<i>N</i> -(5-aminopentyl)sulfonamide (dansyl cadaverine)	100 mg
E2247	1-ethyl-3-(3-dimethylaminopropyl)carbodiimide, hydrochloride (EDAC)	100 mg
H2249	<i>N</i> -hydroxysulfosuccinimide, sodium salt (NHSS)	100 mg
L2424	Lissamine rhodamine B ethylenediamine	10 mg

4.1 Introduction to Avidin–Biotin and Antibody–Hapten Techniques

This chapter is devoted to our biotinylation, desthiobiotinylation and haptenylation reagents (Section 4.2) and our biotin and desthiobiotin (DSB-X™ biotin) conjugates (Section 4.3). For the detection of biotin and hapten conjugates, we prepare a large assortment of labeled avidin and antibody probes, which are described in Section 7.6 and Section 7.4, respectively. Our avidin- and biotin-coated FluoSpheres® microspheres (Section 6.5) and Qdot® nanocrystals (Section 6.6) provide alternative detection technologies that offer a combination of fluorescence intensity and photostability far superior to that of any simple dye conjugate.

Avidin–Biotin and Antibody–Hapten Techniques and Their Applications

The high affinity and specificity of avidin–biotin and antibody–hapten interactions have been exploited for diverse applications in immunology, histochemistry, *in situ* hybridization, affinity chromatography and many other areas.^{1–5} Biotinylation (Table 4.1) and haptenylation (Table 4.2) reagents provide the “tag” that transforms poorly detectable molecules into probes that can be recognized by a labeled detection reagent or an affinity-capture matrix. Once tagged with biotin or a hapten, a molecule of interest—such as an antibody, drug, oligonucleotide, polysaccharide or receptor ligand—can be used to probe cells and tissues, as well as protein and nucleic acid blots and arrays.^{6,7} After finding its target, this tagged molecule can be

* See Section 7.4 for a description of these anti-hapten antibodies. † Both the anti-tetramethylrhodamine and the anti-Texas Red® dye antibodies cross-react with tetramethylrhodamine, Lissamine rhodamine, Rhodamine Red™ and Texas Red® fluorophores. Therefore, these fluorophores should not be used simultaneously to generate separate signals in a multicolor experiment. Similarly, the anti-BODIPY® FL dye antibody may cross-react with other BODIPY® dyes, and the anti-fluorescein/Oregon Green® dye antibody cross-reacts with both fluorescein and Oregon Green® dyes.

Figure 4.1.1 The cytoskeleton of a fixed and permeabilized bovine pulmonary artery endothelial cell detected using mouse monoclonal anti- α -tubulin antibody (A11126), visualized with Alexa Fluor® 647 goat anti-mouse IgG antibody (A21235) and pseudocolored magenta. Endogenous biotin in the mitochondria was labeled with green-fluorescent Alexa Fluor® 488 streptavidin (S11223, S32354) and DNA was stained with blue-fluorescent DAPI (D1306, D3571, D21490).

Figure 4.1.2 The intermediate filaments in bovine pulmonary artery endothelial cells, localized using our anti-desmin antibody (A21283), which was visualized with the Alexa Fluor® 647 goat anti-mouse IgG antibody (A21235). Endogenous biotin in the mitochondria was labeled with Alexa Fluor® 546 streptavidin (S11225) and DNA in the cell was stained with blue-fluorescent DAPI (D1306, D3571, D21490).

Figure 4.1.3 Comparison of the structures of D-biotin (top) and D-desthiobiotin (bottom).

detected with the appropriate avidin or anti-hapten antibody conjugate labeled with a fluorophore, fluorescent microsphere, enzyme, magnetic particle or colloidal gold. Biotinylated molecules can also be captured with various forms of immobilized streptavidin, such as streptavidin agarose (S951), CaptAvidin™ agarose (C21386) or streptavidin-coupled magnetic Dynabeads® (www.invitrogen.com/handbook/dynabeads). Biotinylated probes can be developed for electron microscopy with NANOGOLD® or Alexa Fluor® FluoroNanogold™ streptavidin (N24918, A24926, A24927) or streptavidin-coupled Qdot® nanocrystals^{8–10} (Section 6.6). Our extensive array of avidin and streptavidin conjugates are described in Section 7.6.

Detection Methods Compatible with Avidin–Biotin Techniques

Avidin–biotin and antibody–hapten techniques are compatible with flow cytometry and light, electron and fluorescence microscopy, as well as with solution-based methods such as enzyme-linked immunosorbent assays (ELISAs). Moreover, avidin–biotin and antibody–hapten techniques are frequently combined for simultaneous, multicolor detection of multiple targets in complex tissue samples.¹¹ By judicious choice of detection reagents and sandwich protocols, these techniques can be employed to amplify signals from low-abundance analytes.¹² For example, the bridging method is a common immunohistochemical technique for signal amplification and improved tissue penetration in which avidin or streptavidin serves as a bridge between two biotinylated molecules.¹³ Other amplification strategies include the tyramide signal amplification (TSA™) technology (Section 6.2).

Endogenous Biotin and Biotinidase

Mammalian cells and tissues contain biotin-dependent carboxylases, which are required for a variety of metabolic functions. These biotin-containing enzymes often produce substantial background signals when biotin–avidin or biotin–streptavidin detection systems are used to identify cellular targets^{14,15} (Figure 4.1.1, Figure 4.1.2). Endogenous biotin is particularly prevalent in mitochondria^{16,17} and in kidney, liver and brain tissues.^{14,18} The reagents in the Endogenous Biotin-Blocking Kit (E21390), which is described in Section 7.6, can be used to minimize interference from endogenous biotin in these techniques. In mammalian serum and plasma, biotinylated proteins are susceptible to cleavage by endogenous biotinidases, producing free biotin and unlabeled protein.¹⁹

Modified Avidin and Biotin

CaptAvidin™ Biotin-Binding Protein

Although binding of biotin to native avidin or streptavidin is essentially irreversible, appropriately modified avidins can bind biotinylated probes reversibly, making them valuable reagents for isolating and purifying biotinylated molecules from complex mixtures. In the CaptAvidin™ biotin-binding protein (C21385, Section 7.6), selective nitration of tyrosine residues in the four biotin-binding sites of avidin considerably reduces the affinity of this protein for biotinylated molecules above pH 9.²⁰ Consequently, biotinylated probes can be adsorbed to CaptAvidin™ biotin-binding protein at neutral pH or below and released at ~pH 10.^{20,21} CaptAvidin™ agarose (C21386, Section 7.6) is particularly useful for separating and purifying biotin conjugates from complex mixtures.^{22,23}

DSB-X™ Biotin

In contrast to the modified avidin of the CaptAvidin™ products, our DSB-X™ biotin technology employs a modified biotin to provide a means of labeling and separating biomolecules, including live cells, under extremely gentle conditions.²⁴ The DSB-X™ biotin reagents, which are derivatives of desthiobiotin (Figure 4.1.3) with an additional seven-atom 'X' spacer, have moderate affinity for avidin and streptavidin that is rapidly reversed by low concentrations of free biotin or desthiobiotin at neutral pH and room temperature; the K_d for desthiobiotin binding to streptavidin has been reported to be 1.9 nM.²⁵ The DSB-X™ Biotin Protein Labeling Kit (D20655, Section 4.2) provides a convenient method for labeling proteins with the amine-reactive succinimidyl ester of DSB-X™ biotin and purifying the conjugate.

4.2 Biotinylation and Haptenylation Reagents

We are a primary manufacturer of a diverse array of biotinylation (Table 4.1) and haptenylation (Table 4.2) reagents for labeling biomolecules. Reviews of the methods that we use to prepare biotinylated¹ and fluorescent² conjugates of antibodies have been published. To make the labeling reactions particularly easy, we have developed some very useful kits for labeling proteins with biotin, DSB-X™ biotin, 2,4-dinitrophenyl (DNP) or a choice of several different fluorophores, as described below. Each of the protein labeling kits contains the preferred reactive dye or hapten—many of which have spacers to reduce interactions between the label and the biomolecule—along with a detailed protocol for preparing the conjugates. In most cases, these kits also provide the separation media for purifying labeled protein conjugates from the reaction mixture.

Biotin and Biotinylation Reagents

The primary building blocks for preparing biotinylation reagents are biotin (B1595, B20656), biotin-X and biotin-XX, where “X” represents a seven-atom aminohexanoyl spacer between biotin and the reactive carboxylic acid. This spacer helps to separate the biotin moiety from its point of attachment, potentially reducing the interaction of biotin with the biomolecule to which it is conjugated and enhancing its ability to bind to the relatively deep biotin-binding sites in avidin³ (Figure 4.2.1). D-Desthiobiotin (D20657) is the biological precursor to D-biotin^{4,5} and a key reagent in our DSB-X™ biotin technology.

We also offer biocytin (ϵ -biotinoyl-L-lysine, B1592), biotin ethylenediamine (A1593), biotin cadaverine (A1594) and biotin-X cadaverine (B1596) each of which contains a primary amine that allows it to be fixed in cells with aldehyde-based fixatives, facilitating subsequent detection with conjugates of avidin and streptavidin (Table 7.9). Biocytin derivatives, including probes that contain both biotin and fluorophore moieties, are commonly employed as microinjectable cell tracers and are discussed in Section 4.3 and Section 14.3.

Amine-Reactive Biotinylation Reagents

Although biotin succinimidyl ester (B1513) can be used to biotinylate amines in peptides, proteins and other biomolecules,⁶ we strongly recommend the biotin-X and biotin-XX succinimidyl esters (B1582, B1606), and especially the water-soluble biotin-X and biotin-XX sulfosuccinimidyl esters (B6353, B6352), because their additional 7- and 14-atom spacers greatly facilitate binding to avidin conjugates (Figure 4.2.1). We use biotin-X succinimidyl ester or the biotin-XX derivative to prepare all Molecular Probes® biotinylated protein and dextran conjugates. Red blood cells that were biotinylated with biotin-X succinimidyl ester—but surprisingly not those modified with biotin-X sulfosuccinimidyl ester—could be detected in circulation for almost 100 days after injection into dogs.⁷

The sulfosuccinimidyl esters of biotin-X and biotin-XX (B6353, B6352) have been extensively used as topological probes to label proteins in the outer membrane surface,⁸ yielding conjugates that can be separated by electrophoresis, blotted onto membranes and then detected with a fluorophore- or enzyme-conjugated avidin derivative (Table 7.9). We utilize biotin-XX sulfosuccinimidyl ester as a component in our Fluoreporter® Cell-Surface Biotinylation Kit (F20650).

Figure 4.2.1 ELISA-type assay comparing the binding capacity of bovine serum albumin (BSA) and goat anti-mouse IgG antibody (GAM) biotinylated with either biotin-X succinimidyl ester (B1582) or biotin-XX succinimidyl ester (B1606). The assay was developed using horseradish peroxidase (HRP) streptavidin (S911, 0.2 μ g/mL) and *o*-phenylenediamine dihydrochloride (OPD). The moles of biotin per mole of protein were: 4.0 biotin-X/GAM (●), 4.4 biotin-XX/GAM (○), 6.7 biotin-X/BSA (■) and 6.2 biotin-XX/GAM (□). Error bars on some data points have been omitted for clarity. Reprinted with permission from *Methods Mol Biol* (1995) 45:223.

Amine-Reactive Chromophoric Biotin Derivative

Determining a protein's degree of biotinylation is relatively difficult because of the lack of visible absorbance by the biotin molecule. To facilitate this determination, we offer an amine-reactive chromophoric derivative, biotin-X 2,4-dinitrophenyl-X-L-lysine succinimide ester (DNP-X-biotin-X, SE; B2604; Figure 4.2.2). Following protein conjugation, the extent of biotinylation is easily determined from the absorbance of the DNP chromophore ($\epsilon_{360} = 15,000 \text{ cm}^{-1}\text{M}^{-1}$). Incorporation of the DNP moiety into the biotinylation reagent does not affect its complexation with avidin or with anti-biotin antibodies. Our FluoReporter® Biotin/DNP Protein Labeling Kit (F6348), described below, contains sufficient DNP-X-biotin-X, SE for 5 to 10 protein labeling reactions of 0.2–2 mg each.

Thiol-Reactive Biotinylation Reagents

Although amine-reactive reagents are more commonly employed, the thiol-reactive biotin iodoacetamide, frequently identified in the literature by the acronym BIAM (B1591), biotin maleimide (M1602) and DSB-X™ biotin C₂-iodoacetamide (D30753) derivatives can also be used to label proteins and thiol-modified oligonucleotides.⁹ Biotin iodoacetamide and biotin maleimide are primarily used for biotinylation of free protein thiols in relation to investigations of thiol-disulfide exchange, disulfide isomerization, S-glutathionylation and other posttranslational modification processes.^{10–13}

We also offer TS-Link™ DSB-X™ biotin C₅-thiosulfate (TS-Link™ desthiobiotin-X C₅-thiosulfate, T30754), which is a water-soluble thiosulfate that reacts readily and selectively with a free thiol to form a disulfide bond (Figure 4.2.3). In contrast to the thioether bonds formed by maleimides and iodoacetamides, the disulfide bond formed by this TS-Link™ reagent is reversible—the TS-Link™ DSB-X™ hapten can easily be removed using a reducing agent such as dithiothreitol or tris-(2-carboxyethyl)phosphine (DTT, D1532; TCEP, T2556; Section 2.1), leaving the molecule of interest unchanged.

Click-iT® Biotin Alkyne and Biotin Azide Reagents

Click-iT® labeling and detection technology uses bioorthogonal reactive chemistry in which the reaction partners have no endogenous representation in biological molecules, cells, tissues or model organisms.^{14–16} The click reaction comprises a copper-catalyzed cycloaddition between an alkyne and an azide, forming a stable triazole conjugate (Section 3.1). The azide and alkyne moieties can be used interchangeably; either one can be used to tag the biomolecule of interest, whereas the other is used for subsequent detection. Moreover, the click chemistry labels—either the alkyne or the azide—provide a functional group that typically neither reacts with other cell components nor disrupts normal cell processes. The relative transparency to cell machinery of these labels means that tagged molecules are often acceptable substrates for enzymes that assemble these building blocks into biopolymers.

Figure 4.2.6 Nucleophilic attack of serine on the carbonyl group (C=O) of biotin-X, SSE (B6353) results in the stable O-acylated derivative. In addition to histidine-x-serine, this stable intermediate can be formed in the presence of linear sequences of histidine-x-tyrosine and histidine-x-threonine, where "x" refers to any amino acid.

Biotin alkyne (B10185, Figure 4.2.4) and biotin azide (B10184, Figure 4.2.5) are available for use in the detection and affinity capture of azide- and alkyne-modified biomolecules, respectively, using click chemistry.^{17–19} The biotin conjugate formed by the click reaction can subsequently be detected with a labeled avidin or streptavidin (Table 7.9). We also offer a Click-iT® Biotin Protein Analysis Detection Kit (C33372, Section 9.4) for detection of azide-functionalized glycoproteins in 1D or 2D electrophoresis gels or western blots.

Histidine, Serine and Threonine Modification with Biotin Derivatives

Tripeptide sequences of certain peptides such as gonadotropin releasing hormone (GnRH), wherein serine, threonine or tyrosine residues are separated from a histidine residue by a single amino acid, can be selectively acylated by the succinimidyl ester or sulfosuccinimidyl ester of biotin-X (B1582, B6353). This reaction probably involves formation of an acyl histidine intermediate, followed by intramolecular transfer of the label (Figure 4.2.6). *O*-acylation can be detected by treating the conjugate with hydroxylamine, which cleaves esters of biotin but not amides.²⁰ N-terminal serine and threonine residues of proteins can be oxidized by periodate and then biotinylated with biotin hydrazine derivatives²¹ (B1603, B2600, D20653), which are described below.

Aldehyde Modification with Biotin Hydrazides and Biotin Hydroxylamine (ARP)

As described in Section 3.3, aldehydes generated by periodate oxidation of vicinal diols in glycoproteins, polysaccharides and RNA or of N-terminal serine and threonine residues in proteins can be biotinylated using biotin-XX hydrazide (B2600). In cases where structural integrity may be compromised by periodate oxidation, derivatization with biotin hydrazide via reductive amination at the reducing end provides an alternative method for biotinylating carbohydrates.²² Biocytin hydrazide (B1603) may be preferred over biotin-XX hydrazide in some labeling protocols because of its higher water solubility.²³ As with our other DSB-X™ biotin reagents, DSB-X™ biotin hydrazide (desthiobiotin-X hydrazide, D20653) can be used to produce a DSB-X™ biotin-labeled molecule that exhibits easily reversible binding to avidin- or streptavidin-labeled reagents. Biotin hydrazides are also often used for detection and affinity capture of oxidatively damaged proteins via coupling to carbonyl groups.²⁴

The biotin-containing hydroxylamine derivative ARP (aldehyde-reactive probe, A10550) has been used to modify the exposed aldehyde group at abasic lesions in DNA^{25,26} (Figure 4.2.7). Abasic sites are generated spontaneously or can be caused by free radicals, ionizing radiation or mutagens like methyl methanesulfonate (MMS). A quick and sensitive microplate assay for abasic sites can be performed using ARP.²⁷

In addition, ARP is membrane permeant, permitting detection of abasic sites in live cells.^{28,29} Once the aldehyde group in an abasic site is modified by ARP and the cells are fixed and permeabilized, the resulting biotinylated DNA can be detected with fluorescent dye-, Qdot® nanocrystal- or enzyme-conjugated streptavidin conjugates (Table 7.9). Likewise, ARP can be used to detect and capture 4-hydroxynonenal (HNE)-modified proteins.³⁰ ARP has also been used to immobilize IgG antibodies on streptavidin-coated monolayer surfaces with their binding sites oriented toward the solution phase.³¹

Biotinylation of Carboxylic Acids

The biotin amines and hydrazides can be coupled to chemically activated carboxylic acids³² (Figure 4.2.8). The amine-containing biotin derivatives (B1592, A1593, A1594, B1596, N6356) are versatile intermediates for coupling biotin to DNA, carboxylic acids and array support surfaces.³³ The biotin cadaverines (A1594, B1596) and potentially our unique norbiotinamine³⁴ (N6356, Figure 4.2.9) are useful for transglutaminase-mediated modification of glutamine

Figure 4.2.7 Aldehyde-reactive probe (ARP) used to detect DNA damage. The biotin hydroxylamine ARP (A10550) reacts with aldehyde groups formed when reactive oxygen species depurinate DNA. This reaction forms a covalent bond linking the DNA to biotin. The biotin can then be detected using fluorophore- or enzyme-linked streptavidin.

Figure 4.2.9 Norbiotinamine, hydrochloride (N6356).

Figure 4.2.8 Conversion of a carboxylic acid group into an aliphatic amine. The activated carboxylic acid is derivatized with a half-protected aliphatic diamine (mono-*N*-(*t*-BOC)-propylenediamine, M6248), usually in an organic solvent, followed by removal of the *t*-BOC-protecting group with trifluoroacetic acid.

Figure 4.2.11 Comparison of the structures of D-biotin (top) and D-des-thiobiotin (bottom).

Figure 4.2.12 Identification of cell-surface proteins in Jurkat cells labeled with the FluoReporter® Cell-Surface Biotinylation Kit (F20650). The labeled cells were fractionated by differential detergent extraction into membrane and cytosolic fractions. The proteins were then precipitated with acetone, separated on an SDS-polyacrylamide gel and blotted onto a PVDF membrane. Total proteins were detected with the SYPRO® Ruby protein blot stain component of the kit (left panel); biotinylated proteins were identified with alkaline phosphatase-conjugated streptavidin in combination with the red-fluorescent substrate, DDAO phosphate (right panel). MW = protein molecular weight markers; Con A = biotinylated concanavalin A.

residues in cells and certain proteins^{35,36} (Section 3.4, Figure 4.2.10) and for the microplate assay of transglutaminase activity.^{37–39}

Reactive DSB-X™ Biotin Derivatives

Our unique DSB-X™ biotin technology (Section 4.1) permits the readily reversible binding of DSB-X™ biotin-labeled biomolecules to avidin and streptavidin derivatives.⁴⁰ The DSB-X™ biotin reagents, which are derivatives of desthiobiotin (Figure 4.2.11), have a moderate affinity for avidins (K_d for DSB binding to streptavidin is 1.9 nM^{41}), making DSB-X™ biotin an ideal ligand for transient immobilization of avidin and streptavidin conjugates. DSB-X™ biotin succinimidyl ester, which is a component of the DSB-X™ Biotin Protein Labeling Kit (D20655) described below, can be conjugated to amine-containing molecules in the same way as the biotin succinimidyl esters. Our DSB-X™ biotin C_2 -iodoacetamide (D30753) and TS-Link™ DSB-X™ biotin C_5 -thiosulfate (T30754) are thiol-reactive derivatives for labeling proteins and thiol-modified oligonucleotides. In addition, we offer aldehyde-reactive DSB-X™ biotin hydrazide (D20653).

Convenient Kits for Biotinyating Proteins

Biotin-XX Microscale Protein Labeling Kit

The Biotin-XX Microscale Protein Labeling Kit (B30010) provides a convenient means for biotinyating small amounts (20–100 μg) of purified protein. The kit has been optimized for labeling proteins with molecular weights between 12,000 and 150,000 daltons, and contains everything needed to perform three labeling reactions and to separate the resulting conjugates from excess reactive biotin. Convenient spin columns are used to purify the labeled protein with yields between 60 and 90%, depending primarily on the molecular weight of the starting material. Labeling and purification can be completed in as little as 30 minutes.

Each Biotin-XX Microscale Protein Labeling Kit contains:

- Biotin-XX sulfosuccinimidyl ester
- Sodium bicarbonate
- Reaction tubes
- Purification resin and spin filters
- Protocols for preparing and purifying the biotinylated protein

For determining the degree of labeling, the FluoReporter® Biotin Quantitation Assay Kit for proteins is available separately (F30751) or in combination with the Biotin-XX Microscale Protein Labeling Kit (B30756). When biotinyating larger amounts of protein, we recommend the FluoReporter® Mini-Biotin-XX Protein Labeling Kit, which is optimized for 0.1–3 mg samples of >40,000-dalton proteins, or the FluoReporter® Biotin-XX Protein Labeling Kit, which is optimized for 5–20 mg samples; see below for a description of these kits.

FluoReporter® Mini-Biotin-XX Protein Labeling Kit

The FluoReporter® Mini-Biotin-XX Protein Labeling Kit (F6347) provides a method for efficiently biotinyating small amounts of antibodies or other proteins. The water-soluble biotin-XX sulfosuccinimidyl ester contained in this kit readily reacts with a protein's amines to yield a biotin moiety that is linked to the protein through two tandem aminoheptanoyl chains ("XX"). This 14-atom spacer has been shown to enhance the binding of biotin derivatives to avidin's relatively deep binding sites (Figure 4.2.1).

Figure 4.2.10 Transglutaminase-mediated labeling of a protein using dansyl cadaverine (D113).

Each FluoReporter® Mini-Biotin-XX Labeling Kit contains:

- Biotin-XX sulfosuccinimidyl ester
- Reaction tubes, each containing a magnetic spin bar
- Purification resin, spin columns and collection tubes
- Dialysis tubing (molecular weight cut-off ~12,000–14,000 daltons)
- Protocols for preparing and purifying the biotinylated protein

The ready-to-use spin columns provide an extremely convenient method of purifying the biotinylated protein from excess biotinylation reagents. Alternatively, the researcher may choose to remove excess reagents by dialysis, thereby avoiding further dilution of the biotinylated protein. The FluoReporter® Mini-Biotin-XX Protein Labeling Kit contains sufficient reagents for five biotinylation reactions of 0.1–3 mg of protein each.

FluoReporter® Biotin-XX Protein Labeling Kit

We also offer the FluoReporter® Biotin-XX Protein Labeling Kit (F2610) for larger-scale biotinylation reactions. Once the labeled protein is purified from excess biotin reagent, its degree of biotinylation can be determined using an avidin–biotin displacement assay;^{42,43} biotinylated goat IgG is provided as a control.

The FluoReporter® Biotin-XX Protein Labeling Kit supplies:

- Biotin-XX succinimidyl ester
- Dimethylsulfoxide (DMSO)
- Gel filtration column
- Avidin–HABA complex
- Biotinylated goat IgG
- Protocols for preparing and purifying the biotinylated protein, as well as for quantitating the degree of labeling

The FluoReporter® Biotin-XX Protein Labeling Kit provides sufficient reagents for five labeling reactions of 5–20 mg of protein each.

FluoReporter® Biotin/DNP Protein Labeling Kit

The FluoReporter® Biotin/DNP Protein Labeling Kit (F6348, Table 1.3) is similar to our other FluoReporter® Protein Labeling Kits, except that it contains DNP-X–biotin-X succinimidyl ester as the reactive label. When proteins are labeled with this chromophoric biotin derivative, the degree of biotinylation can be readily assessed from the extinction coefficient of DNP ($EC_{364} = 15,000 \text{ cm}^{-1}\text{M}^{-1}$). An additional feature of the conjugates labeled with DNP-X–biotin-X succinimidyl ester is that they can be recognized by avidin derivatives (or anti-biotin antibodies) and by anti-DNP antibodies, enabling researchers to choose among several detection techniques suitable for fluorescence and electron microscopy.

Each FluoReporter® Biotin/DNP Protein Labeling Kit contains:

- DNP-X–biotin-X succinimidyl ester
- Dimethylsulfoxide (DMSO)
- Reaction tubes, each containing a magnetic spin bar
- Spin columns plus collection tubes
- Protocols for preparing and purifying the protein conjugate, as well as for quantitating the degree of labeling

The FluoReporter® Biotin/DNP Protein Labeling Kit supplies sufficient reagents for 5 to 10 labeling reactions of 0.2–2 mg of protein each.

DSB-X™ Biotin Protein Labeling Kit

Our unique DSB-X™ biotin technology permits the facile reversal of the typically irreversible biotin–avidin interaction under extremely gentle conditions.⁴⁰ DSB-X™ biotin succinimidyl ester, a derivative of desthiobiotin (Figure 4.2.11) with an additional seven-atom spacer, reacts with amine groups of biomolecules to form stable amides. The DSB-X™ biotin conjugate can be detected with any of the avidin or streptavidin derivatives described in Table 7.9. Binding is almost totally reversed by addition of free biotin (B1595, B20656) at neutral pH and normal ionic strength. Significantly, DSB-X™ biotin–conjugated biopolymers can be separated from complex mixtures using agarose affinity matrices.

The DSB-X™ Biotin Protein Labeling Kit (D20655, Table 1.3) contains the reagents required for five protein conjugations of 0.5–3 mg each, including:

- DSB-X™ biotin succinimidyl ester
- Dimethylsulfoxide (DMSO)
- Reaction tubes
- Purification resin, spin columns and collection tubes for small-scale purifications
- Dialysis tubing for larger-scale purifications
- Detailed protocols for conjugations and purifications

FluoReporter® Cell-Surface Biotinylation Kit

Biotin-XX sulfosuccinimidyl ester is a membrane-impermeant, amine-reactive compound that may be used to label proteins exposed on the surface of live cells^{8,44} (Figure 4.2.12). The sulfosuccinimidyl ester forms an extremely stable conjugate with cell-surface proteins, and the biotin provides a convenient hapten for subsequent isolation or analysis with an avidin-based protein, including streptavidin, NeutrAvidin™ and CaptAvidin™ biotin-binding proteins (Table 7.9). Cell-surface biotinylation techniques have been employed to differentially label proteins in the apical and basolateral plasma membranes of epithelial cells.^{45,46} These techniques are also well suited for studying internalization of membrane proteins and cell-surface targeting of proteins.^{47–49}

The FluoReporter® Cell-Surface Biotinylation Kit (F20650) provides a convenient method to label proteins exposed on the cell surface including, but not limited to, membrane proteins. This kit includes:

- Biotin-XX sulfosuccinimidyl ester
- Anhydrous DMSO for preparing stable stock solutions
- Detailed protocols for cell-surface biotinylation

The supplied protocol for cell-surface biotinylation is easy to perform and can typically be completed in less than one hour. Biotinylated proteins can be subsequently identified using western blot techniques and labeled avidin conjugates⁴⁴ described in Section 6.6 and Section 7.6.

Zenon® Biotin Antibody Labeling Kits

Zenon® Antibody Labeling Kits provide a fast, versatile and reliable method for producing antibody conjugates that can be used in any application where a directly labeled primary antibody is suitable,

Figure 4.2.13 Labeling scheme utilized in the Zenon® Antibody Labeling Kits. A) An unlabeled IgG antibody is incubated with the Zenon® labeling reagent, which contains a fluorophore-labeled, Fc-specific anti-IgG Fab fragment. B) This labeled Fab fragment binds to the Fc portion of the IgG antibody. C) Excess Fab fragment is then neutralized by the addition of a nonspecific IgG, preventing cross-labeling by the Fab fragment in experiments where primary antibodies of the same type are present. Note that the Fab fragment used for labeling need not be coupled to a fluorophore, but could instead be coupled to an enzyme (such as HRP) or to biotin.

including microscopy, flow cytometry, high-throughput screening, and others. This enabling technology not only eliminates the need for secondary detection reagents in many protocols, but also simplifies immunolabeling protocols that previously were time consuming or impractical, such as use of multiple antibodies derived from the same species in the same protocol.^{50,51} We have applied our exclusive Zenon® technology (Section 7.3) in several Zenon® Biotin-XX Antibody Labeling Kits, which permit the quantitative biotinylation of even submicrogram quantities of an antibody typically in less than 10 minutes.

The Zenon® Biotin-XX Antibody Labeling Kits include:

- Zenon® Biotin-XX Mouse IgG₁ Labeling Kit (Z25052)
- Zenon® Biotin XX Mouse IgG_{2a} Labeling Kit (Z25152)
- Zenon® Biotin-XX Mouse IgG_{2b} Labeling Kit (Z25252)
- Zenon® Biotin-XX Rabbit IgG Labeling Kit (Z25352)
- Zenon® Biotin-XX Human IgG Labeling Kit (Z25452)

Zenon® Antibody Labeling Kits are designed to label intact primary antibodies in amounts from less than 1 µg to as much as 50 µg, starting with a purified antibody fraction or with a crude antibody preparation such as ascites fluid or a hybridoma supernatant. Zenon® labeling technology takes advantage of the immunoselectivity of the antibody binding reaction by forming a complex between an intact primary IgG antibody and a biotin-labeled Fab fragment directed against the Fc portion of the IgG. Simple mixing of the labeled Fab fragment supplied in the Zenon® Antibody Labeling Kit with the corresponding primary antibody quantitatively produces the Fab-antibody complex typically in under 10 minutes, with no pre- or post-labeling purification required (Figure 4.2.13). This labeled Fab-antibody complex can be immediately used to stain cells, tissues and other targets in the same manner as a covalently labeled primary antibody.

Each Zenon® Biotin Antibody Labeling Kit provides:

- Zenon® antibody labeling reagent
- Zenon® blocking reagent
- Detailed protocols for antibody labeling

The Zenon® Biotin Antibody Labeling Kit contains sufficient reagents for 50 labelings, where one labeling is defined as the amount of Zenon® labeling reagent required to label 1 µg of an intact, affinity-purified IgG antibody at a Fab:antibody molar ratio of 3:1.

Biotin Quantitation Assay Kits

FluoReporter® Biotin Quantitation Assay Kit for Biotinylated Proteins

The FluoReporter® Biotin Quantitation Assay Kit for biotinylated proteins (F30751) is designed to provide a sensitive fluorometric assay for accurately determining the number of biotin labels on a protein. The assay is based on the displacement of a ligand tagged with a quencher dye from the biotin-binding sites of Biotective™ Green reagent⁵² (Figure 4.2.14). The assay can detect from 4 to 80 picomoles of biotin in a sample (Figure 4.2.15), providing a 50-fold higher sensitivity than the traditional HABA biotin-binding assay.⁵³ Furthermore, unlike the HABA biotin-binding assay, which requires ~1 mg of protein sample, the FluoReporter® biotin quantitation assay requires only a minimum of 600 ng of a singly biotinylated IgG of MW 150,000. For proteins of lower molecular weight or multiple biotin labels, less protein can be used. To expose any biotin groups in a multiply labeled protein that are sterically restricted and inaccessible to the Biotective™ Green reagent, this kit includes protease and an optional protocol for digesting the protein. After this preliminary digestion, biotin assay values agree well with MALDI-TOF determinations. With excitation/emission maxima of 495/519 nm, this assay is compatible with any fluorescence-based microplate reader capable of detecting fluorescein (FITC) or Alexa Fluor® 488 dye; it can also be scaled up for fluorometer-based experiments.

Figure 4.2.14 Schematic representation of the FluoReporter® biotin quantitation assay. This assay uses Biotective™ Green reagent, which consists of avidin labeled with a fluorescent dye (D) and with quencher dye ligands (Q) occupying the biotin-binding sites. Through fluorescence resonance energy transfer (FRET), the ligand quenches the fluorescence. Biotin (B) attached to a protein displaces the quencher dye from Biotective™ Green reagent, yielding fluorescence proportional to the amount of added biotin.

Each Fluoreporter® Biotin Quantitation Assay Kit for biotinylated proteins includes:

- Biotective™ Green reagent
- Biotin
- Protease
- Concentrated phosphate-buffered saline (PBS)
- Biotinylated goat anti-mouse IgG antibody
- Detailed protocols

Sufficient reagents are provided for assaying 5 samples independently using eight wells in triplicate for the standard curve and three dilutions of the sample in triplicate (totaling 33 wells per assay). However, fewer wells may be used to conserve sample and a single standard curve can be used for multiple samples in the same experimental session. Biotinylated lysine is provided as a standard for the assay because it more closely represents the form of biotin present after proteolytic cleavage. Biotinylated goat anti-mouse IgG antibody is also provided as a positive control and biotinylated protein standard.

Fluoreporter® Biotin Quantitation Assay Kit for Biotinylated Nucleic Acids

The Fluoreporter® Biotin Quantitation Assay Kit for biotinylated nucleic acids (F30755) provides a sensitive fluorometric assay for determining the number of biotin labels on a nucleic acid. The assay is based on the displacement of a quencher dye from the biotin-binding sites of Biotective™ Green reagent⁵² (Figure 4.2.14). The assay can detect from 4 to 80 picomoles of biotin in a sample (Figure 4.2.16), providing a 50-fold higher sensitivity than the traditional HABA biotin-binding assay.⁵³ Analysis of multiply biotinylated nucleic acids requires a preliminary nuclease digestion step to avoid underestimation caused by steric restriction of avidin binding. This kit is ideal for determining the degree of biotinylation of cDNA samples used in Affymetrix or RLS microarray protocols, and it can be applied to as little as 13 ng of biotin-labeled nucleic acid (Table 4.3).

Each Fluoreporter® Biotin Quantitation Assay Kit for biotinylated nucleic acids includes:

- Biotective™ Green reagent
- Biotin-dUMP
- Nuclease
- Concentrated phosphate-buffered saline (PBS)
- Biotinylated DNA positive control
- Concentrated nucleic acid digestion buffer
- Detailed protocols

Sufficient reagents are provided for assaying 10 samples independently using eight wells in triplicate for the standard curve and three dilutions of the sample in triplicate (totaling 33 wells per assay). However, fewer wells may be used to conserve sample and a single standard curve can be used for multiple samples in the same experimental session.

Haptenylation Reagents

A prerequisite for multicolor applications such as fluorescence *in situ* hybridization is the availability of multiple hapten molecules, along with their complementary binding proteins. The avidin-biotin system can provide only single-color detection, whereas antibody-hapten methods can generate a number of unique signals, limited only by the specificity of the antibody-hapten detection and the ability to distinguish the signals of different antibodies. The characteristics of a suitable hapten include a unique chemical structure that is not commonly found in cells (a bioorthogonal label), a high degree of antigenicity that elicits good antibody production, and a means for incorporating the hapten into the detection system. Our selection of haptenylation reagents enables researchers to covalently attach haptens to proteins, nucleotides and other biomolecules.

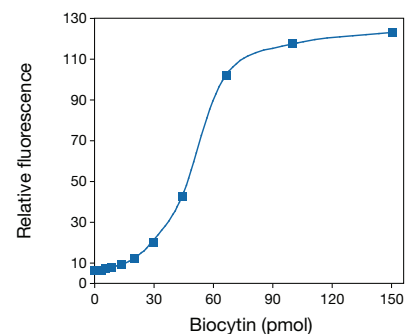

Figure 4.2.15 Standard curve showing dynamic range of the Fluoreporter® Biotin Quantitation Assay Kit. Each reaction consisted of 1X PBS, 1X Biotective™ Green reagent and biotin in a total volume of 100 μ L. After a 5-minute incubation at room temperature in the dark, fluorescence was measured in a microplate reader using excitation at 485 ± 10 nm and fluorescence emission at 530 ± 12.5 nm.

Figure 4.2.16 Standard curve showing dynamic range of the Fluoreporter® Biotin Quantitation Assay Kit. Each reaction consisted of 0.5X PBS, 25 mM CHES buffer, pH 9.3, 1 mM CaCl_2 , 1X Biotective™ Green reagent and biotin-dUMP in a total volume of 100 μ L. After a 5-minute incubation at room temperature in the dark, fluorescence was measured in a microplate reader using excitation at 485 ± 7.5 nm and fluorescence emission at 535 ± 12.5 nm.

Table 4.3 Sensitivity of the Fluoreporter® Biotin Quantitation Assay Kit for biotinylated nucleic acids with varying degrees of biotinylation.

Level of Labeling	Amount of DNA *Within Range of Assay (ng)
1 biotin: 10 bases	13–264
1 biotin: 50 bases	66–1300
1 biotin: 100 bases	132–2640
1 biotin: 200 bases	264–5280

* To convert ng of DNA to nanomoles or picomoles, use 330 g/mole for average molecular weight of a single base.

In addition to our wide range of biotinylation reagents discussed above, we provide many unique haptenylation reagents, including an amine-reactive version of digoxigenin (A2952), dinitrophenyl-X⁵⁴ (DNP-X, SE; D2248) and several fluorophores (Table 4.2). We usually recommend haptenylation reagents that contain spacers between the hapten and the reactive groups to reduce potential interactions with the biomolecule to which it is conjugated and to make the hapten maximally available to secondary detection reagents. Most of the preferred haptenylation reagents in Table 4.2 possess this feature.

Fluorescein has been found to be an excellent hapten for *in situ* hybridization because it binds with high affinity to its anti-fluorescein antibody.^{55–57} Anti-fluorescein antibodies cross-react with all of the Oregon Green® dyes (Section 1.5), permitting their use with conjugates prepared from these dyes. By adding antibodies that recognize the Alexa Fluor® 488, dansyl, tetramethylrhodamine and Texas Red® fluorophores to our line of detection reagents (Section 7.4), we have greatly expanded the number of potential haptens. Because the anti-tetramethylrhodamine and anti-Texas Red® dye antibodies cross-react with the tetramethylrhodamine, Lissamine rhodamine, Rhodamine Red™ and Texas Red® fluorophores, these antibody–fluorophore combinations should not be used simultaneously to generate separate signals in a multicolor experiment. Similarly, our antibody to the BODIPY® FL dye cross-reacts with some of the other BODIPY® dyes (Section 1.4).

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. This sulfonated succinimidyl ester derivative is water soluble and may be dissolved in buffer at ~pH 8 for reaction with amines. Long-term storage in water is NOT recommended due to hydrolysis.
2. The fluorescence lifetime (τ) of the Alexa Fluor® 488 dye in pH 7.4 buffer at 20°C is 4.1 nanoseconds. Data provided by the SPEX Fluorescence Group, Horiba Jobin Yvon Inc.
3. A20100 is an alternative packaging of A20000 but is otherwise identical.
4. Abs and Em of the Alexa Fluor® 488 dye are red-shifted by as much as 16 nm and 25 nm respectively on microarrays relative to aqueous solution values. The magnitude of the spectral shift depends on the array substrate material. (*Biotechniques* (2005) 38:127)
5. The Alexa Fluor® 405 and Cascade Blue® dyes have a second absorption peak at about 376 nm with EC ~80% of the 395–400 nm peak.
6. A30100 is an alternative packaging of A30000 but is otherwise identical.
7. TFP and SDP ester derivatives are water-soluble and may be dissolved in buffer at ~pH 8 for reaction with amines. Long-term storage in water is NOT recommended due to hydrolysis.
8. Iodoacetamides in solution undergo rapid photodecomposition to unreactive products. Minimize exposure to light prior to reaction.
9. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
10. Unstable in water. Use immediately.
11. The absorption and fluorescence spectra of BODIPY® derivatives are relatively insensitive to the solvent.
12. The dissociation constant (K_d) for desthiobiotin binding to streptavidin is 1.9 nM. (*Bioconjug Chem* (2006) 17:366)
13. Absorption and fluorescence of fluorescein derivatives are pH dependent. Extinction coefficients and fluorescence quantum yields decrease markedly at pH <7.
14. Absorption and fluorescence of Oregon Green® 488 derivatives are pH dependent only in moderately acidic solutions (pH <5).
15. This sulfotetrafluorophenyl (STP) ester derivative is water soluble and may be dissolved in buffer at ~pH 8 for reaction with amines. Long-term storage in water is NOT recommended due to hydrolysis.

PRODUCT LIST 4.2 BIOTINYLATION AND HAPTENYLATION REAGENTS

Cat. No.	Description	Quantity
A30000	Alexa Fluor® 405 carboxylic acid, succinimidyl ester	1 mg
A30100	Alexa Fluor® 405 carboxylic acid, succinimidyl ester	5 mg
A20000	Alexa Fluor® 488 carboxylic acid, succinimidyl ester *mixed isomers*	1 mg
A20100	Alexa Fluor® 488 carboxylic acid, succinimidyl ester *mixed isomers*	5 mg
A30005	Alexa Fluor® 488 carboxylic acid, 2,3,5,6-tetrafluorophenyl ester (Alexa Fluor® 488 5-TFP) *5-isomer*	1 mg
A30052	Alexa Fluor® 488 5-SDP ester (Alexa Fluor® 488 sulfodichlorophenyl ester)	1 mg
A2952	3-amino-3-deoxydigoxigenin hemisuccinamide, succinimidyl ester	5 mg
A1593	N-(2-aminoethyl)biotinamide, hydrobromide (biotin ethylenediamine)	25 mg
A10550	N-(2-aminoxyacetyl)-N'-(D-biotinoyl) hydrazine, trifluoroacetic acid salt (ARP)	10 mg
A1594	N-(5-aminopentyl)biotinamide, trifluoroacetic acid salt (biotin cadaverine)	25 mg
B1592	biocytin (ϵ -biotinoyl-L-lysine)	100 mg
B1603	biocytin hydrazide	25 mg
B1595	D-biotin	1 g
B20656	D-biotin *50 mM aqueous solution*	10 mL
B10185	biotin alkyne (PEG ₄ carboxamide-propargyl biotin)	1 mg
B10184	biotin azide (PEG ₄ carboxamide-6-azidohexanyl biotin)	1 mg
B1582	6-((biotinoyl)amino)hexanoic acid, succinimidyl ester (biotin-X, SE; biotinamidocaproate, N-hydroxysuccinimidyl ester)	100 mg
B6353	6-((biotinoyl)amino)hexanoic acid, sulfosuccinimidyl ester, sodium salt (Sulfo-NHS-LC-Biotin; biotin-X, SSE)	25 mg
B1606	6-(((6-((biotinoyl)amino)hexanoyl)amino)hexanoic acid, succinimidyl ester (biotin-XX, SE)	100 mg
B6352	6-(((6-((biotinoyl)amino)hexanoyl)amino)hexanoic acid, sulfosuccinimidyl ester, sodium salt (biotin-XX, SSE)	25 mg
B1591	N-(biotinoyl)-N'-(iodoacetyl)ethylenediamine	25 mg
B1513	D-biotin, succinimidyl ester (succinimidyl D-biotin)	100 mg
B1596	biotin-X cadaverine (5-(((N-(biotinoyl)amino)hexanoyl)amino)pentylamine, trifluoroacetic acid salt)	10 mg
B2604	biotin-X 2,4-dinitrophenyl-X-L-lysine, succinimidyl ester (DNP-X-biocytin-X, SE)	5 mg
B2600	biotin-XX hydrazide (6-(((6-((biotinoyl)amino)hexanoyl)amino)hexanoic acid, hydrazide)	25 mg
B30010	Biotin-XX Microscale Protein Labeling Kit *for 20–100 μ g protein* *3 labelings*	1 kit
B30756	Biotin-XX Microscale Protein Labeling Kit with Fluoreporter® Biotin Quantitation Assay Kit *includes B30010 and F30751*	1 kit
B10006	BODIPY® FL, STP ester, sodium salt	5 mg
C2284	Cascade Blue® acetyl azide, trisodium salt	5 mg

PRODUCT LIST 4.2 BIOTINYLATION AND HAPTENYLATION REAGENTS—*continued*

Cat. No.	Description	Quantity
D20657	D-desthiobiotin *50 mM aqueous solution*	10 mL
D6102	6-((4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-propionyl)amino)hexanoic acid, succinimidyl ester (BODIPY® FL-X, SE)	5 mg
D6104	6-((5-dimethylaminonaphthalene-1-sulfonyl)amino)hexanoic acid, succinimidyl ester (dansyl-X, SE)	25 mg
D2248	6-(2,4-dinitrophenyl)amino)hexanoic acid, succinimidyl ester (DNP-X, SE)	25 mg
D30753	DSB-X™ biotin C ₂ -iodoacetamide (desthiobiotin-X C ₂ -iodoacetamide)	5 mg
D20653	DSB-X™ biotin hydrazide	5 mg
D20655	DSB-X™ Biotin Protein Labeling Kit *5 labelings*	1 kit
F30755	FluoReporter® Biotin Quantitation Assay Kit *for biotinylated nucleic acids* *10 determinations*	1 kit
F30751	FluoReporter® Biotin Quantitation Assay Kit *for biotinylated proteins* *5 determinations*	1 kit
F6348	FluoReporter® Biotin/DNP Protein Labeling Kit *5–10 labelings*	1 kit
F2610	FluoReporter® Biotin-XX Protein Labeling Kit *5 labelings of 5–20 mg protein each*	1 kit
F20650	FluoReporter® Cell-Surface Biotinylation Kit	1 kit
F6347	FluoReporter® Mini-biotin-XX Protein Labeling Kit *5 labelings of 0.1–3 mg protein each*	1 kit
F2181	6-(fluorescein-5-(and-6)-carboxamido)hexanoic acid, succinimidyl ester (5(6)-SFX) *mixed isomers*	10 mg
F6130	fluorescein-5-EX, succinimidyl ester	10 mg
L1338	lucifer yellow iodoacetamide, dipotassium salt	25 mg
M1602	Na-(3-maleimidylpropionyl)biocytin	25 mg
N6356	norbiotinamine, hydrochloride	10 mg
O6185	Oregon Green® 488-X, succinimidyl ester *6-isomer*	5 mg
R6160	Rhodamine Red™-X, succinimidyl ester *5-isomer*	5 mg
T6105	6-(tetramethylrhodamine-5-(and-6)-carboxamido)hexanoic acid, succinimidyl ester (5(6)-TAMRA-X, SE) *mixed isomers*	10 mg
T6134	Texas Red®-X, succinimidyl ester *mixed isomers*	5 mg
T20175	Texas Red®-X, succinimidyl ester *single isomer*	2 mg
T30754	TS-Link™ DSB-X™ biotin C ₅ -thiosulfate (TS-Link™ desthiobiotin-X C ₅ -thiosulfate, sodium salt)	5 mg
Z25452	Zenon® Biotin-XX Human IgG Labeling Kit *50 labelings*	1 kit
Z25052	Zenon® Biotin-XX Mouse IgG ₁ Labeling Kit *50 labelings*	1 kit
Z25152	Zenon® Biotin-XX Mouse IgG _{2a} Labeling Kit *50 labelings*	1 kit
Z25252	Zenon® Biotin-XX Mouse IgG _{2b} Labeling Kit *50 labelings*	1 kit
Z25352	Zenon® Biotin-XX Rabbit IgG Labeling Kit *50 labelings*	1 kit

4.3 Biotin and Desthiobiotin Conjugates

Figure 4.3.1 5-((N-(5-(N-(6-(biotinoyl)amino)hexanoyl)amino)pentyl)thioureidyl)fluorescein (fluorescein biotin, B1370).

Figure 4.3.2 Biotin-4-fluorescein (B10570).

We prepare a wide array of biotin and desthiobiotin conjugates, all of which are included in this section's product list. We will also custom-conjugate biotin, desthiobiotin (DSB-X™), fluorophores or other haptens to proteins or other biomolecules of interest; contact Invitrogen Custom Services to request a quote.

Fluorescent Biotin Derivatives

Fluorescein Biotin

Fluorescein biotin (B1370, Figure 4.3.1) was developed as an alternative to radioactive biotin for detecting and quantitating biotin-binding sites by either fluorescence or absorbance.¹ A fluorescence polarization-based assay that employs competitive binding of fluorescein biotin to assess the degree of protein biotinylation has been reported² (Fluorescence Polarization (FP)—Note 1.4). A similar derivative was used for determining avidin and biotin concentrations by fluorescence depolarization.³

Biotin-4-Fluorescein

Our biotin-4-fluorescein (B10570, Figure 4.3.2) offers a substantially improved method for quantitating biotin-binding sites. Biotin-4-fluorescein binds to avidin much faster than does conventional fluorescein biotin, allowing for rapid analysis.⁴ The strong quenching associated with avidin binding to biotin-4-fluorescein can be used to accurately measure the concentration of avidin or streptavidin⁵ (Figure 4.3.3). Engineered single-chain dimers created by circular

permutation of wild-type streptavidin exhibit substantial binding preference for biotin-4-fluorescein relative to biotin.⁶

Other Fluorescent Biotin Derivatives

In addition to supplying nonfluorescent biocytin (ϵ -biotinoyl-L-lysine, B1592, Section 4.2), we offer:

- Alexa Fluor® 488 biocytin (A12924, Figure 4.3.4)
- Alexa Fluor® 546 biocytin (A12923)
- Alexa Fluor® 594 biocytin (A12922, Figure 4.3.5)
- Lucifer yellow cadaverine biotin-X (L2601)
- Lucifer yellow biocytin (L6950)
- Oregon Green® 488 biocytin (O12920)
- Tetramethylrhodamine biocytin (T12921)

Each of these reagents contains both a fluorophore and biotin moiety in the same molecule. As with fluorescein biotin and biotin-4-fluorescein, which are described above, these reagents can be employed for detecting and quantitating biotin-binding proteins, but their principal application is as aldehyde-fixable polar cell tracers and as tracers for cell-cell communication^{7,8} (Section 14.3). Our lucifer yellow cadaverine biotin-X is reportedly well retained in aldehyde-fixed tissues, even after sectioning, extraction with detergents and several washes.⁹

Biotinylated Dextrans

In addition to the low molecular weight biotinylated tracers described above, we prepare a variety of biotinylated dextrans (Figure 4.3.6, Table 14.4), including dextrans that are double-labeled with fluorophores and biotin moieties for correlated fluorescence and electron microscopy studies. We currently offer the following biotinylated dextrans:

- Dextran, biotin, 3000 MW, lysine fixable (BDA-3000) (D7135)
- Dextran, biotin, 10,000 MW, lysine fixable (BDA-10,000) (D1956)
- Dextran, biotin, 70,000 MW, lysine fixable (BDA-70,000) (D1957)
- Dextran, biotin, 500,000 MW, lysine fixable (BDA-500,000) (D7142)
- Dextran, fluorescein and biotin, 3000 MW, anionic, lysine fixable (micro-emerald) (D7156)
- Dextran, fluorescein and biotin, 10,000 MW, anionic, lysine fixable (mini-emerald) (D7178)
- Dextran, tetramethylrhodamine and biotin, 3000 MW, lysine fixable (micro-ruby) (D7162)
- Dextran, tetramethylrhodamine and biotin, 10,000 MW, lysine fixable (mini-ruby) (D3312)

Figure 4.3.6 Motor neuron in a three-day chick embryo labeled with lysine-fixable, biotinylated 3000 MW dextran (BDA-3000, D7135). Filled neurons were detected with biotinylated horseradish peroxidase (P917) and diaminobenzidine using standard avidin/streptavidin bridging techniques. Reprinted with permission from *J Neurosci Methods* (1993) 50:95.

Figure 4.3.3 Quantitation of biotin-binding sites with 8 nM biotin-4-fluorescein (B10570). Both the fluorescence and absorbance of biotin-4-fluorescein are quenched upon binding to one of the four biotin-binding sites of streptavidin (S888, pink), avidin (A887, A2667; dark blue), or the streptavidin conjugates of the Alexa Fluor® 633 dye (S21375, orange) and alkaline phosphatase (S921, light blue). As a result, when a known concentration of biotin-4-fluorescein is added to a known amount of streptavidin, one can estimate the number of biotin-binding sites.

Figure 4.3.4 Alexa Fluor® 488 biocytin, disodium salt (biocytin Alexa Fluor® 488, A12924).

Figure 4.3.5 Alexa Fluor® 594 biocytin, sodium salt (biocytin Alexa Fluor® 594, A12922).

Dextrans are hydrophilic polysaccharides characterized by their moderate to high molecular weight, good water solubility and low toxicity. They are biologically inert due to their uncommon poly-(α -D-1,6-glucose) linkages, which render them resistant to cleavage by most endogenous cellular glycosidases. Dextrans are widely used as both anterograde and retrograde tracers in neurons and for many other diverse applications; see Section 14.5 for a discussion of the applications of these reagents, particularly as cell tracers.

Biotinylated and DSB-X™ Biotin-Labeled Proteins

Our biotinylated primary and secondary antibodies, F(ab')₂ fragments, phycobiliproteins and enzymes are reliable detection reagents for a broad assortment of assays; for more information, see Chapter 6 and Chapter 7. Biotinylated R-phycoerythrin (P811) and biotinylated horseradish peroxidase (P917) can be used in combination with an avidin or streptavidin bridge to amplify the detection of biotinylated targets.

Biotinylated Primary Antibodies

We prepare biotin conjugates of several primary antibodies, including:

- Anti-bromodeoxyuridine, mouse IgG₁, monoclonal MoBU-1, biotin conjugate (biotinylated anti-BrdU, B35138)
- Anti-HuC/HuD neuronal protein (human), mouse IgG_{2b}, monoclonal 16A11, biotin-XX conjugate (A21272)
- Anti- α -tubulin (bovine), mouse IgG₁, monoclonal 236-10501, biotin-XX conjugate (A21371)
- Anti-dinitrophenyl-KLH, rabbit IgG fraction, biotin-XX conjugate (A6435)

- Anti-fluorescein/Oregon Green®, rabbit IgG fraction, biotin-XX conjugate (A982)
- Anti-lucifer yellow, rabbit IgG fraction, biotin-XX conjugate (A5751)
- Anti-Green Fluorescent Protein (GFP), rabbit IgG fraction, biotin-XX conjugate (A10259)
- Anti-Green Fluorescent Protein (GFP), chicken IgY fraction, biotin-XX conjugate (A10263)

For a complete list of primary antibodies available from Invitrogen, go to www.invitrogen.com/handbook/antibodies.

Biotinylated and DSB-X™ Biotin-Labeled Secondary Antibodies

We prepare biotin and DSB-X™ biotin conjugates of several commonly used secondary antibodies, including:

- Biotin-XX F(ab')₂ fragment of goat anti-mouse IgG (H+L) (B11027)
- Biotin-XX F(ab')₂ fragment of goat anti-rabbit IgG (H+L) (B21078)
- Biotin-XX goat anti-mouse IgG (H+L) (B2763)
- Biotin-XX goat anti-rabbit IgG (H+L) (B2770)
- DSB-X™ biotin goat anti-mouse IgG (H+L) (D20691)
- DSB-X™ biotin goat anti-mouse IgM (μ chain) (D20693)
- DSB-X™ biotin goat anti-rat IgG (H+L) (D20697)
- DSB-X™ biotin goat anti-chicken IgG (H+L) (D20701)
- DSB-X™ biotin donkey anti-goat IgG (H+L) (D20698)

Targets complexed with DSB-X™ biotin-labeled antibodies can be selectively detected with avidin or streptavidin conjugates or isolated on affinity matrices, including streptavidin agarose (S951, D20658; Section 7.6), and then rapidly released with D-biotin (B1595, B20656; Section 4.2) under extremely gentle conditions¹⁰ (Figure 4.3.7). See Section 4.1 for a complete description of our unique DSB-X™ biotin technology.

Figure 4.3.7 Diagram illustrating the use of streptavidin agarose and a DSB-X™ biotin biotin conjugate in affinity chromatography. A DSB-X™ biotin-labeled IgG antibody and its target antigen are used as an example.

BioGEE: A Biotinylated Glutathione Analog

Biotinylated glutathione ethyl ester (BioGEE, G36000; Figure 4.3.8) is a cell-permeant, biotinylated glutathione analog for detecting glutathiolation. Under conditions of oxidative stress, cells may transiently incorporate glutathione into proteins. Stressed cells incubated with BioGEE will also incorporate this biotinylated glutathione derivative into proteins, facilitating the identification of oxidation-sensitive proteins.^{11,12} Once these cells are fixed and permeabilized, glutathiolation levels can be detected with a fluorescent streptavidin conjugate (Section 7.6, Table 7.9) using either flow cytometry or fluorescence microscopy. Proteins glutathiolated with BioGEE can be captured using streptavidin agarose (S951, Section 7.6) and analyzed by mass spectrometry or by western blotting methods.^{13,14}

Figure 4.3.8 Glutathione ethyl ester, biotin amide (BioGEE, G36000).

Biotinylated Microspheres

Biotinylated FluoSpheres® polystyrene microspheres have significant potential for signal amplification techniques, as described in Section 6.5. Like biotinylated R-phycoerythrin (P811), they can be used with bridging techniques to detect biotinylated targets. We currently offer the following biotinylated FluoSpheres® microspheres:

- FluoSpheres® biotin-labeled microspheres, 0.04 μm, yellow-green fluorescent (505/515), 1% solids (F8766)
- FluoSpheres® biotin-labeled microspheres, 0.2 μm, yellow-green fluorescent (505/515), 1% solids (F8767)
- FluoSpheres® biotin-labeled microspheres, 1.0 μm, yellow-green fluorescent (505/515), 1% solids (F8768)
- FluoSpheres® biotin-labeled microspheres, 1.0 μm, nonfluorescent, 1% solids (F8769)

FluoSpheres® polystyrene microspheres satisfy several prerequisites of ideal long-term biological tracers. Because the dyes in our microspheres are incorporated throughout the microsphere rather than just on its surface, the fluorescence output per microsphere is significantly greater than that obtained from protein or dextran conjugates and is relatively immune to photobleaching and other environment-dependent effects. FluoSpheres® microspheres are also biologically inert and physically durable, and are available with a large number of uniform sizes and surface properties.

Biotinylated Qdot® Nanocrystals

The Qdot® 605 and Qdot® 655 Biotin Conjugate Kits (Q10301MP, Q10321MP) provide Qdot® nanocrystals that have been functionalized with biotin on their surface via carbodiimide-mediated coupling. The biotinylated Qdot® 605 or biotinylated Qdot® 655 conjugate typically incorporates 5–7 biotin groups per Qdot® nanocrystal. In addition to biotinylated Qdot® nanocrystals, each kit also provides Qdot® Incubation Buffer, which is formulated specifically to achieve improved signal-to-noise ratios in immunohistochemical applications. Biotinylated Qdot® nanocrystals have been used alongside biotinylated microspheres for analysis of the effects of fluorescent label size on ligand–receptor binding dynamics and equilibrium by fluorescence correlation spectroscopy¹⁵ (Fluorescence Correlation Spectroscopy (FCS)—Note 1.3).

Figure 4.3.9 Biotin-aha-dUTP (B32766).

Biotinylated Nucleotides

Biotinylated nucleic acids are common nonisotopic probes used in hybridization techniques. Nucleoside triphosphate analogs such as our ChromaTide® UTP and dUTP nucleotides and aha-dUTP and aha-dCTP nucleotides (Section 8.2) are important reagents for preparing labeled nucleic acids for use as hybridization probes. The biotinylated aminohexylacrylamido-dUTP (biotin aha-dUTP) and biotinylated aminohexylacrylamido-dCTP (biotin aha-dCTP) derivatives (B32766, Figure 4.3.9; B32772) each contain a long 11-atom spacer between the biotin and its attachment point on the nucleic acid to facilitate its detection and signal amplification by fluorophore and enzyme conjugates of avidin and streptavidin (Section 7.6, Table 7.9).

Biotinylated Site-Selective Probes

Biotin conjugates of moderately low molecular weight ligands provide a means of amplifying the detection of ligand binding using fluorophore- or enzyme-labeled avidins or streptavidins. They may also be useful for immobilizing receptor ligands on streptavidin agarose (S951, D20658) or CaptAvidin™ agarose (C21386, Figure 4.3.10) for affinity isolation of receptors. See Section 7.6 for a description of these avidin conjugates, as well as other affinity isolation methods that use biotin- or DSB-X™ biotin-labeled reagents.

Figure 4.3.10 Diagram of the use of CaptAvidin™ agarose (C21386) in affinity chromatography. A biotinylated IgG molecule and target antigen are used as an example.

Figure 4.3.11 Early endosomes in live HeLa cells identified after a 10-minute incubation with green-fluorescent Alexa Fluor® 488 epidermal growth factor (E13345). The cells were subsequently fixed with formaldehyde and labeled with an antibody to the late endosomal protein, RhoB. That antibody was visualized with a red-orange-fluorescent secondary antibody. Nuclei were stained with TO-PRO®-3 iodide (T3605, pseudocolored blue). The image was contributed by Harry Mellor, University of Bristol.

Figure 4.3.12 Lightly fixed human epidermoid carcinoma cells (A431) stained with biotinylated epidermal growth factor (EGF) complexed to Texas Red® streptavidin (E3480). An identical cell preparation stained in the presence of a 100-fold excess of unlabeled EGF (E3476) showed no fluorescent signal (data not shown).

Our biotinylated ligands include:

- Biotin-X conjugate of annexin V (A13204, Section 15.5), for detecting the externalization of phosphatidylserine, an early indicator of apoptosis
- Biotin-XX conjugate of α -bungarotoxin¹⁶⁻¹⁹ (B1196, Section 16.2), for labeling the nicotinic acetylcholine receptor (nAChR)
- Biotin-XX cholera toxin subunit B (C34779, Section 7.7), which binds to cell-surface ganglioside G_{M1} receptors and is a marker of lipid rafts²⁰
- Biotin-XX conjugate of epidermal growth factor²¹⁻²³ (EGF, E3477), as well as biotinylated EGF complexed with Alexa Fluor® 488 streptavidin (E13345, Figure 4.3.11), Alexa Fluor® 555 streptavidin (E35350), Alexa Fluor® 647 streptavidin (E35351) or Texas Red® streptavidin (E3480, Figure 4.3.12), for labeling EGF receptors (Section 16.1)
- Biotin-XX conjugate of isolectin IB₄ from *Griffonia simplicifolia*²⁴ (I21414, Section 7.7), for detecting α -galactosyl moieties in microglia and other glycoproteins
- Biotin-XX conjugate of phalloidin^{25,26} (B7474, Section 11.1), for labeling F-actin
- Biotin-XX conjugate of transferrin²⁷ (T23363, Section 16.1), for following intracellular trafficking of this iron-carrying protein
- Biotin-XX tyramide, which is an amplification reagent used in several of our TSA™ Kits (Section 6.2, Table 6.1) for high-sensitivity detection of targets in cells and tissues

Biotinylated Lipids

Our extensive selection of labeled phospholipids includes two phospholipid derivatives of biotin and biotin-X:

- Biotin DHPE (*N*-(biotinoyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine (B1550, Figure 4.3.13)
- Biotin-X DHPE (*N*-((6-(biotinoyl)amino)hexanoyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine (B1616, Figure 4.3.14)

These biotinylated lipids, which are also described in Section 13.2, can be used to prepare liposomes that retain high affinity for avidin conjugates and can be captured for downstream analysis using streptavidin agarose²⁸ (S951, Section 7.6).

Figure 4.3.13 Biotin DHPE (*N*-(biotinoyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt, B1550).

Notes

1. α -Bungarotoxin, EGF and phallotoxin conjugates have approximately 1 label per peptide.
2. Absorption and fluorescence of fluorescein derivatives are pH dependent. Extinction coefficients and fluorescence quantum yields decrease markedly at pH <7.
3. Chloroform is the most generally useful solvent for preparing stock solutions of phospholipids (including sphingomyelins). Glycerophosphocholines are usually freely soluble in ethanol. Most other glycerophospholipids (phosphoethanolamines, phosphatidic acids and phosphoglycerols) are less soluble in ethanol, but solutions up to 1–2 mg/mL should be obtainable, using sonication to aid dispersion if necessary. Labeling of cells with fluorescent phospholipids can be enhanced by addition of cyclodextrins during incubation. (*J Biol Chem* (1999) 274:35359)
4. Although this phallotoxin is water soluble, storage in water is not recommended, particularly in dilute solution.
5. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
6. ND = not determined.
7. E3480 is a complex of E3477 with Texas Red® streptavidin, which typically incorporates 3 dyes/streptavidin (MW ~52,800).
8. E13345 is a complex of E3477 with Alexa Fluor® 488 streptavidin, which typically incorporates 5 dyes/streptavidin (MW ~52,800).
9. E35350 is a complex of E3477 with Alexa Fluor® 555 streptavidin, which typically incorporates 3 dyes/streptavidin (MW ~52,800).
10. E35351 is a complex of E3477 with Alexa Fluor® 647 streptavidin, which typically incorporates 3 dyes/streptavidin (MW ~52,800).
11. Absorption and fluorescence of Oregon Green® 488 derivatives are pH dependent only in moderately acidic solutions (pH <5).

PRODUCT LIST 4.3 BIOTIN AND DESTHIOBIOTIN CONJUGATES

Cat. No.	Description	Quantity
A12924	Alexa Fluor® 488 biocytin, disodium salt (biocytin Alexa Fluor® 488)	250 µg
A12923	Alexa Fluor® 546 biocytin, sodium salt (biocytin Alexa Fluor® 546)	250 µg
A12922	Alexa Fluor® 594 biocytin, sodium salt (biocytin Alexa Fluor® 594)	250 µg
A13204	annexin V, biotin-X conjugate *100 assays*	500 µL
A6435	anti-dinitrophenyl-KLH, rabbit IgG fraction, biotin-XX conjugate *2 mg/mL*	0.5 mL
A982	anti-fluorescein/Oregon Green®, rabbit IgG fraction, biotin-XX conjugate *1 mg/mL*	0.5 mL
A10263	anti-Green Fluorescent Protein, chicken IgY fraction, biotin-XX conjugate (anti-GFP, IgY, biotin-XX conjugate) *2 mg/mL*	100 µL
A10259	anti-Green Fluorescent Protein, rabbit IgG fraction, biotin-XX conjugate (anti-GFP, IgG, biotin-XX conjugate) *2 mg/mL*	100 µL
A21272	anti-HuC/HuD neuronal protein (human), mouse IgG _{2b} , monoclonal 16A11, biotin-XX conjugate	100 µg
A5751	anti-lucifer yellow, rabbit IgG fraction, biotin-XX conjugate *3 mg/mL*	0.5 mL
A21371	anti-α-tubulin (bovine), mouse IgG ₁ , monoclonal 236-10501, biotin-XX conjugate	50 µg
B32772	biotin-aha-dCTP *1 mM in TE buffer*	25 µL
B32766	biotin-aha-dUTP *1 mM in TE buffer*	25 µL
B1550	biotin DHPE (N-(biotinoyl)-1,2-dihexadecanoyl-sn-glycero-3-phosphoethanolamine, triethylammonium salt)	10 mg
B10570	biotin-4-fluorescein	5 mg
B1370	5-((N-(5-(N-(6-(biotinoyl)amino)hexanoyl)amino)pentyl)thioureidyl)fluorescein (fluorescein biotin)	5 mg
B1616	biotin-X DHPE (N-((6-(biotinoyl)amino)hexanoyl)-1,2-dihexadecanoyl-sn-glycero-3-phosphoethanolamine, triethylammonium salt)	5 mg
B11027	biotin-XX F(ab) ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 µL
B21078	biotin-XX F(ab) ₂ fragment of goat anti-rabbit IgG (H+L) *2 mg/mL*	250 µL
B2763	biotin-XX goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
B2770	biotin-XX goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
B7474	biotin-XX phalloidin	50 U
B35138	BrdU, mouse monoclonal antibody (Clone MoBU-1), biotin conjugate (anti-BrdU, biotin conjugate) *0.2 mg/mL*	350 µL
B1196	α-bungarotoxin, biotin-XX conjugate	500 µg
C34779	cholera toxin subunit B (recombinant), biotin-XX conjugate	100 µg
D7135	dextran, biotin, 3000 MW, lysine fixable (BDA-3000)	10 mg
D1956	dextran, biotin, 10,000 MW, lysine fixable (BDA-10,000)	25 mg
D1957	dextran, biotin, 70,000 MW, lysine fixable (BDA-70,000)	25 mg
D7142	dextran, biotin, 500,000 MW, lysine fixable (BDA-500,000)	10 mg
D7156	dextran, fluorescein and biotin, 3000 MW, anionic, lysine fixable (micro-emerald)	5 mg
D7178	dextran, fluorescein and biotin, 10,000 MW, anionic, lysine fixable (mini-emerald)	10 mg
D7162	dextran, tetramethylrhodamine and biotin, 3000 MW, lysine fixable (micro-ruby)	5 mg
D3312	dextran, tetramethylrhodamine and biotin, 10,000 MW, lysine fixable (mini-ruby)	10 mg
D20658	DSB-X™ Bioconjugate Isolation Kit #1 *with streptavidin agarose* *5 isolations*	1 kit
D20698	DSB-X™ biotin donkey anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
D20701	DSB-X™ biotin goat anti-chicken IgG (H+L) *2 mg/mL*	0.5 mL
D20691	DSB-X™ biotin goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
D20693	DSB-X™ biotin goat anti-mouse IgM (µ chain) *2 mg/mL*	250 µL
D20697	DSB-X™ biotin goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
E3477	epidermal growth factor, biotin-XX conjugate (biotin EGF)	20 µg
E13345	epidermal growth factor, biotinylated, complexed to Alexa Fluor® 488 streptavidin (Alexa Fluor® 488 EGF complex)	100 µg
E35350	epidermal growth factor, biotinylated, complexed to Alexa Fluor® 555 streptavidin (Alexa Fluor® 555 EGF complex)	100 µg
E35351	epidermal growth factor, biotinylated, complexed to Alexa Fluor® 647 streptavidin (Alexa Fluor® 647 EGF complex)	100 µg
E3480	epidermal growth factor, biotinylated, complexed to Texas Red® streptavidin (Texas Red® EGF complex)	100 µg
F8769	FluoSpheres® biotin-labeled microspheres, 1.0 µm, nonfluorescent *1% solids*	0.4 mL
F8766	FluoSpheres® biotin-labeled microspheres, 0.04 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
F8767	FluoSpheres® biotin-labeled microspheres, 0.2 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
F8768	FluoSpheres® biotin-labeled microspheres, 1.0 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
G36000	glutathione ethyl ester, biotin amide (BioGEE) *glutathiolation detection reagent* *special packaging*	10 x 100 µg
I21414	isolectin GS-IB ₄ from <i>Griffonia simplicifolia</i> , biotin-XX conjugate	500 µg
L6950	lucifer yellow biocytin, potassium salt (biocytin lucifer yellow)	5 mg
L2601	lucifer yellow cadaverine biotin-X, dipotassium salt	10 mg
O12920	Oregon Green® 488 biocytin (biocytin Oregon Green® 488)	5 mg
P917	peroxidase from horseradish, biotin-XX conjugate	10 mg
P811	R-phycoerythrin, biotin-XX conjugate *4 mg/mL*	0.5 mL
Q10301MP	Qdot® 605 Biotin Conjugate Kit	1 kit
Q10321MP	Qdot® 655 Biotin Conjugate Kit	1 kit
T12921	5-(and-6)-tetramethylrhodamine biocytin (biocytin TMR)	5 mg
T23363	transferrin from human serum, biotin-XX conjugate	5 mg

5.1 Introduction to Crosslinking and Photoactivatable Reagents

Chemical and Photoreactive Crosslinkers

Bifunctional "crosslinking" reagents contain two reactive groups, thereby providing a means of covalently linking two target groups. The reactive groups in a chemical crosslinking reagent (Section 5.2) typically belong to the classes of functional groups—including succinimidyl esters, maleimides and iodoacetamides—described in Chapter 1 and Chapter 2.

In contrast, one of the reactive groups in each of our photoreactive crosslinking reagents (Section 5.3) requires light activation before reacting with a target group. Crosslinking of a biopolymer (such as an antibody, enzyme, avidin or nucleic acid) to a low molecular weight molecule (such as a drug, toxin, peptide or oligonucleotide) or to another biopolymer yields a stable heteroconjugate. This bioconjugate can serve as a detection reagent in a wide variety of research and diagnostic assays or as an immunogen designed to elicit antibody production. Crosslinking reagents are also useful for probing the spatial relationships and interactions within and between biomolecules.

In homobifunctional crosslinking reagents (Section 5.2), the reactive groups are identical. These reagents couple like functional groups—typically two thiols, two amines, two acids or two alcohols—and are predominantly used to form intramolecular crosslinks or to prepare polymers from monomers. When used to conjugate two different biomolecules, for example an enzyme to an antibody, these relatively non-specific reagents tend to yield high molecular weight aggregates.

In heterobifunctional crosslinking reagents (Section 5.2, Table 5.1), the reactive groups have dissimilar chemistry, allowing the formation of crosslinks between unlike functional groups (Figure 5.2.2). As with homobifunctional crosslinking reagents, heterobifunctional crosslinking reagents can still form multiple intermolecular crosslinks to yield high molecular weight aggregates, but conjugations that use these reagents

can be more easily controlled so as to optimize the stoichiometry of the target molecules. Thus, heterobifunctional crosslinking reagents are very useful for preparing conjugates between two different biomolecules.

The photoreactive crosslinking reagents (Section 5.3) are a special subset of the heterobifunctional crosslinking reagents. Upon UV illumination, these reagents react with nucleophiles or form C–H insertion products (Figure 5.1.1, Figure 5.1.2, Figure 5.1.3).

Figure 5.1.1 Photoreactive crosslinking reaction of a simple aryl azide.

Figure 5.1.2 Photoreactive crosslinking reaction of a fluorinated aryl azide.

Figure 5.1.3 Photoreactive crosslinking reaction of a benzophenone derivative.

Table 5.1 Molecular Probes® heterobifunctional crosslinkers.

Cat. No.	Crosslinker	Reactivity

* Azides react with alkynes via the copper-catalyzed azide–alkyne cycloaddition reaction, as discussed in Section 3.1 (where these products are also described). † Reacts nonspecifically with available sites upon UV illumination. ‡ These reagents contain cryptic thiols that are exposed by disulfide reduction (SPDP or PEAS) or deacetylation (SATA) and can be subsequently disulfide-coupled to other thiolated molecules or thioether-coupled to maleimides or iodoacetamides. § EDAC couples amines to carboxylic acids.

An additional variation is the "zero-length" crosslinking reagent—a reagent that forms a chemical bond between two groups without itself being incorporated into the product (Figure 5.1.4). The water-soluble carbodiimide EDAC (E2247, Section 5.2), which is used to couple carboxylic acids to amines, is an example of a zero-length crosslinking reagent.

A noncovalent interaction between two molecules that has very slow dissociation kinetics can also function as a crosslink. For example, reactive derivatives of phospholipids can be used to link the liposomes or cell membranes in which they are incorporated to antibodies or enzymes. Biotinylation and haptenylation reagents (Chapter 4) can also be thought of as heterobifunctional crosslinking reagents because they comprise a chemically reactive group as well as a biotin or hapten moiety that binds with high affinity to avidin or an anti-hapten antibody, respectively. Similarly, avidin, streptavidin, NeutrAvidin™ biotin-binding protein and CaptAvidin™ biotin-binding protein (Section 7.6) can tightly bind up to four molecules of a biotinylated target.

Figure 5.1.4 Conversion of a carboxylic acid group into an aliphatic amine. The activated carboxylic acid is derivatized with a half-protected aliphatic diamine (mono-*N*-(*t*-BOC)-propylene diamine, M6248), usually in an organic solvent, followed by removal of the *t*-BOC-protecting group with trifluoroacetic acid.

Photoactivatable (Caged) Probes

In addition to the photoreactive crosslinking reagents that are briefly mentioned above and described in detail in Section 5.3, we prepare photoactivatable probes. Flash photolysis of photoactivatable or "caged" probes provides a means of controlling the release—both spatially and temporally—of biologically active products or other reagents of interest.^{1,2} The chemical caging process may also confer membrane permeability on the caged ligand, as is the case for caged cAMP³ and caged luciferin.⁴ Our selection of caged nucleotides, chelators, second messengers and neurotransmitters has tremendous potential for use with both live cells and isolated proteins (Section 5.3).

We prepare caged versions of biologically active molecules, as well as caged fluorescent dyes that are essentially nonfluorescent until after photolysis. These caged fluorophores have proven useful for photoactivation of fluorescence (PAF) experiments, which are analogous to fluorescence recovery after photobleaching (FRAP) experiments except that the fluorophore is activated upon illumination rather than bleached. Measuring the fluorescent signal of the photoactivated fluorophore against a dark background is intrinsically more sensitive than measuring a dark photobleached region against a bright field.⁵

5.2 Chemical Crosslinking Reagents

The most common schemes for forming a well-defined heteroconjugate require the indirect coupling of an amine group on one biomolecule to a thiol group on a second biomolecule, usually by a two- or three-step reaction sequence. The high reactivity of thiols (Chapter 2) and—with the exception of a few proteins such as β -galactosidase—their relative rarity in most biomolecules make thiol groups ideal targets for controlled chemical crosslinking. If neither molecule contains a thiol group, then one or more can be introduced using one of several thiolation methods. The thiol-containing biomolecule is then reacted with an amine-containing biomolecule using a heterobifunctional crosslinking reagent such as one of those described in Amine–Thiol Crosslinking, below.

Thiolation of Biomolecules

Introducing Thiol Groups into Biomolecules

Several methods are available for introducing thiols into biomolecules, including the reduction of intrinsic disulfides, as well as the conversion of amine or carboxylic acid groups to thiol groups:

- Disulfide crosslinks of cystines in proteins can be reduced to cysteine residues by dithiothreitol¹ (DTT, D1532) or tris-(2-carboxyethyl)phosphine (TCEP, T2556; Figure 5.2.1). However, reduction may

result in loss of protein activity or specificity. Excess DTT must be carefully removed under conditions that prevent reformation of the disulfide,² whereas excess TCEP usually does not need to be removed before carrying out the crosslinking reaction. TCEP is also more stable at higher pH values and at higher temperatures than is the air-sensitive DTT reagent.³

- Amines can be indirectly thiolated by reaction with succinimidyl acetylthioacetate⁴ (SATA, S1553), followed by removal of the acetyl group with 50 mM hydroxylamine or hydrazine at near-neutral pH (Figure 5.2.2). This reagent is most useful when disulfides are essential for activity, as is the case for some peptide toxins.
- Amines can be indirectly thiolated by reaction with succinimidyl 3-(2-pyridyldithio)propionate⁵ (SPDP, S1531), followed by reduction of the 3-(2-pyridyldithio)propionyl conjugate with DTT or TCEP (Figure 5.2.3). Reduction releases the 2-pyridinethione chromophore, which can be used to determine the degree of thiolation.
- Thiols can be incorporated at carboxylic acid groups by an EDAC-mediated reaction with cystamine, followed by reduction of the disulfide with DTT or TCEP;^{6,7} see Amine–Carboxylic Acid Crosslinking below.
- Tryptophan residues in thiol-free proteins can be oxidized to mercaptotryptophan residues, which can then be modified by iodoacetamides or maleimides.^{8–10}

Our preferred reagent combination for protein thiolation is SPDP/DTT or SPDP/TCEP.¹¹ We use SPDP to prepare a reactive R-phycoerythrin derivative (P806, Section 6.4), providing researchers with the optimal number of pyridyldisulfide groups for crosslinking the phycobiliprotein to thiolated antibodies, enzymes and other biomolecules through disulfide linkages.¹² More commonly, the pyridyldisulfide groups are first reduced to thiols, which are then reacted with maleimide- or iodoacetamide-derivatized proteins (Figure 5.2.3). SPDP can also be used to thiolate oligonucleotides¹³ and—like all of the thiolation reagents in this section—to introduce the highly reactive thiol group into peptides, onto cell surfaces or onto affinity matrices for subsequent reaction with fluorescent, enzyme-coupled or other thiol-reactive reagents (Chapter 2). In addition, because the 3-(2-pyridyldithio)propionyl conjugate releases the 2-pyridinethione chromophore upon reduction, SPDP is useful for quantitating the number of reactive amines in an affinity matrix.¹⁴

Measuring Thiolation of Biomolecules

To ensure success in forming heterocrosslinks, it is important to know that a molecule has the proper degree of thiolation. We generally find that two to three thiol residues per protein are optimal. Following removal of excess reagents, the degree of thiolation in proteins or other molecules thiolated with SPDP can be directly determined by measuring release of the 2-pyridinethione chromophore⁵ (EC ~8000 cm⁻¹M⁻¹ at 343 nm).

Alternatively, the degree of thiolation and presence of residual thiols in a solution can be assessed using 5,5'-dithiobis-(2-nitrobenzoic acid) (DTNB, Ellman's reagent; D8451), which stoichiometrically yields the 5-mercapto-2-nitrobenzoic acid chromophore (EC ~13,600 cm⁻¹M⁻¹ at 410 nm) upon reaction with a thiol group.^{15,16} DTNB can also be used to quantitate residual phosphines in aqueous solutions, including TCEP;¹⁷ in this case, two molecules of 5-mercapto-2-nitrobenzoic acid are formed per reaction with one molecule of a phosphine.

Measure-iT™ Thiol Assay Kit

The Measure-iT™ Thiol Assay Kit (M30550) provides easy and accurate quantitation of thiol. The kit supplies concentrated assay reagent, dilution buffer, and concentrated thiol standard. The assay has

Figure 5.2.1 Tris-(2-carboxyethyl)phosphine, hydrochloride (TCEP, T2556).

Figure 5.2.2 Schematic illustration of the heterobifunctional crosslinker succinimidyl acetylthioacetate (SATA, S1553): **A**) attachment to an aminosilane-modified surface, **B**) deprotection with base and **C**) reaction with a thiol-reactive biomolecule.

Figure 5.2.3 SPDP derivatization reactions. SPDP (S1531) reacts with an amine-containing biomolecule at pH 7 to 9, yielding a pyridyldithiopyropionyl mixed disulfide. The mixed disulfide can then be reacted with a reducing agent such as DTT (D1532) or TCEP (T2556) to yield a 3-mercaptopropionyl conjugate or with a thiol-containing biomolecule to form a disulfide-linked tandem conjugate. Either reaction can be quantitated by measuring the amount of 2-pyridinethione chromophore released during the reaction.

Figure 5.2.4 Linearity and sensitivity of the Measure-iT™ thiol assay. Triplicate 10 μL samples of glutathione were assayed using the Measure-iT™ Thiol Assay Kit (M30550). Fluorescence was measured using excitation/emission of 490/520 nm and plotted versus glutathione concentration. The variation (CV) of replicate samples was <2%.

a linear range of 0.05–5 μM thiol (Figure 5.2.4), making it up to 400 times more sensitive than colorimetric methods based on DTNB (Ellman's reagent).

Each Measure-iT™ Thiol Assay Kit contains:

- Measure-iT™ thiol quantitation reagent (100X concentrate in 1,2-propanediol)
- Measure-iT™ thiol quantitation buffer (50 mM potassium phosphate buffer)
- Measure-iT™ thiol quantitation standard (reduced glutathione)
- Detailed protocols

Simply dilute the reagent 1:100, load 100 μL into the wells of a microplate, add 1–10 μL sample volumes, mix, then read the fluorescence. Maximum fluorescence signal is attained within 5 minutes and is stable for at least 1 hour. The assay is performed at room temperature, and common contaminants are well tolerated in the assay. The Measure-iT™ Thiol Assay Kit provides sufficient materials for 500 assays, based on a 100 μL assay volume in a 96-well microplate format; this thiol assay can also be adapted for use in cuvettes or 384-well microplates.

Thiol and Sulfide Quantitation Kit

Ultrasensitive colorimetric quantitation of both protein and nonprotein thiols can also be achieved using the Thiol and Sulfide Quantitation Kit (T6060). In this assay, which is based on a method reported by Singh,^{18,19} thiols reduce a disulfide-inhibited derivative of papain, stoichiometrically releasing the active enzyme. Activity of the enzyme is then measured using the chromogenic papain substrate L-BAPNA via spectrophotometric detection of *p*-nitroaniline release at 412 nm (Figure 5.2.5). Although thiols can also be quantitated using DTNB (Ellman's reagent), the enzymatic amplification step in this quantitation kit enables researchers to detect as little as 0.2 nanomoles of a thiol—a sensitivity that is about 100-fold better than that achieved with DTNB.^{20,21} Thiols in proteins and potentially in other high molecular weight molecules can be detected indirectly by incorporating the disulfide cystamine into the solution. Cystamine undergoes an exchange reaction with protein thiols, yielding 2-mercaptoethylamine (cysteamine), which then releases active papain. Thiols that are alkylated by maleimides, iodoacetamides and other reagents are excluded from detection and can therefore be assayed subtractively.²²

Figure 5.2.5 Chemical basis for thiol detection using the Thiol and Sulfide Quantitation Kit (T6060): **A**) the inactive disulfide derivative of papain, papain-SSCH₃, is activated in the presence of thiols; **B**) active papain cleaves the substrate L-BAPNA, releasing the *p*-nitroaniline chromophore; **C**) protein thiols, often poorly accessible, exchange with cystamine to generate 2-mercaptoethylamine (cysteamine), which is easily detected.

The Thiol and Sulfide Quantitation Kit contains:

- Papain-SSCH₃, the disulfide-inhibited papain derivative
- L-BAPNA, a chromogenic papain substrate
- DTNB (Ellman's reagent), for calibrating the assay
- Cystamine
- L-Cysteine, a thiol standard
- Buffer
- Detailed protocols for measuring thiols, inorganic sulfides and maleimides

Sufficient reagents are provided for approximately 50 assays using 1 mL assay volumes and standard cuvettes or 250 assays using a microplate format.

Thiol–Thiol Crosslinking

Oxidation

Thiol residues in close proximity can be oxidized to disulfides by either an intra- or intermolecular reaction. In many circumstances, however, this oxidation reaction is reversible and difficult to control.

Fluorescent Thiol–Thiol Crosslinkers

Dibromobimane (bBBr, D1379; Figure 5.2.6) is an interesting crosslinking reagent for proteins because it is unlikely to fluoresce until both of its alkylating groups have reacted.²³ It has been used to crosslink thiols in myosin,²⁴ actin,²⁵ hemoglobin,²⁶ *Escherichia coli* lactose permease²⁷ and mitochondrial ATPase.²⁸ It has also been shown to intramolecularly crosslink thiols in a complex of nebulin and calmodulin.²⁹ In addition, dibromobimane has been used to probe for the proximity of dual-cysteine mutagenesis sites in ArsA ATPase³⁰ and P-glycoprotein.^{31–33} Dibromobimane, a stimulator of the ATPase activity of a cysteine-free P-glycoprotein, was used with cysteine-scanning mutagenesis to identify amino acid residues important for function.³⁴

In addition to dibromobimane, we offer the thiol-reactive homobifunctional crosslinker bis-((*N*-iodoacetyl)piperazinyl)sulfonerhodamine (B10621), which is derived from a relatively rigid rhodamine dye (Figure 5.2.7). This crosslinker is similar to a thiol-reactive rhodamine-based crosslinking reagent that was used to label regulatory light-chains of chicken gizzard myosin for fluorescence polarization experiments.³⁵ Researchers have attached bis-((*N*-iodoacetyl)piperazinyl)sulfonerhodamine to the kinesin motor domain and determined the orientation of kinesin bound to microtubules in the presence of a non-hydrolyzable ATP analog by fluorescence polarization microscopy.^{36,37} Images of single molecules of chicken calmodulin crosslinked between two engineered cysteines by bis-((*N*-iodoacetyl)piperazinyl)sulfonerhodamine have been used to generate comparisons of experimental and theoretical super-resolution point-spread functions³⁸ (PSF).

Amine–Amine Crosslinking

The scientific literature contains numerous references to reagents that form crosslinks between amines of biopolymers. Homobifunctional amine crosslinkers include glutaraldehyde, bis(imido esters), bis(succinimidyl esters), diisocyanates and diacid chlorides.³⁹ These reagents, however, tend to yield high molecular weight aggregates, making them unsuitable for reproducibly preparing well-defined conjugates between two different amine-containing biomolecules. For example, glutaraldehyde is still used by some companies and research laboratories to couple horseradish peroxidase, which has only six lysine residues,⁴⁰ to proteins with a larger number of lysine residues. Unfortunately, this practice can result in variable molecular weights and batch-to-batch inconsistency.

Well-defined conjugates between two amine-containing molecules are more reliably prepared by thiolating one or more amines on one of the biomolecules and converting one or more amines on the second biomolecule to a thiol-reactive functional group such as a maleimide or iodoacetamide, as described below in Amine–Thiol Crosslinking. For example, we prepare our horseradish peroxidase conjugates (Section 7.2, Section 7.6) using SPDP- and SMCC-mediated reactions (Figure 5.2.3, Figure 5.2.8).

Direct amine–amine crosslinking routinely occurs during fixation of proteins, cells and tissues with formaldehyde or glutaraldehyde. These common aldehyde-based fixatives are also used to crosslink amine and hydrazine derivatives to proteins and other amine-containing polymers. For example, lucifer yellow CH (L453, Section 14.3) is nonspecifically conjugated to surrounding biomolecules by aldehyde-based fixatives in order to preserve the dye's staining pattern during subsequent tissue manipulations.⁴¹ Also, biotin hydrazides (Section 4.2) have been directly coupled to nucleic acids with glutaraldehyde,^{42,43} a reaction that is potentially useful for conjugating fluorescent hydrazides and hydroxylamines to DNA.

Figure 5.2.6 Dibromobimane (bBBr, D1379).

Figure 5.2.7 bis-((*N*-iodoacetyl)piperazinyl)sulfonerhodamine (B10621).

Figure 5.2.8 Two-step reaction sequence for crosslinking biomolecules using the heterobifunctional crosslinker SMCC (S1534).

Amine–Thiol Crosslinking

Indirect crosslinking of the amines in one biomolecule to the thiols in a second biomolecule is the predominant method for forming a heteroconjugate. If one of the biomolecules does not already contain one or more thiol groups, it is necessary to introduce them using one of the thiolation procedures described above in Thiolation of Biomolecules. Thiol-reactive groups such as maleimides are typically introduced into the second biomolecule by modifying a one or more of its amines with a heterobifunctional crosslinker containing both a succinimidyl ester and a maleimide. The maleimide-modified biomolecule is then reacted with the thiol-containing biomolecule to form a stable thioether crosslink (Figure 5.2.8). Chromatographic methods are usually employed to separate the higher molecular weight heteroconjugate from the unconjugated biomolecules.

Introducing Maleimides at Amines

Succinimidyl *trans*-4-(maleimidylmethyl)cyclohexane-1-carboxylate⁴⁴ (SMCC, S1534) is our reagent of choice for introducing thiol-reactive groups at amine sites because of the superior chemical stability of its maleimide and its ease of use⁴⁵ (Figure 5.2.8).

Introducing Disulfides at Amines

Our preferred method for preparing heteroconjugates employs the thiolation reagent SPDP (S1531). The pyridyldisulfide intermediate that is initially formed by reaction of SPDP with amines can form an unsymmetrical disulfide through reaction with a second thiol-containing molecule^{5,12} (Figure 5.2.3). The thiol-containing target can be a molecule such as β -galactosidase that contains intrinsic thiols or a molecule in which thiols have been introduced using one of the thiolation procedures described above in Thiolation of Biomolecules. In either case, it is essential that all reducing agents, such as DTT and TCEP, are absent. The heteroconjugate's disulfide bond is about as stable and resistant to reduction as disulfides found in proteins; it can be reduced with DTT or TCEP to generate two thiol-containing biomolecules.

Protein–Protein Crosslinking Kit

Our Protein–Protein Crosslinking Kit (P6305) provides all of the reagents and purification media required to perform three protein–protein conjugations in which neither protein contains thiol residues. The chemistry used to thiolate the amines of one of the proteins with SPDP and to convert the amines of the second protein to thiol-reactive maleimides with SMCC is shown in Figure 5.2.3 and Figure 5.2.8, respectively. Included in the kit are:

- SPDP, for thiolating amines
- SMCC, for converting amines to thiol-reactive maleimides
- TCEP, for reducing the pyridyldisulfide intermediate
- *N*-ethylmaleimide (NEM), for capping residual thiols
- Six reaction tubes, each containing a magnetic stir bar
- Spin columns plus collection tubes
- Dimethylsulfoxide (DMSO)
- Detailed crosslinking protocols

The Protein–Protein Crosslinking Kit was designed to prepare and purify protein–protein conjugates; however, it can be readily modified for generating peptide–protein or enzyme–nucleic acid conjugates or for conjugating biomolecules to affinity matrices.

We have considerable experience in preparing protein–protein conjugates and will apply this expertise to a researcher's particular application through our custom synthesis service. We provide custom conjugation services on an exclusive or nondisclosure basis when requested. For more information or a quote, please go to www.invitrogen.com/handbook/custom/bioconjugates.

Assaying Maleimide- and Iodoacetamide-Modified Biomolecules

The potential instability of maleimide derivatives and the photosensitivity of iodoacetamide derivatives may make it advisable to assay the modified biomolecule for thiol reactivity before conjugation with a thiol-containing biomolecule. SAMSA fluorescein (A685, Figure 5.2.9), which is currently our only fluorescent reagent that can generate a free thiol group, was designed for assaying whether or not a biomolecule is adequately labeled with a heterobifunctional maleimide or iodoacetamide crosslinker. Brief treatment of SAMSA fluorescein with NaOH at pH 10 liberates a free thiol. By adding base-treated SAMSA fluorescein to a small aliquot of the crosslinker-modified biomolecule, the researcher can check to see whether the biomolecule has been sufficiently labeled before proceeding to the next step. The degree of modification can be approximated from either the absorbance or the fluorescence of the conjugate following quick purification on a gel-filtration column.

Alternatively, thiol reactivity of the modified biomolecule can be assayed using the reagents provided in our Thiol and Sulfide Quantitation Kit (T6060), a product that is described above.^{19,22} Once unconjugated reagents have been removed, a small aliquot of the maleimide- or iodoacetamide-modified biomolecule can be reacted with excess cysteine. Thiol-reactive groups can then be quantitated by determining the amount of cysteine consumed in this reaction with the Thiol and Sulfide Quantitation Kit.

Amine–Carboxylic Acid Crosslinking

1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDAC, E2247) can react with biomolecules to form "zero-length" crosslinks, usually within a molecule or between subunits of a protein complex. In this chemistry, the crosslinking reagent is not incorporated into the final product. The water-soluble carbodiimide EDAC crosslinks a specific amine and carboxylic acid between subunits of allophycocyanin, thereby stabilizing its assembly;⁴⁶ we use EDAC to stabilize allophycocyanin in its allophycocyanin conjugates (Section 6.4). EDAC has also been

Figure 5.2.9 5-(2-(and-3)-5-(acetylmercapto)succinoyl)amino)fluorescein (SAMSA fluorescein, A685)

used to form intramolecular crosslinks in myosin subfragment-1,⁴⁷ intermolecular crosslinks in actomyosin,⁴⁸ intersubunit crosslinks of chloroplast subunits⁴⁹ and DNA–protein crosslinks.⁵⁰ Addition of *N*-hydroxysuccinimide or *N*-hydroxysulfosuccinimide (NHSS, H2249) is reported to enhance the yield of carbodiimide-mediated conjugations,⁵¹ indicating the *in situ* formation of a succinimidyl ester–activated protein (Figure 5.2.10). EDAC has been reported to be impermeant to cell membranes,⁵² which should permit selective surface labeling of cellular carboxylic acids with fluorescent amines.

Reaction of carboxylic acids with cystamine ($\text{H}_2\text{NCH}_2\text{CH}_2\text{S}-\text{SCH}_2\text{CH}_2\text{NH}_2$) and EDAC followed by reduction with DTT results in thiolation at carboxylic acids.⁷ This indirect route to amine–carboxylic acid coupling is particularly suited to acidic proteins with few amines, carbohydrate polymers,⁶ heparin, poly(glutamic acid) and synthetic polymers lacking amines. The thiolated biomolecules can also be reacted with any of the probes described in Chapter 2.

Figure 5.2.11 6-((acryloyl)amino)hexanoic acid, succinimidyl ester (acryloyl-X, SE, A20770).

Crosslinking Amines to Acrylamide Polymers

The succinimidyl ester of 6-((acryloyl)amino)hexanoic acid (acryloyl-X, SE; A20770; Figure 5.2.11) reacts with amines of proteins, amine-modified nucleic acids and other biomolecules to yield acrylamides that can be copolymerized into polyacrylamide matrices or onto surfaces, such as in microarrays and in biosensors. For example, streptavidin acrylamide (S21379, Section 7.6) copolymerizes with acrylamide on polymeric surfaces to create a uniform monolayer of the immobilized protein. The immobilized streptavidin can then bind biotinylated ligands, including biotinylated hybridization probes, enzymes, antibodies and drugs.⁵³

Figure 5.2.10 Stabilization of an unstable *O*-acylisourea intermediate by *N*-hydroxysuccinimide in a carbodiimide-mediated (EDAC, E2247) modification of a carboxylic acid with a primary amine.

- Notes**
- Iodoacetamides in solution undergo rapid photodecomposition to unreactive products. Minimize exposure to light prior to reaction.
 - Bimanes are almost nonfluorescent until reacted with thiols. For monobromobimane conjugated to glutathione, Abs = 394 nm, Em = 490 nm (QY ~0.1–0.3) in pH 8 buffer. (Methods Enzymol (1987) 143:76, Methods Enzymol (1995) 251:133)
 - D8451 reaction product with thiols has Abs = 410 nm (EC = 14,000 cm⁻¹M⁻¹). (Methods Enzymol (1994) 233:380)
 - After conjugation of S1531 the degree of substitution can be determined by measuring the amount of 2-pyridinethione formed by treatment with DTT (D1532) or TCEP (T2556) from its absorbance at 343 nm (EC = 8000 cm⁻¹M⁻¹). (Biochem J (1978) 173:723)

PRODUCT LIST 5.2 CHEMICAL CROSSLINKING REAGENTS

Cat. No.	Product	Quantity
A685	5-((2-(and-3)-S-(acetylmercapto)succinoyl)amino)fluorescein (SAMSA fluorescein) *mixed isomers*	25 mg
A20770	6-((acryloyl)amino)hexanoic acid, succinimidyl ester (acryloyl-X, SE)	5 mg
B10621	bis-((N-iodoacetyl)piperazinyl)sulfonerhodamine	5 mg
D1379	dibromobimane (bBBr)	25 mg
D8451	5,5'-dithiobis-(2-nitrobenzoic acid) (DTNB; Ellman's reagent)	10 g
D1532	dithiothreitol (DTT)	1 g
E2247	1-ethyl-3-(3-dimethylaminopropyl)carbodiimide, hydrochloride (EDAC)	100 mg
H2249	N-hydroxysulfosuccinimide, sodium salt (NHSS)	100 mg
M30550	Measure-iT™ Thiol Assay Kit *500 assays*	1 kit
P6305	Protein-Protein Crosslinking Kit *3 conjugations*	1 kit
S1553	succinimidyl acetylthioacetate (SATA)	100 mg
S1534	succinimidyl trans-4-(maleimidylmethyl)cyclohexane-1-carboxylate (SMCC)	100 mg
S1531	succinimidyl 3-(2-pyridyldithio)propionate (SPDP)	100 mg
T6060	Thiol and Sulfide Quantitation Kit *50–250 assays*	1 kit
T2556	tris-(2-carboxyethyl)phosphine, hydrochloride (TCEP)	1 g

5.3 Photoactivatable Reagents, Including Photoreactive Crosslinkers and Caged Probes

This section describes two types of photoactivatable probes: products that form short-lived, high-energy intermediates that can chemically couple to nearby residues, and "caged" probes that are designed to be biologically inactive until UV light-mediated photolysis releases a natural product. Photolysis of each of these photoactivatable probes can be accomplished with high spatial and temporal resolution, releasing active probe at the site of interest.

Nonfluorescent Photoreactive Crosslinking Reagents

In contrast to chemical crosslinking reagents (Section 5.2), which are often used to prepare bioconjugates, photoreactive crosslinking

reagents are important tools for determining the proximity of two sites. These probes can be employed to define relationships between two reactive groups that are on a single protein, on a ligand and its receptor or on separate biomolecules within an assembly. In the latter case, photoreactive crosslinking reagents can potentially reveal interactions among proteins, nucleic acids and membranes in live cells. The general scheme for defining spatial relationships usually involves photoreactive crosslinking reagents that contain a chemically reactive group as well as a photoreactive group. These crosslinkers are first chemically reacted with one molecule, for example a receptor ligand, and then this modified molecule is coupled to a second molecule, for example the ligand's receptor, using UV illumination. Depending on the reactive properties of the chemical and photoreactive groups, these crosslinkers can be used to couple like or unlike functional groups.

We offer three types of photoreactive reagents for covalent labeling:

- Simple aryl azides that upon illumination (usually at <360 nm) generate reactive intermediates that form bonds with nucleophilic groups (Figure 5.3.1)
- Fluorinated aryl azides that upon UV photolysis generate reactive nitrenes, thereby producing more C–H insertion products than the simple aryl azides (Figure 5.3.2)
- Benzophenone derivatives that can be repeatedly excited at <360 nm until they generate covalent adducts, without loss of reactivity (Figure 5.3.3)

Simple Aryl Azide Crosslinker

The “transferable” aryl azide *N*-(2-pyridyldithio)ethyl-4-azidosalicylamide (PEAS; AET; P6317; Figure 5.3.4) is a unique reagent for assessing protein–protein or protein–nucleic acid interactions. This aryl azide undergoes disulfide–thiol interchange of its pyridyldisulfide groups with the thiol groups of biomolecules to form mixed disulfides in the same way as SPDP¹ (S1531, Section 5.2). UV photolysis induces covalent crosslinking to residues or biomolecules adjacent to the crosslinker. The mixed disulfide can then be cleaved with DTT or TCEP (D1532, T2556; Section 5.2). If the phenolic PEAS reagent is radioiodinated before the coupling and photolysis steps, then only the resulting target biomolecule will be radioactive at the conclusion of the reaction.

Fluorinated Aryl Azides: True Nitrene-Generating Reagents

Although the simple aryl azides may be initially photolyzed to electron-deficient aryl nitrenes, it has been shown that these rapidly ring-expand to form dehydroazepines—molecules that tend to react with nucleophiles rather than form C–H insertion products.^{2,3} In contrast, Keana and Cai have shown that the photolysis products of the fluorinated aryl azides are clearly aryl nitrenes⁴ and undergo characteristic nitrene reactions such as C–H bond insertion with high efficiency. Moreover, conjugates prepared from the amine-reactive succinimidyl ester of 4-azido-2,3,5,6-tetrafluorobenzoic acid (ATFB, SE; A2522) may have quantum yields for formation of photocrosslinked products that are superior to those of the nonfluorinated aryl azides. An important application of the succinimidyl ester of ATFB is the photo-functionalization of polymer surfaces^{5,6} (Figure 5.3.5).

Benzophenone-Based Photoreactive Reagents

Benzophenones generally have higher crosslinking yields than the aryl azide photoreactive reagents.⁷ Benzophenone maleimide (B1508) has been used for efficient irreversible protein crosslinking of actin,⁸ calmodulin,^{9,10} myosin,^{11,12} tropomyosin,¹³ troponin,^{14–17} ATP synthase^{18,19} and other proteins. The succinimidyl ester of 4-benzoylbenzoic acid (B1577, Figure 5.3.6) and benzophenone isothiocyanate (B1526, Figure 5.3.7) have proven useful for synthesizing photoreactive peptides^{20–23} and oligonucleotides.^{24,25} A benzophenone-labeled ATP probe (BzBzATP, B22358) is described in Other Photoreactive Reagents below.

Other Photoreactive Reagents

Ethidium Monoazide for Photoreactive Fluorescent Labeling of Nucleic Acids

Ethidium monoazide (E1374, Figure 5.3.8) can be photolyzed in the presence of DNA or RNA to yield fluorescently labeled nucleic acids, both in solution and in cells.^{26–29} The efficiency of the irreversible photolytic coupling of ethidium monoazide, which intercalates into nucleic acids like ethidium bromide, is unusually high³⁰ (>40%). The membrane-impermeant ethidium monoazide is reported to label only those cells with compromised membranes and can therefore serve as a fixable cell viability probe. This property, allied to the blocking of transcription caused by photoreaction of ethidium monoazide with DNA, provides a method for suppressing PCR amplification of dead-cell DNA.^{31,32} Similarly, multiphoton-targeted photochemistry of vertebrate cells labeled with ethidium monoazide was used to selectively inactivate gene expression.³³ A mixed population of live and dead cells labeled with ethidium monoazide retains its staining pattern after aldehyde-based fixation, thereby reducing the investigator's exposure to potentially pathogenic cells during cell viability analysis.^{34,35}

Bimane Azide for Photoaffinity Labeling of Proteins

Bimane azide (B30600, Figure 5.3.9) is a small blue-fluorescent photoreactive alkyl azide (excitation/emission maxima ~375/458 nm) for photoaffinity labeling of proteins. This reactive fluorophore's small size may reduce the likelihood that the label will interfere with the function of the biomolecule, an important advantage for site-selective probes.

Photoreactive ATP Derivative for Labeling Nucleotide-Binding Proteins

Functional ion channels can be assembled from both homomeric and heteromeric combinations of the seven P2X purinergic receptor subunits so far identified (P2X_{1–7}). Due to the lack of specific agonists or antagonists for P2X receptors, it is difficult to determine which receptor subtypes mediate particular cellular responses. We offer one of the most potent and widely used P2X receptor agonists,^{36–39} BzBzATP (2'-(or 3')-O-(4-benzoylbenzoyl)adenosine 5'-triphosphate, B22358; Figure 5.3.10). BzBzATP also has more general applications for site-directed irreversible modification of nucleotide-binding proteins via photoaffinity labeling.^{40,41}

Figure 5.3.10 2'-(or 3')-O-(4-benzoylbenzoyl)adenosine 5'-triphosphate, tris(triethylammonium) salt (BzBzATP, B22358).

Caged Probes and Their Photolysis

Flash photolysis of photoactivatable or "caged" probes provides a means of controlling the release—both spatially and temporally—of biologically active products or other reagents of interest.^{42–48} The chemical caging process may also confer membrane permeability on the caged ligand, as is the case for caged cAMP⁴⁹ and caged luciferin.⁵⁰ Our extensive selection of caged nucleotides, second messengers (Figure 5.3.11), chelators and neurotransmitters has tremendous potential for use with both live cells and isolated proteins. These caged probes provide researchers with important tools for delivering physiological stimuli by naturally active biomolecules with spatial and temporal precision that far exceeds that of microinjection or perfusion. A recent review by Ellis-Davies describes the optical and chemical properties of many of our caged compounds, as well as of several common caging groups.⁵¹

Caging Groups

The caging moiety (Table 5.2) is designed to *maximally* interfere with the binding or activity of the molecule. It is detached in microseconds to milliseconds by flash photolysis at ≤ 360 nm, resulting in a pulse (concentration jump) of active product. Uncaging can easily be accomplished with UV illumination in a fluorescence microscope or with a UV laser or UV flashlamp. Low-cost light-emitting diodes⁵² (LED) and 405 nm violet diode lasers⁵³ are providing increased access to experimentation using caged compounds. The effects of photolytic release are frequently monitored either with fluorescent probes that measure calcium, pH, other ions or membrane potential, or with electrophysiological techniques.

Most of the caged reagents described in the literature have been derivatives of *o*-nitrobenzyl compounds. The nitrobenzyl group is synthetically incorporated into the biologically active molecule by linkage to a heteroatom (usually O, S or N) as an ether, thioether, ester (including phosphate or thiophosphate esters), amine or similar functional group. Both the structure of the nitrobenzyl compound and the atom to which it is attached affect the efficiency and wavelength required for uncaging. We currently use six different photolabile protecting groups in our caged probes.⁴⁴ Their properties are summarized in Table 5.2.

- Probes caged with our α -carboxy-2-nitrobenzyl (CNB) caging group generally have the most advantageous properties. These include good water solubility, very fast uncaging rates in the microsecond range, high photolysis quantum yields (from 0.2–0.4) and biologically inert photolytic by-products. Although the absorption

maximum of the CNB caging group is near 260 nm, its absorption spectrum tails out to approximately 360 nm, allowing successful photolysis using light with wavelengths ≤ 360 nm.

- The 1-(2-nitrophenyl)ethyl (NPE) caging group has properties similar to those of CNB and can also be photolyzed at ≤ 360 nm.
- As compared with CNB and NPE, the 4,5-dimethoxy-2-nitrobenzyl (DMNB) and 1-(4,5-dimethoxy-2-nitrophenyl)ethyl (DMNPE) caging groups have longer-wavelength absorption (absorption maximum ~ 355 nm) and therefore absorb 340–360 nm light more efficiently. However, photolysis rates and quantum yields of DMNB- and DMNPE-caged probes are generally lower than those obtained for CNB-caged probes.
- The 5-carboxymethoxy-2-nitrobenzyl (CMNB) caging group provides an absorption maximum of intermediate wavelength (absorption maximum ~ 310 nm), while imparting significant water solubility to the caged probe. Its photolysis rate and quantum yield are intermediate between those of CNB- and DMNB-caged probes.
- The nitrophenyl (NP) caging group is available on the caged calcium reagent NP-EGTA (N6802), a photolabile Ca^{2+} chelator that can be used to rapidly deliver a pulse of Ca^{2+} upon illumination with ultraviolet light, with a high photolysis quantum yield of 0.23.

Experiments utilizing probes caged with any of the above caging groups, except the CNB caging group, may require the addition of dithiothreitol (DTT, D1532; Section 2.1). This reducing reagent prevents the potentially cytotoxic reaction between amines and the 2-nitrosobenzoyl photolytic by-products.⁵⁴

Figure 5.3.11 Confocal linescan image of calcium "puffs" in a *Xenopus* oocyte. Oregon Green® 488 BAPTA-1 (O6806) was used as the calcium indicator and Ca^{2+} liberation was evoked by flash photolysis of NPE-caged Ins 1,4,5- P_3 (I23580). Image contributed by Ian Parker and Nick Callamaras, University of California at Irvine.

Table 5.2 Properties of six different caging groups.

Caging Group	Uncaging Rate *	Photolysis Quantum Yield *	Inertness of Photolysis By-product	Confers Water Solubility	Long-Wavelength Absorption (≥ 360 nm)
CNB	++++	+++++	+++++	+++++	++
NPE	+++	+++	+++	+	++
DMNPE	+++	+++	+++	+	+++++
DMNB	+++	+++	++	+	+++++
CMNB	+++	+++	+	++++	+++
NP	+++	+++	+	+	++

+++++ = Optimal response. + = Poor response. * Both the structure of the nitrobenzyl moiety and the atom to which it is attached have some effect on the efficiency and wavelength required for uncaging.

Caged Nucleotides

Photoactivatable nucleotides and phosphates have contributed significantly to our understanding of cytoskeleton dynamics, signal transduction pathways and other critical cellular processes.⁴⁶ Some of our caged nucleotides are available with a choice of caging group:

- Caged ATP (A1048, Figure 5.3.12; A1049, Figure 5.3.13), which has been shown to release ATP in skinned muscle fibers,⁵⁵ sarcoplasmic reticulum vesicles,⁵⁶ submitochondrial particles⁵⁷ and membrane fragments containing Na⁺/K⁺-ATPase⁵⁸
- Caged ADP (A7056, Figure 5.3.14), which has been used to investigate the molecular basis of contraction of skeletal muscle fibers,^{59,60} as well as transport by an ADP/ATP carrier⁶¹
- Caged cAMP (D1037, Figure 5.3.15), which is cell-permeant and rapidly photolyzed to cAMP⁶²
- Caged inositol 1,4,5-triphosphate^{63–67} (I23580, Figure 5.3.16) and caged cADP-ribose^{68,69} (C7074, Figure 5.3.17), which are important probes for second messenger studies (Section 17.2)

NPE-caged Ins 1,4,5-P₃ can be used to generate rapid and precisely controlled release of Ins 1,4,5-P₃ in intact cells (Figure 5.3.11) and is widely employed in studies of Ins 1,4,5-P₃-mediated second messenger pathways.⁶³ Our NPE-caged Ins 1,4,5-P₃ (I23580) is a mixture of the physiologically inert, singly esterified P⁴ and P⁵ esters (Figure 5.3.16) and does not contain the somewhat physiologically active P¹ ester. NPE-caged Ins 1,4,5-P₃ exhibits essentially no biological activity prior to photolytic release of the biologically active Ins 1,4,5-P₃ (I3716, Section 17.2).

Cyclic ADP-ribose (cADP-ribose) is a potent intracellular Ca²⁺-mobilizing agent that functions as a second messenger in an Ins 1,4,5-P₃-independent pathway.^{70–75} Our NPE-caged cADP-ribose (C7074, Figure 5.3.17) induces Ca²⁺ mobilization in sea urchin egg homogenates only after photolysis, and this Ca²⁺ release is inhibited by the specific cADP-ribose antagonist 8-amino-cADP-ribose⁶⁹ (A7621, Section 17.2). Furthermore, when microinjected into live sea urchin eggs, NPE-caged cADP-ribose was shown to mobilize Ca²⁺ and activate cortical exocytosis after illumination with a mercury-arc lamp.⁶⁹

Caged Ca²⁺ Reagents: NP-EGTA and DMNP-EDTA

Caged ions and caged chelators can be used to influence the ionic composition of both solutions and cells, particularly for ions such as Ca²⁺ that are present at low concentrations under normal physiological conditions. Developed by Ellis-Davies and Kaplan,⁷⁶ nitrophenyl EGTA (NP-EGTA) is a photolabile Ca²⁺ chelator that exhibits a high selectivity for Ca²⁺ ions, a dramatic increase in its K_d for Ca²⁺ upon illumination (from 80 nM to 1 mM) and a high photolysis quantum yield (0.23). NP-EGTA's affinity for Ca²⁺ decreases ~12,500-fold upon photolysis. Furthermore, its K_d for Mg²⁺ of 9 mM makes NP-EGTA essentially insensitive to

physiological Mg^{2+} concentrations. We exclusively offer the tetrapotassium salt (N6802) and the acetoxymethyl (AM) ester (N6803) of NP-EGTA. The NP-EGTA salt can be complexed with Ca^{2+} to generate a caged Ca^{2+} reagent that will rapidly deliver Ca^{2+} upon photolysis^{67,77,78} (Figure 5.3.18). The cell-permeant AM ester of NP-EGTA does not bind Ca^{2+} unless its AM ester groups are removed. This AM ester can serve as a photolabile chelator in cells because, once converted to NP-EGTA by intracellular esterases, it will bind free Ca^{2+} until photolyzed with UV light.

The first caged Ca^{2+} reagent described by Kaplan and Ellis-Davies was 1-(4,5-dimethoxy-2-nitrophenyl) EDTA (DMNP-EDTA, D6814), which they named DM-Nitrophen[™]^{79,80} (now a trademark of Calbiochem-Novabiochem Corp.). Because its structure more resembles that of EDTA than EGTA, we named it as a caged EDTA derivative (Figure 5.3.19). Upon illumination, DMNP-EDTA's affinity for Ca^{2+} decreases ~600,000-fold and its K_d for Ca^{2+} rises from 5 nM to 3 mM. Thus, photolysis of DMNP-EDTA complexed with Ca^{2+} results in a pulse of free Ca^{2+} . DMNP-EDTA has a stronger absorbance at longer wavelengths than does NP-EGTA (Figure 5.3.20), which facilitates uncaging. Furthermore, DMNP-EDTA has significantly higher affinity for Mg^{2+} ($K_d = 2.5 \mu M$)⁷⁹ than does NP-EGTA ($K_d = 9 mM$)⁷⁶, making it a potentially useful caged Mg^{2+} reagent. Two reviews by Ellis-Davies discuss the uses and limitations of DMNP-EDTA.^{51,81}

Diazo-2: A Photoactivatable Ca^{2+} Knockdown Reagent

In contrast to NP-EGTA and DMNP-EDTA, diazo-2 (D3034) is a photoactivatable Ca^{2+} scavenger. Diazo-2 (Figure 5.3.21), which was introduced by Adams, Kao and Tsien,^{82,83} is a relatively weak chelator (K_d for $Ca^{2+} = 2.2 \mu M$). Following flash photolysis at ~360 nm, however, cytosolic free Ca^{2+} rapidly binds to the diazo-2 photolysis product, which has a high affinity for Ca^{2+} ($K_d = 73 nM$). Intracellular loading of NP-EGTA, DMNP-EDTA and diazo-2 is best accomplished by patch pipette infusion with the carboxylate salt form of the caged compound added to the internal pipette solution at 1–10 mM. These reagents are increasingly being applied *in vivo* for controlled intervention in calcium-regulated fundamental processes in neurobiology⁸⁴ and developmental biology.⁸⁵

Caged Amino Acid Neurotransmitters

Once activated, caged amino acid neurotransmitters rapidly initiate neurotransmitter action (Figure 5.3.22), providing tools for kinetic studies of receptor binding or channel opening.^{42,46} We offer caged carbamylcholine^{86–94} (*N*-(CNB-caged) carbachol, C13654, Figure 5.3.23) and caged γ -aminobutyric acid^{67,95–97} (*O*-(CNB-caged) GABA, A7110, Figure 5.3.24), as well as two caged versions of L-glutamic acid^{96,98–104} (C7122, G7055), all of which are biologically inactive before photolysis.⁴⁴

Figure 5.3.22 CNB-caged L-glutamic acid (G7055). The CNB-caging group is rapidly photocleaved with UV light to release L-glutamic acid.

Figure 5.3.26 5-carboxyfluorescein-bis-(5-carboxymethoxy-2-nitrobenzyl) ether, β -alanine-carboxamide, succinimidyl ester (CMNB-caged carboxyfluorescein, SE, C20050).

Figure 5.3.27 Schematic representation of photoactivated fluorescence combined with sample masking. Initially, no fluorescence is observed from samples stained with a CMNB-caged fluorescein-labeled secondary detection reagent (A). The desired mask is then placed over the sample (B), after which the sample is exposed to UV light. The mask is then removed; fluorescein molecules present in the unmasked portion of the sample are uncaged by the UV light and fluoresce brightly when viewed with the appropriate filters (C). Uncaged fluorescein may now also serve as a hapten for further signal amplification using our anti-fluorescein/Oregon Green[®] antibody. For example, probing with the anti-fluorescein/Oregon Green[®] antibody followed by staining with the Alexa Fluor[®] 594 goat anti-mouse IgG antibody can be used to change the color of the uncaged probe to red fluorescent (D).

Figure 5.3.28 Caging of a carboxylic acid using the hydrazone precursor of DMNPE, a reagent that is provided in the 1-(4,5-Dimethoxy-2-nitrophenyl)diazoethane Generation Kit (D2516).

Caged Luciferin

Luciferase produces light by the ATP-dependent oxidation of luciferin. The 560 nm chemiluminescence from this reaction peaks within seconds, with light output that is proportional to luciferase activity or ATP concentrations. DMNPE-caged luciferin (L7085, Figure 5.3.25) readily crosses cell membranes, allowing more efficient delivery of luciferin into intact cells.⁵⁰ Once the caged luciferin is inside the cell, active luciferin can be released either instantaneously by a flash of UV light, or continuously by the action of endogenous intracellular esterases found in many cell types.

Caged Fluorescent Dyes

Photoactivatable fluorescent dyes, which are generally colorless and nonfluorescent until photolyzed with UV light,⁵¹ are particularly useful for investigating cell lineage¹⁰⁵ and for spatiotemporal interrogation of fluid flows.^{106–108} In addition to CMNB-caged fluorescein¹⁰⁷ (F7103), we prepare the succinimidyl ester of CMNB-caged carboxyfluorescein (C20050, Figure 5.3.26), which can be used to attach the caged fluorophore to primary amine groups of a variety of biomolecules. CMNB-caged carboxyfluorescein succinimidyl ester is a key starting material in the preparation of probes for super-resolution photoactivation microscopy.^{109,110} Furthermore, caged fluorescein probes are immunochemically cryptic; i.e., the probe is immunoreactive with anti-fluorescein/Oregon Green[®] antibodies (Section 7.4) after but not before photoactivation (Figure 5.3.27).

Kit for Caging Carboxylic Acids

Using organic synthesis methods, researchers can cage a diverse array of molecules. One of the preferred caging groups is the 1-(4,5-dimethoxy-2-nitrophenyl)ethyl (DMNPE) ester. Because the diazoethane precursor to DMNPE esters is unstable, we offer a kit (D2516) for the generation of 1-(4,5-dimethoxy-2-nitrophenyl)diazoethane and the subsequent preparation of DMNPE esters. This kit includes:

- 25 mg of the hydrazone precursor
- MnO₂ for oxidation
- Celite[®] for filtration of the reaction mixture
- Detailed protocols for caging carboxylic acids

A wide range of compounds containing a weak oxy acid (with a pK_a between 3 and 7), including carboxylic acids, phenols and phosphates, should react with the diazoethane to form the DMNPE-caged analogs⁵⁴ (Figure 5.3.28).

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Caged nucleotide esters are free of contaminating free nucleotides when initially prepared. However, some decomposition may occur during storage.
- All photoactivatable probes are sensitive to light. They should be protected from illumination except when photolysis is intended.
- This compound has weaker visible absorption at >300 nm but no discernible absorption peaks in this region.
- Spectral data of the 2-mercaptoethanol adduct.
- The molecular weight (MW) of this product is approximate because the degree of hydration and/or salt form has not been conclusively established.
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- This product can be activated by long-wavelength ultraviolet light (>300 nm) for photoaffinity labeling of proteins.
- This product is colorless and nonfluorescent until it is activated by ultraviolet photolysis. Photoactivation generates a fluorescein derivative with spectral characteristics similar to C1359.

DATA TABLE 5.3 PHOTOACTIVATABLE REAGENTS, INCLUDING PHOTOREACTIVE CROSSLINKERS AND CAGED PROBES—continued

9. The Ca^{2+} dissociation constant of diazo-2 is 2200 nM before photolysis and 73 nM after ultraviolet photolysis. The absorption spectrum of the photolysis product is similar to that of B1204. (J Am Chem Soc (1989) 111:7957)
10. $K_d(\text{Ca}^{2+})$ increases from 5 nM to 3 mM after ultraviolet photolysis. K_d values determined in 130 mM KCl, 10 mM HEPES, pH 7.1. (Proc Natl Acad Sci U S A (1988) 85:6571)
11. E1374 spectral data are for the free dye. Fluorescence is weak, but intensity increases ~15-fold on binding to DNA. After photocrosslinking to DNA, Abs = 504 nm (EC ~4000 $\text{cm}^{-1}\text{M}^{-1}$), $E_m = 600$ nm. (Nucleic Acids Res (1978) 5:4891, Biochemistry (1980) 19:3221)
12. Unstable in water. Use immediately.
13. Ultraviolet photolysis of I23580 generates I3716 (Section 17.2).
14. L7085 is converted to bioluminescent luciferin (L2911, Section 10.6) upon ultraviolet photoactivation.
15. $K_d(\text{Ca}^{2+})$ increases from 80 nM to 1 mM after ultraviolet photolysis. K_d values determined in 100 mM KCl, 40 mM HEPES, pH 7.2. (Proc Natl Acad Sci U S A (1994) 91:187)
16. This product is intrinsically a liquid or an oil at room temperature.
17. N6803 is converted to N6802 via hydrolysis of its acetoxymethyl ester (AM) groups.
18. The absorption spectrum of P6317 includes an additional shoulder at 306 nm (EC = 10,000 $\text{cm}^{-1}\text{M}^{-1}$).

PRODUCT LIST 5.3 PHOTOACTIVATABLE REAGENTS, INCLUDING PHOTOREACTIVE CROSSLINKERS AND CAGED PROBES

Cat. No.	Product	Quantity
A7056	adenosine 5'-diphosphate, P^2 -(1-(2-nitrophenyl)ethyl) ester, monopotassium salt (NPE-caged ADP)	5 mg
A1048	adenosine 5'-triphosphate, P^3 -(1-(2-nitrophenyl)ethyl) ester, disodium salt (NPE-caged ATP)	5 mg
A1049	adenosine 5'-triphosphate, P^3 -(1-(4,5-dimethoxy-2-nitrophenyl)ethyl) ester, disodium salt (DMNPE-caged ATP)	5 mg
A7110	γ -aminobutyric acid, α -carboxy-2-nitrobenzyl ester, trifluoroacetic acid salt (O-(CNB-caged) GABA)	5 mg
A2522	4-azido-2,3,5,6-tetrafluorobenzoic acid, succinimidyl ester (ATFB, SE)	25 mg
B1526	benzophenone-4-isothiocyanate	100 mg
B1508	benzophenone-4-maleimide	100 mg
B1577	4-benzoylbenzoic acid, succinimidyl ester	100 mg
B22358	2'-(or-3')-O-(4-benzoylbenzoyl)adenosine 5'-triphosphate, tris(triethylammonium) salt (BzBzATP) *5 mM in buffer*	2 mL
B30600	bimane azide	5 mg
C20050	5-carboxyfluorescein-bis-(5-carboxymethoxy-2-nitrobenzyl) ether, β -alanine-carboxamide, succinimidyl ester (CMNB-caged carboxyfluorescein, SE)	1 mg
C13654	N-(CNB-caged) carbachol (N-(α -carboxy-2-nitrobenzyl)carbamylcholine, trifluoroacetic acid salt)	5 mg
C7122	N-(CNB-caged) L-glutamic acid (N-(α -carboxy-2-nitrobenzyl)-L-glutamic acid)	5 mg
C7074	cyclic adenosine 5'-diphosphate ribose, 1-(1-(2-nitrophenyl)ethyl) ester (NPE-caged cADP-ribose) *mixed isomers*	50 μg
D3034	diazo-2, tetrapotassium salt *cell impermeant*	1 mg
D6814	1-(4,5-dimethoxy-2-nitrophenyl)-1,2-diaminoethane- N,N,N' -tetraacetic acid (DMNP-EDTA) *cell impermeant*	5 mg
D1037	4,5-dimethoxy-2-nitrobenzyl adenosine 3',5'-cyclicmonophosphate (DMNB-caged cAMP)	5 mg
D2516	1-(4,5-Dimethoxy-2-nitrophenyl)diazoethane Generation Kit	1 kit
E1374	ethidium monoazide bromide (EMA)	5 mg
F7103	fluorescein bis-(5-carboxymethoxy-2-nitrobenzyl) ether, dipotassium salt (CMNB-caged fluorescein)	5 mg
G7055	L-glutamic acid, γ -(α -carboxy-2-nitrobenzyl) ester, trifluoroacetic acid salt (γ -(CNB-caged) L-glutamic acid)	5 mg
I23580	D- <i>myo</i> -inositol 1,4,5-triphosphate, $P_{4(5)}$ -(1-(2-nitrophenyl)ethyl) ester, tris(triethylammonium) salt (NPE-caged Ins 1,4,5- P_3)	25 μg
L7085	D-luciferin, 1-(4,5-dimethoxy-2-nitrophenyl)ethyl ester (DMNPE-caged luciferin)	5 mg
N6803	<i>o</i> -nitrophenyl EGTA, AM (NP-EGTA, AM) *cell permeant* *special packaging*	20 x 50 μg
N6802	<i>o</i> -nitrophenyl EGTA, tetrapotassium salt (NP-EGTA) *cell impermeant*	1 mg
P6317	N-(2-pyridyldithio)ethyl-4-azidosalicylamide (PEAS; AET)	10 mg

6.1 Introduction to Signal Amplification

Signal Amplification: Why and How

The number of target molecules per unit volume of sample is a key variable in all biological detection applications. Although it is possible to control target abundance through strategies such as recombinant protein overexpression and siRNA knockdowns, there is an associated risk of fundamentally perturbing the finely balanced and intertwined molecular interaction networks that underlie cellular function. There is therefore always some degree of need to detect molecules at their native abundance levels, which can vary by many orders of magnitude. For example, proteins in mammalian cells have abundances varying by at least seven orders of magnitude ($\sim 10^1$ – 10^8 copies per cell). Furthermore, the distribution of target molecules within the cell is neither spatially uniform nor temporally static—indeed, these spatial and temporal variations are often the subject for experimental investigation. Many functionally important proteins such as transcription factors and cell-surface cytokine receptors have native expression levels below the detection threshold of labeled primary and secondary antibodies and other affinity reagents. In this chapter, we describe a collection of signal amplification strategies that can be used facilitate the detection of low-abundance molecular targets either *in situ* or *ex situ*¹ (e.g., on microarrays). The signal amplification strategies described below are essentially of two types—enzyme labeling and macrofluorophore labeling. These two approaches are not necessarily singular and may be used in combination for additive effect.²

Enzyme labeling utilizes an enzyme linked to a target-specific affinity reagent, either by direct conjugation or through a secondary complex (Figure 6.1.1). The enzyme turns over multiple copies of a

Figure 6.1.1 Schematic diagram of primary and secondary detection reagents. **A)** In primary detection methods, the target-specific molecule includes one or more detectable moieties, shown here as radiant orbs. **B)** In secondary detection methods, the target-specific molecule contains binding sites or haptens that can be selectively recognized by secondary detection reagents. For example, these sites might be antigenic epitopes that bind antibodies. Alternatively, the target-specific molecule might be conjugated to either biotin or fluorescent dyes, thereby creating a molecule that can be detected with any of our avidin and streptavidin conjugates or our anti-fluorescent dye antibodies. As shown here, the target-specific molecule may contain multiple sites for binding the secondary detection reagent, thereby providing a simple system for amplifying the signal.

fluorogenic or chromogenic substrate (Chapter 10), resulting in much higher target-associated signal levels than are obtainable by dye-labeled affinity reagents. The two most widely used enzymes for this purpose are horseradish peroxidase (HRP, Section 6.2) and alkaline phosphatase (Section 6.3). Major applications of enzyme labeling include immunocytochemical and immunohistochemical detection and enzyme-linked immunosorbent assays (ELISAs). In immunocytochemical and immunohistochemical detection applications, it is essential that the product of the enzyme reaction is localized in the vicinity of the enzyme conjugate in order to convey information on the spatial distribution of the target. Tyramide substrates for HRP (Section 6.2, Figure 6.1.2) and our ELF[®] substrates for alkaline phosphatase (Section 6.3, Figure 6.1.3) fulfill this requirement. In ELISAs, the objective is macroscopic

Figure 6.1.2 Tyramide signal amplification of immunofluorescent staining in mouse brain sections. Mice were transcardially perfused with phosphate-buffered saline followed by 4% formaldehyde in phosphate buffer. Serial sections (30 μ m) were cut in a freezing microtome and transferred to phosphate-buffered saline. Free-floating sections were incubated with 1% hydrogen peroxide to quench endogenous peroxidase activity, blocked in 5% normal goat serum, then stained with a rabbit polyclonal antibody to calbindin D-28K (Chemicon) at a 1:1000 dilution. After washing, sections were incubated with Alexa Fluor[®] 488 goat anti-rabbit IgG antibody (A11008) at 5 μ g/mL (**A**) or HRP-goat anti-rabbit IgG antibody at 1 μ g/mL, followed by Alexa Fluor[®] 488 tyramide (in TSA[™] Kit #12, T20922; **B**). Sections were washed, mounted on slides, coverslipped with ProLong[®] antifade reagent (in Kit P7481) and imaged under identical conditions (10 \times magnification, 250 millisecond exposure) using a bandpass filter set appropriate for fluorescein (FITC).

Figure 6.1.3 Endogenous phosphatase activity of osteoblast cells in a cartilaginous element of an adult zebrafish head was localized using the ELF[®] 97 Endogenous Phosphatase Detection Kit (E6601) to stain a cryosection. In addition to the yellow-green fluorescence of the ELF[®] 97 alcohol precipitate, the section was stained with red-fluorescent Texas Red[®]-X wheat germ agglutinin (W21405) and with the blue-fluorescent Hoechst 33342 nucleic acid stain (H1399, H3570, H21492). The triple-exposure image was acquired using bandpass filter sets appropriate for ELF[®] 97 alcohol, Texas Red[®] dye and DAPI.

quantitation rather than microscopic localization of the target, so substrates that yield diffusible products such as our fluorogenic Amplex® UltraRed substrate for HRP (Section 6.2) and our CSPD® and CDP-Star® chemiluminescent substrates for alkaline phosphatase (Section 6.3) are typically used. Detection signals that are amplified using enzyme reactions are necessarily time dependent. Therefore, in both immunocytochemical and immunoassay applications of enzyme labeling, careful control of timing is an essential prerequisite for obtaining quantitative and reproducible results.

Macrofluorophores are collections of fluorophores numbering in the tens (phycobiliproteins, Section 6.4) to millions (fluorescent microspheres, Section 6.5) attached to or incorporated in a common scaffold. The scaffold is coupled to a target-specific affinity reagent such as an antibody or streptavidin, and the incorporated fluorophores are thereby collectively associated with the target upon binding. From a physical perspective, quantum dot nanocrystals (Qdot® nanocrystals, Section 6.6) are single fluorophores, albeit ones with extraordinary photon output capacity. From a utilization standpoint however, they resemble macrofluorophores and are similar in size to our smallest fluorescent microspheres. Macrofluorophores are not subject to the time-dependent signal development considerations introduced by enzyme labeling but are more susceptible to nonspecific binding. Even phycobiliproteins, the smallest and most biocompatible of these macrofluorophores, are not immune to these effects.³

There are several other noteworthy approaches to the detection of low-abundance targets that may be applied either in combination with or as alternatives to the labeling technologies described in this chapter. In the case of nucleic acids, the capacity for self-replication allows the amount of target to be amplified through application of the polymerase chain reaction (PCR). Attempts to increase target-associated signals should generally be pursued in parallel with attempts to decrease off-target background signals. Blocking reagents such as our BlockAid™ blocking solution for use with fluorescent microspheres (B10710, Section 6.5) and our Image-iT® FX signal enhancer (I36922, Section 23.1) for use with dye-labeled antibodies can be employed in pursuit of this objective. For fluorescence detection in general, single-molecule detection techniques represent perhaps the ultimate in background reduction strategies.⁴

Primary and Secondary Detection Reagents

Both enzyme and macrofluorophore labels can be coupled directly to target-specific affinity reagents (primary detection) or to more generic affinity reagents that form stable complexes with unlabeled primary reagents, usually on the basis of immunorecognition (secondary detection). As indicated schematically in Figure 6.1.1, secondary detection inherently provides some degree of signal amplification, although sometimes at the expense of additional background due to nonspecific binding. These basic concepts of primary and secondary detection apply not only to the signal amplification techniques addressed in the current chapter but also to the dye-labeled affinity reagents described in Chapter 7.

Primary Detection Reagents

Any easily detectable molecule that binds directly to a specific target is a primary detection reagent. Such reagents are detected by fluorescence, chemiluminescence, absorption or electron diffraction conferred by stably attached labels. The conjugation and crosslinking chemistries used to create these stable attachments are discussed in detail in Chapter 1, Chapter 2 and Chapter 5. In addition to our fluorophore-labeled anti-dye antibodies (Section 7.4) and monoclonal antibodies (www.invitrogen.com/handbook/antibodies), many of the Molecular Probes® site-selective products can be considered primary detection reagents. These include our fluorescent lectins (Section 7.7), nucleic acid stains (Chapter 8), protein and glycoprotein stains (Section 9.3, Section 9.4), phallotoxins (Section 11.1), membrane probes (Chapter 13), annexin V conjugates for detecting apoptotic cells (Section 15.5) and various drug and toxin analogs (Section 16.2, Section 16.3). These primary detection reagents can typically be detected by fluorescence microscopy, fluorometry or flow cytometry methods.

Secondary Detection Reagents

Although many biomolecules, such as antibodies and lectins, bind selectively to a biological target, they usually need to be chemically modified before they can be detected. Often the biomolecule is conjugated to a fluorescent or chromophoric dye or to a heavy atom complex such as colloidal gold. However, the researcher may wish to avoid the time and expense required for these conjugations, choosing instead to use a more generic secondary detection reagent. Typically, secondary detection reagents recognize a particular class of molecules. For example, labeled goat anti-mouse IgG antibodies can be used to localize a tremendous variety of target-specific mouse monoclonal antibodies. Our extensive secondary antibody offering (Section 7.2) provides a wide selection of labels including our superior Alexa Fluor® dye series, phycobiliproteins, Alexa Fluor® dye-phycobiliprotein tandem fluorophores, Qdot® nanocrystals, biotin and enzyme labels (HRP and alkaline phosphatase). We also offer many options in terms of immunoreactivity, an essential consideration in avoiding confounding cross-reactivity when performing simultaneous secondary immunodetection of two or more targets. Our labeled secondary antibody portfolio contains antibodies against IgG and IgM from several mammalian species, including various isotypes of mouse IgG, as well as antibodies against avian (chicken) IgY. Our Zenon® antibody labeling technology (Section 7.3) uses conjugates of an Fc-specific anti-IgG Fab fragment for the rapid and quantitative labeling of the corresponding mouse, rabbit, goat or human antibody.

6.2 TSA and Other Peroxidase-Based Signal Amplification Techniques

Principles of Tyramide Signal Amplification

We are committed to the extensive development of tyramide signal amplification (TSA) in combination with our Alexa Fluor® dyes to achieve high-resolution signal amplification in cell and tissue applications. TSA—sometimes called CARD, for Catalyzed Reporter Deposition—is an enzyme-mediated detection method that utilizes the catalytic activity of horseradish peroxidase (HRP) to generate high-density labeling of a target protein or nucleic acid sequence *in situ*.^{1–5} TSA has been reported to increase detection sensitivity up to 100-fold, as compared with conventional avidin–biotinylated enzyme complex (ABC) procedures.^{3,6–12} Moreover, for multiparameter detection of targets in either live or fixed cells or tissues, TSA can be combined with several other important technologies, including our nucleic acid labeling kits (Section 8.2), primary and secondary antibodies, avidin and lectin conjugates (Chapter 7), cytoskeletal stains (Chapter 11), organelle probes (Chapter 12) and cell tracers (Chapter 14). The Zenon® Horseradish Peroxidase Antibody Labeling Kits (Section 7.3, Table 7.7), which are described below, are of particular utility when used in combination with TSA technology.

TSA labeling is a combination of three (or four) elementary processes (Figure 6.2.1) that typically comprise:

- Binding of a probe to the target via immunoaffinity (proteins) or hybridization (nucleic acids) followed by secondary detection of the probe with an HRP-labeled antibody or streptavidin conjugate. Peroxidase conjugates of other targeting proteins such as lectins and receptor ligands are likely to be suitable for labeling targets, as is endogenous peroxidase activity.^{13,14} Unconjugated HRP is also useful as a neuronal tracer; its use in combination with TSA is demonstrated in Figure 6.2.2.
- Activation of multiple copies of a labeled tyramide derivative by HRP. Most often a fluorescent or biotinylated tyramide has been used; however, labeling with other hapten-conjugated tyramides^{15,16} or with polymeric reagents, including tyramide-conjugated gold particles, has also been reported.¹⁷
- Covalent coupling of the resulting highly reactive, short-lived tyramide radicals to residues (principally the phenol moiety of protein tyrosine residues) in the vicinity of the HRP–target interaction site, resulting in minimal diffusion-related loss of signal localization (Figure 6.2.3). In a unique application, fluorescein-labeled tyramine has been used to detect protein oxidation by reactive oxygen species (ROS, Section 18.2) in fibroblasts exposed to oxidative stress¹⁸ and in the extracellular proteins of endothelial cells exposed to an oxidative burst from phorbol myristate acetate-activated neutrophils.¹⁹

Figure 6.2.2 Horseradish peroxidase (HRP)-filled reticulospinal neurons of the hindbrain of a whole-mount zebrafish larva were detected using green-fluorescent Alexa Fluor® 488 tyramide (TSA™ Kit #2, T20912). The spinal cord was labeled by transection in the presence of HRP (1 mg/mL). After a 2-hour incubation, the specimen was fixed and the HRP was visualized using Alexa Fluor® 488 tyramide. This figure represents a projection (performed with AutoQuant Imaging, Inc., software) of a stack of 30 images.

Figure 6.2.1 Schematic representation of TSA detection methods applied to immunolabeling of an antigen. The antigen is detected by a primary antibody, followed by a horseradish peroxidase (HRP)-labeled secondary antibody in conjunction with a dye-labeled tyramide, resulting in localized deposition of the activated tyramide derivative (Stage 1). Further dye deposition, and therefore higher levels of signal amplification, can be generated by detecting dye deposited in Stage 1 with a HRP-labeled anti-dye antibody in conjunction with a dye-labeled tyramide (Stage 2).

Figure 6.2.3 Coupling of Alexa Fluor® 488 tyramide to protein tyrosine side chains via peroxidase-mediated formation of an O,O'-dityrosine adduct.

Figure 6.2.4 Golgi in HeLa cells detected with Alexa Fluor® 546 tyramide. Cells were fixed and permeabilized, then labeled with anti-human Golgin-97 antibody (A21270) and detected using HRP-conjugated goat anti-mouse IgG antibody and Alexa Fluor® 546 tyramide, which are components of the TSA™ Kit #3 (T20913). The nuclei were counterstained using DAPI (D1306, D3571, D21490). The images were acquired using filters appropriate for DAPI and Alexa Fluor® 546 and processed using MetaMorph® software from Universal Imaging Corp.

Figure 6.2.5 Nuclear and non-nuclear incorporation of 5-bromo-2'-deoxyuridine in live cells. Bovine pulmonary arterial endothelial (BPAE) cells were labeled with 5-bromo-2'-deoxyuridine (BrdU, B23151) applied at a concentration of 10 μ M for 30 minutes. After fixation with 4% formaldehyde in phosphate-buffered saline for 30 minutes, chromatin was denatured by treatment with 2 M HCl for 20 minutes. Incorporated BrdU was detected with mouse monoclonal anti-bromodeoxyuridine antibody followed by HRP-conjugated goat anti-mouse IgG antibody and Oregon Green® 488 tyramide (TSA™ Kit #9, T20919). Tyramide labeling was further amplified and converted for visualization by bright-field microscopy by detection of the Oregon Green® 488 dye hapten using the HRP conjugate of anti-fluorescein/Oregon Green® antibody (A21253) and diaminobenzidine (DAB) staining. Both nuclear and non-nuclear (presumably mitochondrial) incorporation of BrdU is clearly visible in the resulting image.

In direct TSA protocols, the fluorescent signal can be immediately detected, resulting in both excellent spatial resolution (Figure 6.2.4) and high signal intensity. When using a hapten-labeled tyramide such as biotin-XX tyramide, a subsequent detection step is required using a bioconjugate that recognizes the hapten, in this case a fluorescent streptavidin (Section 7.6). Alternatively, the hapten-labeled tyramide can be detected using an alkaline phosphate- or HRP-labeled hapten recognizer in conjunction with a fluorogenic or chromogenic substrate (Figure 6.2.5), resulting in another enzyme-amplified detection step. Chemiluminescent detection of an HRP-deposited biotin tyramide has also been reported.²⁰ The streptavidin conjugate of NANOGOLD® 1.4 nm gold clusters (N24918, Section 7.6) has been used to make biotin tyramide conjugates visible in light and electron microscopy.^{21,22} The antibody and streptavidin conjugates of Alexa Fluor® FluoroNanogold™ 1.4 nm gold clusters (Section 7.2, Section 7.6) can also be used with hapten-labeled tyramides for correlated fluorescence, light and electron microscopy studies.

The signal amplification conferred by the turnover of multiple tyramide substrates per peroxidase label translates into practical benefits, namely ultrasensitive detection of low-abundance targets in fluorescence *in situ* hybridization,^{3,23,24} immunohistochemistry,^{6,25} neuroanatomical tracing^{7,26} and other applications. For example, we have utilized TSA and Alexa Fluor® 488 tyramide to detect expression of low-abundance epidermal growth factor (EGF) and estrogen receptors by flow cytometry with far greater sensitivity than can be obtained using a directly labeled EGF probe (Figure 6.2.6) or fluorophore- or hapten-labeled antibodies to the estrogen receptor (Figure 6.2.7). Application of TSA resulted in significantly increased detectability of estrogen receptors in urinary bladder carcinomas, as compared with conventional immunohistochemical analysis.²⁷

A Variety of Kits for TSA Detection

TSA™ Kits

We have developed a number of TSA™ Kits that combine the versatile tyramide signal amplification technology with our high-performance Alexa Fluor® tyramides, Oregon Green® 488 tyramide or biotin-XX tyramide (Table 6.1). Each kit provides sufficient materials to stain 50–150 slide preparations and includes the following components:

- Tyramide labeled with an Alexa Fluor® dye, Oregon Green® 488 dye or biotin-XX
- HRP-conjugated anti-mouse IgG antibody, anti-rabbit IgG antibody or streptavidin
- Amplification reaction buffer
- H₂O₂ reaction additive
- TSA blocking reagent
- Detailed protocols for tyramide labeling

Our fluorescent and biotin-XX tyramides are not currently available as stand-alone reagents.

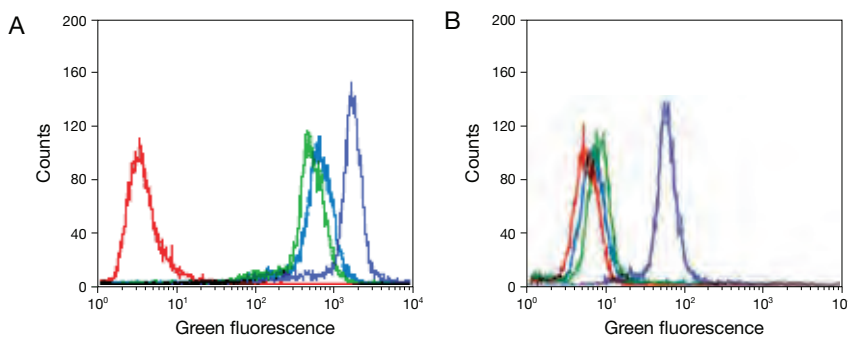

Figure 6.2.6 Detection of epidermal growth factor (EGF) receptors directly or with signal amplification. Cells expressing high (A431 cells, panel A) and low (NIH 3T3 cells, panel B) levels of EGF receptors were either directly labeled with the preformed Alexa Fluor® 488 complex of biotinylated epidermal growth factor (E13345, blue) or indirectly labeled with biotinylated EGF (E3477) followed by either Alexa Fluor® 488 streptavidin (S11223, green) or HRP-conjugated streptavidin and Alexa Fluor® 488 tyramide (purple), components of our TSA™ Kit #22 (T20932).

Zenon® Horseradish Peroxidase Antibody Labeling Kits

Our Zenon® Horseradish Peroxidase Antibody Labeling Kits, available for mouse IgG (Z25054, Z25154, Z25254), rabbit IgG (Z25354) and human IgG (Z25454), make it possible to quantitatively label even submicrogram quantities of a primary antibody with HRP immediately before it is applied to the sample (Section 7.3, Table 7.7, Figure 6.2.8). Antibodies labeled with HRP using these Zenon® Antibody Labeling Kits can replace the HRP-labeled goat anti-mouse IgG and goat anti-rabbit IgG antibody conjugates in any of the TSA™ Kits containing these secondary detection reagents.

Zenon® Antibody Labeling Kit Enhanced with TSA Technology

For mouse IgG₁ primary antibodies, we have developed the Zenon® Alexa Fluor® 488 Mouse IgG₁ Labeling Kit enhanced with TSA technology (Z25090), which provides the necessary reagents from both the Zenon® Horseradish Peroxidase Mouse IgG₁ Labeling Kit and the Alexa Fluor® 488 TSA™ Kit, for researchers who want both the ease of labeling mouse IgG₁ antibodies with Zenon® labeling reagents and the signal amplification afforded by TSA technology. Each kit provides sufficient reagents for 25 labelings, including:

- Zenon® HRP mouse IgG₁ labeling reagent
- Zenon® mouse IgG blocking reagent
- Alexa Fluor® 488 tyramide
- Dimethylsulfoxide (DMSO)
- TSA blocking reagent
- TSA amplification buffer
- Hydrogen peroxide (H₂O₂)
- Detailed protocols for Zenon® complex formation and tyramide labeling

The Zenon® HRP mouse IgG₁ labeling reagent contains Fab fragments of goat IgG antibodies directed against the Fc portion of intact mouse IgG₁ antibodies. These Fab fragments have been purified to ensure their selectivity for the Fc portion of the mouse IgG₁ antibody and then labeled with HRP. This Zenon® HRP mouse IgG₁ labeling reagent is simply mixed with any mouse IgG₁

Figure 6.2.7 Enhancement of estrogen receptor detection sensitivity by tyramide signal amplification (TSA™). SKBR3 cells with characteristically low levels of estrogen receptor expression were fixed, permeabilized and treated with H₂O₂ to inhibit endogenous peroxidase activity. A mouse anti-human estrogen receptor monoclonal antibody (Chemicon) was labeled with the Alexa Fluor® 488 dye or with biotin using our Zenon® Alexa Fluor® 488 Mouse IgG₁ Labeling Kit (Z25002) or Zenon® Biotin-XX Mouse IgG₁ Labeling Kit (Z25052), respectively. Detection of estrogen receptors using the labeled antibodies was performed on a Becton Dickinson FACScan™ flow cytometer with excitation at 488 nm. The cellular fluorescence intensity histograms represent detection with Alexa Fluor® 488 dye-labeled antibodies (green), biotinylated antibodies coupled to Alexa Fluor® 488 streptavidin (S11223, red) and biotinylated antibodies coupled to HRP-streptavidin and Alexa Fluor® 488 tyramide (TSA™ Kit #22, T20932; orange). The blue histogram represents unstained cells.

Figure 6.2.8 Labeling scheme utilized in the Zenon® Antibody Labeling Kits. An unlabeled IgG antibody is incubated with the Zenon® labeling reagent, which contains a fluorophore-labeled, Fc-specific anti-IgG Fab fragment (A). This labeled Fab fragment binds to the Fc portion of the IgG antibody (B). Excess Fab fragment is then neutralized by the addition of a nonspecific IgG (C), preventing cross-labeling by the Fab fragment in experiments where primary antibodies of the same type are present. Note that the Fab fragment used for labeling need not be coupled to a fluorophore, but could instead be coupled to an enzyme (such as HRP) or to biotin.

Table 6.1 Tyramide Signal Amplification (TSA) Kits.

Tyramide (Ex/Em) *	Peroxidase Conjugate

Figure 6.2.9 The cytoskeleton of a fixed and permeabilized bovine pulmonary artery endothelial cell detected using mouse monoclonal anti- α -tubulin antibody (A11126), visualized with Alexa Fluor® 647 goat anti-mouse IgG antibody (A21235) and pseudocolored magenta. Endogenous biotin in the mitochondria was labeled with green-fluorescent Alexa Fluor® 488 streptavidin (S11223) and DNA was stained with blue-fluorescent DAPI (D1306, D3571, D21490).

Figure 6.2.10 Immunohistochemical detection using tyramide signal amplification. A transverse section of fixed zebrafish retina was probed with mouse monoclonal FRet 34 antibody and subsequently developed for visualization using HRP-conjugated goat anti-mouse IgG antibody and Alexa Fluor® 488 tyramide, which are supplied in the TSA™ Kit #2 (T20912). The section was counterstained with the blue-fluorescent Alexa Fluor® 350 wheat germ agglutinin (W11263) and the far red-fluorescent TOTO-3 nuclear stain (T3604).

primary antibody to form the Fab–mouse IgG₁ complexes, which can be used for immunolabeling similar to that of primary antibodies covalently labeled with HRP. TSA technology is then used to detect the target-bound Fab–mouse IgG₁ complex. Each HRP label on the Fab–mouse IgG₁ complexes can activate multiple copies of the Alexa Fluor® 488 tyramide to produce short-lived tyramide radicals that are highly reactive with residues near the interaction site, yielding an amplified green-fluorescent signal with minimal diffusion.

Other Horseradish Peroxidase Conjugates for Secondary Detection

For use in signal amplification of antibody- or biotin-labeled targets, we offer the horseradish peroxidase conjugates of:

- Streptavidin and NeutrAvidin™ biotin-binding protein (S911, A2664; Section 7.6)
- Goat anti-mouse IgG antibody (A10551, A10668, A10677, A10685, G21040)
- Goat anti-mouse F(ab')₂ fragment (F21453)
- Goat anti-rabbit IgG antibody (G21234)
- Goat anti-rabbit F(ab')₂ fragment (A10547)
- Goat anti-rat IgG antibody (A10549)
- Goat anti-rat F(ab')₂ fragment (A10548)
- Mouse anti-human IgG antibody (A10648, A10654)
- Rabbit anti-goat IgG antibody (R21459)
- Rabbit anti-mouse IgG antibody (R21455)

A more thorough discussion of our secondary antibodies can be found in Section 7.2 (Table 7.1).

Applying TSA Technology to Cells and Tissues

TSA technology has been used successfully for over two decades,^{1,28} and there are many reports of the use of biotin tyramide for indirect target labeling and fluorescent tyramides for direct target labeling. Direct labeling methods have the considerable advantage of saving a second step in the detection scheme. Moreover, labeling targets with fluorescent tyramides instead of biotin tyramide has the further advantage of avoiding amplification of endogenous biotin in cells and tissues, such as we have observed in mitochondrial staining with streptavidin conjugates in the absence of a biotinylated probe (Figure 6.2.9). In most of the early reports, the biotin tyramide used did not have the additional 14-atom spacer that we utilize in our biotin-XX tyramide to make the probe more accessible to avidin conjugates, nor are the specific fluorescent dyes available in our TSA™ Kits. Therefore, the specific methods described in these references should be considered guides rather than definitive protocols, and results using our TSA reagents may differ from those reported. In our experience, the Alexa Fluor® 488 tyramide (Table 6.1) provides greater signal and significantly greater photostability than fluorescein tyramide, and the other Alexa Fluor® tyramides also yield intense staining of targets.

Immunohistochemical Detection Using TSA

TSA detection can be applied to a variety of immunohistochemical specimen preparations, including cryostat sections, formaldehyde-fixed paraffin-embedded sections, plastic-embedded sections and cultured cells. In immunohistochemical applications (Figure 6.2.10), sensitivity enhancements derived from TSA allow primary antibody dilutions to be increased—up to a 1:1,000,000 antibody dilution was possible in one reported case,¹⁰ although a 5- to 50-fold increase over the normal dilution factor is more common⁹—in order to reduce nonspecific background signals.⁷ Additionally, the strong signal amplification provided by the TSA method can overcome relatively high autofluorescence of cells and tissues.⁶ Furthermore, because TSA and diaminobenzidine (DAB) oxidation are both peroxidase-mediated reactions, TSA is readily adaptable for correlated fluorescence and electron microscopy studies.^{29,30} The significantly lower detection threshold of TSA as compared with fluorescent secondary antibodies allows detection of two targets by primary antibodies raised in the same host species, without substantial crosstalk between the signals.³¹ The first target was detected using TSA and a primary antibody concentration that was so low that it was essentially undetectable by fluorescent secondary antibodies; the second target was then detected by conventional secondary immunofluorescence labeling.

Fluorescence *In Situ* Hybridization Using TSA

The increased sensitivity afforded by TSA (Figure 6.2.11) can be critically important for detecting relatively short oligonucleotide probes and low-abundance mRNAs by fluorescence *in situ* hybridization^{3,32} (FISH). Cosmid detection in formalin-fixed, paraffin-embedded sections is cumbersome, and the ability to use smaller cosmid probes of less than 1000 bases in conjunction with TSA detection technology is likely to be an important technique for FISH.²³ TSA is also faster than traditional FISH detection schemes, allowing definitive results to be obtained within a single day. In addition, a two-stage amplification method for ultrasensitive mRNA detection has been reported that combines TSA detection of biotinylated riboprobes with alkaline phosphatase-mediated fluorescence generation using Molecular Probes® ELF® 97 phosphatase substrate³³ (Section 6.3).

TSA, however, is not a panacea for FISH sensitivity problems. Because both specifically and nonspecifically bound probe signals are amplified, TSA will not compensate for suboptimal hybridization conditions. Optimal probe concentrations are typically 2- to 10-fold lower for TSA-detected FISH than for conventional immunocytochemical detection procedures, again saving on the cost of expensive hybridization probes.²⁴ Typically, FISH probes are labeled by indirect methods that use streptavidin- or antibody-conjugated HRP. Techniques for direct labeling of oligonucleotide probes have been developed to eliminate background signals due to nonspecific binding of peroxidase conjugates.^{4,34,35}

As with some other detection systems, TSA technology allows several probes to be hybridized simultaneously to identify multiple targets. Signal development using multicolored fluorescent tyramides must then be carried out sequentially, with a peroxidase inactivation step between each TSA reaction to prevent crosstalk²⁴ (Figure 6.2.12). TSA amplification followed by peroxidase inactivation through mild acid treatment with 0.01 M HCl for 10 minutes at room temperature³⁶ and then reapplication of TSA using a fluorescent tyramide of a different fluorescent color has been used for triple-labeled *in situ* hybridization.^{4,36}

Detection of Hapten-Labeled Tyramides

When a tyramide labeled with a hapten such as biotin-XX is used for TSA in an indirect labeling technique, a signal-generation reagent or scheme is necessary. A fluorescent tyramide such as our Oregon Green® 488 tyramide can also be utilized as a hapten for subsequent detection and amplification by an anti-fluorescein/Oregon Green® dye antibody (Section 7.4). Various reagents and reagent combinations have been reported for detecting enzyme-deposited biotin tyramide or fluorescein tyramide that should be equally suitable for use with our biotin-XX tyramide and Oregon Green® 488 tyramide, including:

- Streptavidin conjugate of alkaline phosphatase (S921, Section 7.6) in combination with NBT/BCIP^{37,38} (N6495, N6547; Section 6.3)
- Streptavidin conjugate of HRP (S911, Section 7.6) or the rabbit anti-fluorescein/Oregon Green® antibody conjugate of HRP^{32,39-42} (A21253, Section 7.4) in combination with a traditional chromogenic peroxidase substrate such as diaminobenzidine (DAB)^{43,44} (Figure 6.2.5)
- Fluorescent conjugates of avidin or streptavidin (Section 7.6).
- Qdot® nanocrystal streptavidin conjugates⁴⁵ (Section 6.6)
- Diaminobenzidine (DAB) Histochemistry Kits (D22185, D22187; see below), for direct use with biotin-XX tyramide or conversion of fluorescent signals to permanent staining
- NANOGOLD® and Alexa Fluor® FluoroNanogold™ conjugates of antibodies (Section 7.2) and streptavidin (Section 7.6), for target localization using a combination of light and electron microscopy^{21,46}

Anti-fluorescein/Oregon Green® antibody conjugates of HRP (Section 7.4, Table 7.8) have been used with fluorescein-labeled probes and TSA to detect:

- Embryonic gene expression at the cellular level by FISH⁴⁷
- mRNA in paraffin sections of organotypic multicellular spheroids⁴⁸
- mRNA probe for a calcium transporter protein⁴⁹
- Somatostatin receptor protein⁴¹
- Tissue antigens, with a 10- to 100-fold increase in sensitivity over conventional staining methods³⁹

Figure 6.2.11 Digital image analysis comparison of *in situ*-hybridized biotinylated α -satellite probes detected using TSA™ Kit #23 (T20933) with HRP-streptavidin and Alexa Fluor® 546 tyramide (right) or Alexa Fluor® 546 streptavidin (S11225, left). Both images were converted to pixel intensity values using MetaMorph® software (Universal Imaging Corporation) and transferred to a Microsoft® Excel spreadsheet for plotting. Alexa Fluor® 546 dye and DAPI (counterstain) intensity values are shown in red and blue, respectively. Alexa Fluor® 546 dye intensity values below 35% of maximum were omitted for clarity.

Figure 6.2.12 *In situ* hybridization of α -satellite probes to human chromosomes 1, 15 and 17 detected by tyramide signal amplification. α -Satellite probes to chromosomes 1, 15 and 17 were labeled by nick translation with biotin-11-dUTP, ChromaTide® Texas Red®-12-dUTP (C7631) and ChromaTide® Oregon Green® 488-5-dUTP, respectively. Following simultaneous hybridization of all three probes, the biotinylated chromosome 1 probe was detected with HRP-streptavidin conjugate and Alexa Fluor® 546 tyramide (TSA™ Kit #23, T20933). HRP activity from this first TSA detection step was then quenched by treatment with 1% hydrogen peroxide for 30 minutes. Lastly, the Oregon Green® 488 dye-labeled chromosome 17 probe was detected with anti-fluorescein/Oregon Green® antibody (A6421) followed by HRP-conjugated goat anti-mouse IgG antibody and Alexa Fluor® 594 tyramide (TSA™ Kit #5, T20915). HRP activity from this second TSA detection step was then quenched by treatment with 1% hydrogen peroxide for 30 minutes. The Texas Red® dye-labeled chromosome 15 probe was then detected with rabbit anti-Texas Red® antibody (A6399) followed by HRP-conjugated goat anti-rabbit IgG antibody and Alexa Fluor® 488 tyramide (TSA™ Kit #12, T20922). After counterstaining with Hoechst 33258 (H1398, H3569, H21491), the images were acquired using filters appropriate for DAPI, FITC, TRITC and Texas Red® dyes.

Similarly, our anti-Green Fluorescent Protein (anti-GFP) antibodies (Section 7.5) can be used in combination with TSA for ultrasensitive immunocytochemical detection of GFP in situations where the expression level is insufficient for direct fluorescence detection.⁵⁰

Double and Sequential Amplification with TSA

To achieve greater signal amplification, sequential rounds of amplification can be achieved using TSA⁵¹ (Figure 6.2.1). For example, in the first round biotin-XX tyramide can be deposited on a target using one of our biotin-XX tyramide TSA™ Kits (Table 6.1). In a subsequent step, the peroxidase conjugate of streptavidin that is used in TSA™ Kit #21 (T20931) is used again, but this time in combination with an Alexa Fluor® tyramide, Oregon Green® 488 tyramide or another round of biotin-XX tyramide. Presumably, this amplification can be continued for at least a third round, although some loss of spatial resolution may result. Biotin tyramide that has first been deposited at the binding site of a biotin-labeled riboprobe using the streptavidin conjugate of HRP has been further amplified with the streptavidin conjugate of alkaline phosphatase (S921, Section 7.6) in conjunction with ELF® 97 phosphate for the ultrasensitive detection of a scarce leptin receptor mRNA.³³ In another example demonstrating the versatility of the TSA technology, several labeling technologies were combined sequentially to detect the HIV-1 virus:⁵²

1. *In situ* hybridization with a 15-base peptide nucleic acid probe labeled with a single fluorescein dye
2. Complexation with an HRP conjugate of anti-fluorescein antibody
3. Incubation with biotin tyramide
4. Incubation with the streptavidin conjugate of HRP
5. Re-incubation with biotin tyramide
6. Detection with the Alexa Fluor® 488 conjugate of streptavidin (S11223, Section 7.6)

Alternatively, for detection by light microscopy, the sample was incubated with the streptavidin conjugate of HRP in conjunction with DAB instead of Alexa Fluor® 488 streptavidin.

Additional Tips on Using TSA Technology

Use of the TSA technology is not without its precautions. Among these is the possibility of endogenous peroxidase activity in certain cells, especially eosinophils.¹⁴ This activity can be at least partially blocked by incubation with 0.3–3% hydrogen peroxide for about 60 minutes. Second, when using biotin-XX tyramide, endogenous biotinylated proteins are a potential problem (Figure 6.2.9). Third, because of the significant signal amplification capability of TSA, nonspecific binding of labeled hybridization probes, antibodies and other targeting probes can lead to unacceptably high background staining. This nonspecific staining can be alleviated to some degree with appropriate blocking reagents.⁵³ Furthermore, the high sensitivity of TSA permits antibodies and nucleic acid probes to be highly diluted, far below the amount required for target saturation, thus reducing nonspecific background. Antibody and nucleic acid probe dilution can also substantially reduce the cost of an assay and the amount of a rare material required for staining.²²

Mammalian cells and tissues contain biotin-dependent carboxylases, which are required for a variety of metabolic functions. These biotin-containing enzymes produce substantial background signals when biotin-streptavidin detection systems are used to identify cellular targets⁵⁴ (Figure 6.2.9). Because the TSA technology is so sensitive, we recommended preblocking endogenous biotin in cells with our

Endogenous Biotin-Blocking Kit (E21390, Section 7.6) when using TSA™ Kits containing biotin-XX tyramide and the streptavidin conjugate of HRP. The Endogenous Biotin-Blocking Kit provides streptavidin and biotin solutions in convenient dropper bottles and an easy-to-follow protocol; sufficient material is provided for approximately one hundred 18 mm × 18 mm glass coverslips.

Improvement of TSA detection by post-incubation heating has been reported.³³ Addition of viscosity-increasing dextran sulfate, poly(vinyl alcohol), poly(ethylene glycol) or poly(vinyl pyrrolidone) to the medium is reported to decrease diffusion of the phenoxy radical intermediate, resulting in superior localization of the signal.^{51,55} Hybridization probes that are directly labeled with HRP are reportedly useful for lowering nonspecific binding when working with labeled tyramides.^{4,35,56} Endogenous peroxidase can be sufficient to yield labeling at the site of this activity in cells, as in the case of eosinophils.¹⁴ The review by Speel, Hopman and Komminoth gives additional practical suggestions and references.³

Chromogenic and Chemiluminescent Peroxidase Substrates

DAB Histochemistry Kits

The use of HRP for enzyme-amplified immunodetection—commonly referred to as immunoperoxidase labeling—is a well-established standard histochemical technique.^{57,58} The most widely used HRP substrate for these applications is diaminobenzidine (DAB), which generates a brown-colored polymeric oxidation product localized at HRP-labeled sites. The DAB reaction product can be visualized directly by bright-field light microscopy or, following osmication, by electron microscopy. We offer DAB Histochemistry Kits for detecting mouse IgG primary antibodies (D22185) and biotinylated antibodies and tracers (D22187). Each kit contains sufficient materials to stain approximately 200 slides, including:

- Diaminobenzidine (DAB)
- HRP-labeled goat anti-mouse IgG antibody (in Kit D22185) or streptavidin (in Kit D22187) conjugate
- H₂O₂ reaction additive
- Blocking reagent
- Staining buffer
- Detailed staining protocols

Luminol and MCLA: Chemiluminescent Peroxidase Substrates

Nonisotopic immunoassays utilizing peroxidase conjugates and the chemiluminescent horseradish peroxidase substrate luminol (L8455) have provided a rapid and sensitive method for quantitating a wide variety of analytes, including cholesterol,⁵⁹ digoxin⁶⁰ and acetylcholine.⁶¹ Addition of trace amounts of luciferin (L2911, L2912, L2916; Section 10.6) has been shown to considerably enhance the sensitivity in the assay of thyroxine, digoxin, α-fetoprotein and other analytes.⁶² A method that employs luminol has been developed for the quantitation of very limiting samples of human DNA from single hairs, saliva, small blood stains and paraffin-embedded and fixed tissue sections. Using a biotinylated oligodeoxynucleotide probe to membrane-immobilized DNA, horseradish peroxidase streptavidin and luminol, researchers have detected 150 pg of human DNA.⁶³

MCLA (M23800) is principally utilized as a superoxide-sensitive chemiluminescent probe (Section 18.2). MCLA has also been utilized for the determination of both horseradish peroxidase⁶⁴ and myeloperoxidase.^{65,66,67}

Peroxidase-Based Amplex® ELISA Kits

The Amplex® ELISA Development Kits for Mouse IgG (A33851) and for Rabbit IgG (A33852) provide a comprehensive set of components for creating fluorescence-based ELISAs using mouse and rabbit detection antibodies, respectively.⁶⁸ This assay is based on the Amplex® UltraRed reagent, a fluorogenic substrate for horseradish peroxidase (HRP) that reacts with H₂O₂ in a 1:1 stoichiometric ratio to produce a brightly fluorescent and strongly absorbing reaction product (excitation/emission maxima ~568/581 nm). Because the Amplex® UltraRed peroxidation product has long-wavelength spectra, there is little interference from the blue or green autofluorescence found in most biological samples.

With a high extinction coefficient, good quantum efficiency and resistance to autooxidation, the fluorescence-based Amplex® UltraRed reagent delivers better sensitivity and a broader assay range than colorimetric reagents. In a sandwich ELISA format we can routinely detect 1 pg of C-reactive protein using HRP-conjugated goat anti-rabbit IgG antibody (Figure 6.2.13); this detection limit is 25-fold lower than that obtained from the same sandwich ELISA format using the common colorimetric reagent TMB.

Each Amplex® ELISA Development Kit contains:

- Amplex® UltraRed reagent
- Dimethylsulfoxide (DMSO)
- Concentrated phosphate-buffered saline (PBS), pH 7.2
- Horseradish peroxidase conjugate of goat anti-mouse IgG antibody (in A33851) or goat anti-rabbit IgG antibody (in A33852)
- Amplex® stop reagent
- Hydrogen peroxide (H₂O₂)
- 0.1 M sodium bicarbonate buffer, pH ~9.3
- Bovine serum albumin (BSA)
- Tween® 20
- Nunc-Immuno™ MaxiSorp™ U96 plate
- Detailed protocols

Sufficient reagents are provided in each kit for 500 microplate assays in a 96-well fluorescence microplate format (100 µL per assay).

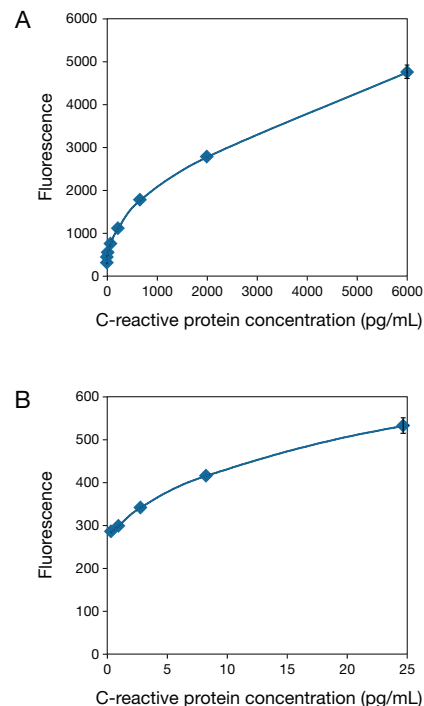

Figure 6.2.13 Detection range of C-reactive protein (CRP) using the Amplex® ELISA Development Kit for Rabbit IgG (A33852). The sandwich ELISA was carried out using a mouse anti-CRP capture antibody, CRP in a concentration range between 6000 pg/mL and 0.10 pg/mL and a rabbit polyclonal anti-CRP primary antibody (10 µL per well of a 50 ng/mL solution). The Z' factor analysis of the data obtained gives a lower detection level for CRP in this assay of 1 pg/mL or 0.1 pg/mL (based on a well volume of 100 µL in the sandwich ELISA).

PRODUCT LIST 6.2 TSA AND OTHER PEROXIDASE-BASED SIGNAL AMPLIFICATION TECHNIQUES

Cat. No.	Product	Quantity
A33851	Amplex® ELISA Development Kit for Mouse IgG *with Amplex® UltraRed reagent* *500 assays*	1 kit
A33852	Amplex® ELISA Development Kit for Rabbit IgG *with Amplex® UltraRed reagent* *500 assays*	1 kit
D22185	Diaminobenzidine (DAB) Histochemistry Kit #1 *with goat anti-mouse IgG-HRP*	1 kit
D22187	Diaminobenzidine (DAB) Histochemistry Kit #3 *with streptavidin-HRP*	1 kit
L8455	luminol (3-aminophthalhydrazide)	25 g
M23800	2-methyl-6-(4-methoxyphenyl)-3,7-dihydroimidazo[1,2-a]pyrazin-3-one, hydrochloride (MCLA)	5 mg
T20911	TSA™ Kit #1 *with HRP-goat anti-mouse IgG and biotin-XX tyramide* *50-150 slides*	1 kit
T20912	TSA™ Kit #2 *with HRP-goat anti-mouse IgG and Alexa Fluor® 488 tyramide* *50-150 slides*	1 kit
T20913	TSA™ Kit #3 *with HRP-goat anti-mouse IgG and Alexa Fluor® 546 tyramide* *50-150 slides*	1 kit
T20914	TSA™ Kit #4 *with HRP-goat anti-mouse IgG and Alexa Fluor® 568 tyramide* *50-150 slides*	1 kit
T20915	TSA™ Kit #5 *with HRP-goat anti-mouse IgG and Alexa Fluor® 594 tyramide* *50-150 slides*	1 kit
T20916	TSA™ Kit #6 *with HRP-goat anti-mouse IgG and Alexa Fluor® 647 tyramide* *50-150 slides*	1 kit
T20917	TSA™ Kit #7 *with HRP-goat anti-mouse IgG and Alexa Fluor® 350 tyramide* *50-150 slides*	1 kit
T20921	TSA™ Kit #11 *with HRP-goat anti-rabbit IgG and biotin-XX tyramide* *50-150 slides*	1 kit
T20922	TSA™ Kit #12 *with HRP-goat anti-rabbit IgG and Alexa Fluor® 488 tyramide* *50-150 slides*	1 kit
T20923	TSA™ Kit #13 *with HRP-goat anti-rabbit IgG and Alexa Fluor® 546 tyramide* *50-150 slides*	1 kit
T20924	TSA™ Kit #14 *with HRP-goat anti-rabbit IgG and Alexa Fluor® 568 tyramide* *50-150 slides*	1 kit
T20925	TSA™ Kit #15 *with HRP-goat anti-rabbit IgG and Alexa Fluor® 594 tyramide* *50-150 slides*	1 kit
T20926	TSA™ Kit #16 *with HRP-goat anti-rabbit IgG and Alexa Fluor® 647 tyramide* *50-150 slides*	1 kit
T20927	TSA™ Kit #17 *with HRP-goat anti-rabbit IgG and Alexa Fluor® 350 tyramide* *50-150 slides*	1 kit
T20931	TSA™ Kit #21 *with HRP-streptavidin and biotin-XX tyramide* *50-150 slides*	1 kit
T20932	TSA™ Kit #22 *with HRP-streptavidin and Alexa Fluor® 488 tyramide* *50-150 slides*	1 kit
T20933	TSA™ Kit #23 *with HRP-streptavidin and Alexa Fluor® 546 tyramide* *50-150 slides*	1 kit
T20934	TSA™ Kit #24 *with HRP-streptavidin and Alexa Fluor® 568 tyramide* *50-150 slides*	1 kit
T20935	TSA™ Kit #25 *with HRP-streptavidin and Alexa Fluor® 594 tyramide* *50-150 slides*	1 kit
T20936	TSA™ Kit #26 *with HRP-streptavidin and Alexa Fluor® 647 tyramide* *50-150 slides*	1 kit
T20937	TSA™ Kit #27 *with HRP-streptavidin and Alexa Fluor® 350 tyramide* *50-150 slides*	1 kit
T20939	TSA™ Kit #29 *with HRP-streptavidin and Oregon Green® 488 tyramide* *50-150 slides*	1 kit
T30953	TSA™ Kit #40 *with HRP-goat anti-mouse IgG and Alexa Fluor® 555 tyramide* *50-150 slides*	1 kit
T30954	TSA™ Kit #41 *with HRP-goat anti-rabbit IgG and Alexa Fluor® 555 tyramide* *50-150 slides*	1 kit
T30955	TSA™ Kit #42 *with HRP-streptavidin and Alexa Fluor® 555 tyramide* *50-150 slides*	1 kit
Z25090	Zenon® Alexa Fluor® 488 Mouse IgG ₁ Labeling Kit *enhanced with TSA technology* *25 labelings*	1 kit
Z25454	Zenon® Horseradish Peroxidase Human IgG Labeling Kit *25 labelings*	1 kit
Z25054	Zenon® Horseradish Peroxidase Mouse IgG ₁ Labeling Kit *25 labelings*	1 kit
Z25154	Zenon® Horseradish Peroxidase Mouse IgG _{2a} Labeling Kit *25 labelings*	1 kit
Z25254	Zenon® Horseradish Peroxidase Mouse IgG _{2b} Labeling Kit *25 labelings*	1 kit
Z25354	Zenon® Horseradish Peroxidase Rabbit IgG Labeling Kit *25 labelings*	1 kit

6.3 Phosphatase-Based Signal Amplification Techniques

When detecting specific biomolecules in cells, in tissues and on microarrays, enzyme-mediated detection methods can provide significant signal amplification due to the catalytic turnover of fluorogenic, chemiluminescent or chromogenic substrates. Because fluorescence and chemiluminescence methods are potentially much more sensitive than colorimetric methods, we have been actively engaged in research to develop substrates for phosphatase-mediated detection and offer two complementary technologies—Enzyme-Labeled Fluorescence (ELF[®]) signal amplification and CSPD[®] and CDP-Star[®] chemiluminescent substrates.

Principles of ELF[®] Signal Amplification

ELF[®] signal amplification is based on ELF[®] 97 phosphate, a substrate for both alkaline phosphatase and acid phosphatase.¹ Upon enzymatic cleavage (Figure 6.3.1), this weakly blue-fluorescent substrate yields a bright yellow-green-fluorescent precipitate that exhibits an unusually large Stokes shift (Figure 6.3.2) and excellent photostability (Figure 6.3.3). Water-soluble ELF[®] 97 phosphate (E6588, E6589) is converted to insoluble ELF[®] 97 alcohol (E6578), by action of a phosphatase (Figure 6.3.1). Like other crystalline fluorescent molecules containing an intramolecular hydrogen bond, the ELF[®] 97 alcohol precipitate provides a fluorescent signal that is not only extremely photostable but also has an exceptionally large Stokes shift.^{2–4} The ELF[®] 97 signal is more photostable than signals achieved using either direct or indirect detection with fluorescein conjugates^{1,5} (Figure 6.3.3). As a result of its extremely high photostability, the ELF[®] 97 phosphate-generated signal is well suited for immunolabeling targets to be viewed by UV-light-excited confocal laser-scanning microscopy⁶ (Figure 6.3.4).

Furthermore, because the fluorescence emission of the ELF[®] 97 alcohol precipitate is separated from its excitation maximum by over 180 nm (Figure 6.3.2), the ELF[®] 97 signal can be clearly distinguished from most cell and tissue autofluorescence, which generally has a Stokes shift of

Figure 6.3.1 Principle of enzyme-mediated formation of the fluorescent ELF[®] 97 alcohol precipitate from the ELF[®] 97 phosphatase substrate.

Figure 6.3.2 The normalized fluorescence excitation and emission spectra of the ELF[®] 97 alcohol precipitate (E6578), which is generated by enzymatic cleavage of the soluble ELF[®] 97 phosphatase substrate (E6588, E6589).

Figure 6.3.3 Photostability comparison for ELF[®] 97 alcohol- and fluorescein-labeled tubulin preparations. Tubulin in acetone-fixed CRE BAG 2 mouse fibroblasts was labeled with an anti- β -tubulin monoclonal antibody and then detected using biotin-XX goat anti-mouse IgG antibody (B2763) in conjunction with either our ELF[®] 97 Cytological Labeling Kit (E6603, ■) or fluorescein streptavidin (S869, ●). Alternatively, anti-tubulin labeling was detected directly using fluorescein goat anti-mouse IgG antibody (F2761, ○). The photostability of labeling produced by the three methods was compared by continuously illuminating stained samples on a fluorescence microscope using Omega[®] Optical longpass optical filter sets. Images were acquired every 5 seconds using a Star 1 CCD camera (Photometrics[®]); the average fluorescence intensity in the field of view was calculated with Image-1 software (Universal Imaging Corp.) and expressed as a fraction of the initial intensity. Three data sets, representing different fields of view, were averaged for each conjugate to obtain the plotted time courses.

Figure 6.3.4 The ELF[®] 97 Cytological Labeling Kit (E6603) was used to label endogenous alkaline phosphatase activity of zebrafish kidney. The ELF[®] 97 fluorescence intensity was measured from each of 1000 consecutive scans on a confocal laser-scanning microscope (Bio-Rad[®] MRC 1024) with UV illumination (UV/Vis Coherent Innova Enterprise Model 622 argon-ion laser, 60 mW output) using the 363 nm spectral line at 100% power with a 40 \times objective. Fluorescence intensity, expressed as a percentage of initial value, is plotted against scan number. In this example, 970 scans were required to reduce the signal by 50%. This figure was contributed by J. Paul Robinson and Jennie Sturgis, Purdue University.

Figure 6.3.5 HeLa cell nuclei incubated with a mouse monoclonal antibody directed against nuclear-localized antigens (a gift from Benjamin Blencowe and Phil Sharp, Massachusetts Institute of Technology) in conjunction with Texas Red[®]-X streptavidin (S6370) and with a human anti-nuclear antibody in conjunction with biotin-XX goat anti-human IgG antibody. The reagents in the ELF[®] 97 Cytological Labeling Kit (E6603) were then used to detect the biotinylated secondary antibody. Cells were counterstained with Hoechst 33258 (H1398, H3569, H21491). Multiple exposures were taken using filters appropriate for the Texas Red[®] dye, fluorescein and DAPI.

Figure 6.3.6 Endogenous alkaline phosphatase activity of osteoblast cells in a cartilaginous element of an adult zebrafish head cryosection. The activity was localized with the ELF[®] 97 Endogenous Phosphatase Detection Kit (E6601). In addition to the yellow-green fluorescence of the ELF[®] 97 precipitate, the section was stained with Texas Red[®]-X wheat germ agglutinin (W21405) and counterstained with the Hoechst 33342 nucleic acid stain (H1399, H3570, H21492). The triple-exposure image was acquired using bandpass filter sets appropriate for the ELF[®] precipitate, Texas Red[®] dye and AMCA.

Figure 6.3.7 The yellow-green fluorescence of the ELF[®] 97 alcohol precipitate, demonstrating localization of endogenous alkaline phosphatase activity in the ciliary body of the zebrafish eye. Adult zebrafish cryosections were first stained with Texas Red[®]-X wheat germ agglutinin (W21405) followed by the ELF[®] 97 phosphate substrate in the ELF[®] 97 Endogenous Phosphatase Detection Kit (E6601), and finally the nuclei were counterstained with the blue-fluorescent Hoechst 33342 nucleic acid stain (H1399, H3570, H21492). The triple-exposure image was acquired using bandpass filters appropriate for the Texas Red[®] dye, ELF[®] 97 alcohol precipitate and AMCA.

much less than 100 nm.⁵ This extremely high Stokes shift also makes the ELF[®] 97 phosphatase substrate ideal for use in multicolor applications (Figure 6.3.5, Figure 6.3.6, Figure 6.3.7). The yellow-green-fluorescent ELF[®] 97 signal can be visualized simultaneously with blue-fluorescent probes, such as Alexa Fluor[®] 350 and Alexa Fluor[®] 405 conjugates (Section 1.7), or with the DAPI and Hoechst counterstains (Section 12.5) using a fluorescence microscope fitted with a standard DAPI/Hoechst nuclear longpass optical filter set.⁵ In addition, the excitation spectra of tetramethylrhodamine, Texas Red[®] and Alexa Fluor[®] dyes with absorption maxima beyond 530 nm are very well separated from that of the ELF[®] 97 alcohol precipitate, allowing sequential visualization with the appropriate optical filter sets without bleed-through.⁵ Also, ELF[®] 97 alcohol signals can be distinguished from fluorescein, Oregon Green[®] 488 and Alexa Fluor[®] 488 dye signals because their excitation wavelengths do not significantly overlap.

Applications of ELF[®] Signal Amplification

Histochemical applications often require reliable, sensitive and stable detection of targets in complex samples that may have significant background from either natural sample autofluorescence or fluorescence created during sample preparation. Many histochemical procedures utilize enzyme-amplified detection methods in conjunction with chromophoric substrates such as 5-bromo-4-chloro-3-indolyl phosphate (BCIP), nitro blue tetrazolium (NBT) for phosphatase (N6495, N6547; see below) or diaminobenzidine (DAB; D22185, D22187; Section 6.2) for peroxidase to yield colored precipitates at the site of labeling. The ELF[®] technology yields staining that can be equal to or superior to NBT/BCIP staining and that forms an exceptionally persistent product. We have observed that ELF[®] 97 phosphate-based staining of fixed samples can persist for months to years with little if any loss of signal. ELF[®] 97 staining can also be combined with staining by other fluorophores to permit simultaneous analysis of multiple targets in the sample. Combination of the ELF[®] technology with TSA technology (Section 6.2) provides exceptional detection limits for low-abundance targets in cells and tissues that are not possible with existing histochemical methods.^{7,8}

A general scheme for the secondary detection methods used to develop the ELF[®] 97 signal for *in situ* hybridization, cytological labeling, immunohistochemistry and microarrays⁹⁻¹¹ is shown in Figure 6.3.8. Please note that the components of these ELF[®] 97 Kits are not interchangeable. Through the course of our product development, we have discovered that to achieve optimal

Figure 6.3.8 Schematic diagram of the method employed in our ELF[®] 97 mRNA *In Situ* Hybridization (E6604, E6605), Cytological Labeling (E6603) and Immunohistochemistry (E6600) Kits. Samples are probed with haptened or biotinylated target-specific probes such as antibodies or hybridization probes. Next, alkaline phosphatase conjugates of streptavidin or the hapten-specific probe are applied. Alternatively, a biotinylated antibody and biotinylated alkaline phosphatase can be used with standard bridging methods to increase the penetration in tissue, a method that is employed in our ELF[®] 97 Immunohistochemistry Kit. The sample is then incubated with the ELF[®] 97 phosphatase substrate, which forms an intense yellow-green-fluorescent ELF[®] 97 alcohol precipitate at the site of alkaline phosphatase activity.

sensitivity in each type of biological application requires substrate formulations, buffers and protocols that are tailored to the application. For this reason, we strongly recommend that each kit be used only for the applications for which it was developed. However, we also offer the ELF[®] 97 phosphate (E6588, E6589) as well as the ELF[®] 97 alcohol cleavage product (E6578) separately, for those researchers who want to develop their own applications. We have found that addition of 1–5 μ M ELF[®] 97 alcohol (E6578) to the enzyme detection medium usually improves the quality of precipitation by reducing the crystal size. Addition of other components to the buffers may also be required to maximize the signal intensity and localize the signal to the target.

ELF[®] 97 mRNA *In Situ* Hybridization Kits

The optimized reagents and protocols in our ELF[®] 97 mRNA *In Situ* Hybridization Kits (Kit #1, E6604; Kit #2 with streptavidin, alkaline phosphatase conjugate, E6605) provide a rapid and sensitive assay for detecting mRNA *in situ* hybridization signals in cells and tissue sections¹² (Figure 6.3.9, Figure 6.3.10).

The ELF[®] 97 mRNA *In Situ* Hybridization Kits include:

- Alkaline phosphatase streptavidin (only in Kit #2, E6605)
- ELF[®] wash, blocking and developing buffers
- Application-specific ELF[®] 97 phosphatase substrate solution
- Hoechst 33342 nucleic acid counterstain
- ELF[®] mounting medium
- 50 plastic coverslips
- Detailed protocols

The ELF[®] 97 mRNA *In Situ* Hybridization Kit #2 (E6605), which contains alkaline phosphatase streptavidin, can be used to detect biotinylated DNA probes, biotinylated RNA probes or digoxigenin-labeled probes in conjunction with a biotinylated anti-digoxigenin antibody.¹³ The ELF[®] 97 mRNA *In Situ* Hybridization Kit #1 (E6604), which does not include alkaline phosphatase streptavidin, is designed for use with other alkaline phosphatase conjugates that have been applied to detect DNA or RNA probes labeled with haptens other than biotin. Each kit contains sufficient reagents for 50 slides or coverslips.

ELF[®] 97 Cytological Labeling Kit

The ELF[®] 97 Cytological Labeling Kit (E6603) facilitates the detection of a broad range of cellular targets, including cell-surface sites, cytoplasmic organelles, nuclear antigens and cytoskeletal networks¹⁴ (Figure 6.3.11). This versatile kit can potentially be used to detect any subcellular structure that can be selectively labeled with a biotinylated or haptened ligand (Figure 6.3.12).

Figure 6.3.12 Cellular targets developed for visualization with the reagents in our ELF[®] 97 Cytological Labeling Kit (E6603), using the methods described in Figure 6.3.8. A) Nuclei in a commercial preparation of human epithelial cells (HEp-2) that have been labeled with human anti-nuclear antibodies and then incubated with biotin-XX goat anti-human IgG antibody. B) Acetone-fixed mouse fibroblast (CRE BAG 2) cells that have been treated with Triton X-100 and then incubated with biotin-XX phalloidin (B7474), a probe specific for actin stress fibers. C) Formaldehyde-fixed human carcinoma cells that have been incubated with biotin-XX epidermal growth factor (E3477). D) Mouse fibroblast cells that have been probed with antibodies directed against rat medial Golgi cisternae (a gift from Vivek Malhotra, University of California, San Diego) and then incubated with biotin-XX goat anti-rabbit IgG antibody (B2770). In each case, the biotinylated probe was detected with alkaline phosphatase streptavidin, followed by incubation with the ELF[®] 97 phosphatase substrate.

Figure 6.3.9 Tissue from a prostate carcinoma that has been fixed with formalin, embedded in paraffin, sectioned and hybridized with a biotinylated antisense RNA probe to gastrin-releasing peptide (GRP) receptor mRNA. Following *in situ* hybridization, the biotinylated probe was developed for visualization with alkaline phosphatase-mediated techniques using the ELF[®] 97 mRNA *In Situ* Hybridization Kit (E6604, E6605). Image contributed by Marty Bartholdi, Berlex Biosciences, Berlex Laboratories, Inc.

Figure 6.3.10 *lacZ* mRNA in transformed mouse fibroblasts (CRE BAG 2 cells) hybridized with a singly biotinylated, complementary oligonucleotide. Hybrids were then detected by incubation with a streptavidin-alkaline phosphatase conjugate in combination with the ELF[®] 97 alkaline phosphatase substrate, both of which are provided in our ELF[®] 97 mRNA *In Situ* Hybridization Kit (E6604, E6605). Cells were counterstained with DAPI (D1306, D3571, D21490) and photographed using a longpass optical filter appropriate for DAPI.

Figure 6.3.11 Mouse fibroblast microtubules labeled with a mouse monoclonal anti- β -tubulin antibody in conjunction with biotin-XX goat anti-mouse IgG antibody (B2763) and then developed for visualization with alkaline phosphatase-mediated techniques using the ELF[®] 97 Cytological Labeling Kit (E6603). This kit's novel ELF[®] 97 phosphatase substrate yields a yellow-green-fluorescent precipitate at the site of alkaline phosphatase activity. Prior to antibody labeling, mouse fibroblasts were fixed and permeabilized in the presence of cytoskeletal stabilizing buffer and treated with paclitaxel (P3456) to stabilize microtubule structures. The image was deconvolved using Huygens software (Scientific Volume Imaging, <http://www.svi.nl/>).

Figure 6.3.13 A transverse section of fixed zebrafish retina probed with FRet 43, a monoclonal antibody that binds to double cone cells, and developed for visualization with enzyme-mediated immunohistochemical techniques using our ELF® 97 Immunohistochemistry Kit (E6600). The yellow-green-fluorescent double cones stained with the ELF® 97 alcohol precipitate are oriented so that their outer segments are at the top of the stained configuration and the synaptic pedicles are at the bottom. This section has been counterstained with tetramethylrhodamine wheat germ agglutinin (W849), which makes the rod outer segments (top left) and the inner plexiform layer and ganglion cell axons (bottom right) appear bright red. Wheat germ agglutinin also binds in the region occupied by the cone outer segments and synaptic pedicles, which appear bright yellow because they are double-labeled with both the ELF® 97 alcohol precipitate and tetramethylrhodamine. Although this section has also been counterstained with Hoechst 33342 (H1399, H3570, H21492), the blue-stained nuclei are barely visible in this photomicrograph. However, the double cones' inner fibers traverse the region occupied by the Hoechst 33342 dye-stained rod nuclei, and thus appear light blue. The inner segments, myoids and nuclei of these double-cone cells are labeled only with the ELF® 97 alcohol precipitate, giving them a characteristic green appearance. The image was obtained by triple-exposure through optical filters appropriate for DAPI, tetramethylrhodamine and the ELF® precipitate. Used with permission from (J Histochem Cytochem (1995) 43:77).

Figure 6.3.14 A transverse section through adult zebrafish retina that has been probed with anti-glial fibrillary acidic protein antibody (anti-GFAP antibody, A21282) and then developed for visualization with alkaline phosphatase-mediated techniques using our ELF® 97 Immunohistochemistry Kit (E6600). This kit's ELF® 97 phosphatase substrate yields an extremely photostable yellow-green signal at the site of anti-GFAP binding, clearly showing that this antibody binds to Müller cells in the zebrafish retina. The retinal section has been counterstained with Hoechst 33342 (H1399, H3570, H21492), which stains all nuclei blue, and with tetramethylrhodamine wheat germ agglutinin (W849), which stains both the inner and outer plexiform layers as well as the photoreceptor outer segments red.

The ELF® 97 Cytological Labeling Kit includes:

- Alkaline phosphatase streptavidin
- Application-specific ELF® 97 phosphatase substrate solution plus additives
- ELF® wash, blocking and developing buffers
- ELF® mounting medium
- Detailed protocols

Each kit provides sufficient reagents for 50 slides or coverslips.

ELF® 97 Immunohistochemistry Kit

The extremely high Stokes shift for the ELF® 97 alcohol precipitate—greater than 180 nm—is an important advantage for immunohistochemistry applications. Although the ELF® 97 dye is excited in the ultraviolet range where autofluorescence from cells, tissues, paraffin sections and various fixatives can be quite high,¹⁵ the high intensity of ELF® 97 staining overcomes most of this background. Because the ELF® 97 alcohol precipitate is extremely photostable, the background can be further reduced by pre-bleaching the entire sample with ultraviolet light before measuring the specific fluorescence of the ELF® 97 alcohol precipitate.^{16,17}

The ELF® 97 phosphatase substrate in our ELF® 97 Immunohistochemistry Kit has been specially formulated to reduce nonspecific staining in immunohistochemical preparations and contains the key reagents for detecting antigens in tissue sections, including streptavidin and biotinylated alkaline phosphatase. The streptavidin provided in the kit is used to link the biotinylated alkaline phosphatase with a biotinylated secondary antibody—a common immunohistochemical technique for optimizing tissue penetration. We have used the ELF® 97 Immunohistochemistry Kit to characterize a number of antibodies generated against the zebrafish retina (Figure 6.3.13, Figure 6.3.14) and found that the ELF® 97 alcohol staining pattern was identical to that seen with fluorophore-conjugated secondary reagents.⁵ The ELF® 97 signal could easily be visualized despite this tissue's considerable autofluorescence. Moreover, the staining was approximately 500 times more photostable than that produced by fluorescein-labeled secondary reagents.⁵ ELF® 97 phosphate has been used to measure endogenous phosphatase activity and, in combination with alkaline phosphatase-conjugated immunoreagents, to detect intracellular cell cycle-associated proteins such as cyclin B1 by flow cytometry.^{18–20}

The ELF® 97 Immunohistochemistry Kit (E6600) provides sufficient reagents for preparing 50 mL of detection solution, which is adequate for staining 250 to 1000 sections.

Figure 6.3.15 The intermediate filaments in bovine pulmonary artery endothelial cells, localized using our anti-desmin antibody (A21283), which was visualized with the Alexa Fluor® 647 goat anti-mouse IgG antibody (A21235). Endogenous biotin in the mitochondria was labeled with Alexa Fluor® 546 streptavidin (S11225) and DNA in the cell was stained with blue-fluorescent DAPI (D1306, D3571, D21490).

Figure 6.3.16 The cytoskeleton of a fixed and permeabilized bovine pulmonary artery endothelial cell detected using mouse monoclonal anti- α -tubulin antibody (A11126), visualized with Alexa Fluor® 647 goat anti-mouse IgG antibody (A21235) and pseudocolored magenta. Endogenous biotin in the mitochondria was labeled with green-fluorescent Alexa Fluor® 488 streptavidin (S11223) and DNA was stained with blue-fluorescent DAPI (D1306, D3571, D21490).

The ELF® 97 Immunohistochemistry Kit includes:

- Application-specific ELF® 97 phosphatase substrate solution
- Streptavidin
- Biotinylated alkaline phosphatase
- ELF® reaction buffer
- ELF® mounting medium
- Detailed protocol

Mammalian cells and tissues contain biotin-dependent carboxylases, which are required for a variety of metabolic functions. These biotin-containing enzymes produce substantial background signals when biotin–streptavidin detection systems are used to identify cellular targets^{21,22} (Figure 6.3.15, Figure 6.3.16). Because the ELF® technology is so sensitive, we recommend preblocking endogenous biotin in cells with our Endogenous Biotin-Blocking Kit (E21390, Section 7.6) when staining cells using our ELF® 97 Kits containing streptavidin conjugates.

ELF® 97 Endogenous Phosphatase Detection Kit

We have used the ELF® 97 phosphatase substrate to develop a novel fluorescence-based assay for detecting phosphatases in tissue sections and cells²³ (Figure 6.3.17, Figure 6.3.18, Figure 6.3.19). The ELF® 97 Endogenous Phosphatase Detection Kit (E6601) provides several advantages over traditional approaches to phosphatase histochemistry.^{5,23}

The ELF® 97 endogenous phosphatase detection system uses a simple protocol and is compatible with many types of tissue preparations, including tissue cryosections, paraffin-embedded sections and cultured cells. The fluorescence excitation and emission maxima (~365/530 nm) of the ELF® 97 alcohol precipitate are well separated, allowing researchers to easily distinguish the signal from autofluorescence and from other fluorescent labels.

Phosphatases have been commonly used as enzyme markers, allowing researchers to identify primordial germ cells,²⁴ to distinguish subpopulations of bone marrow stromal cells²⁵ and to investigate *in vitro* differentiation in carcinoma cell lines.^{26–28} A particularly prominent application of the ELF® 97 endogenous phosphatase detection system is the detection of TRAP (tartrate-resistant acid phosphatase) activity, a marker of osteoclast differentiation from hematopoietic stem cells^{29–32} (HSC). Because ELF® 97 phosphate is intrinsically membrane impermeant, it can be utilized as a marker for membrane integrity in which the intracellular phosphatase activity of membrane-compromised cells is detected.³³ The patterns of ELF® 97 alcohol staining in intestine (Figure 6.3.17), kidney (Figure 6.3.20), ovary and gills (Figure 6.3.19) are essentially identical

Figure 6.3.17 Lightly fixed adult zebrafish intestine stained with the substrate contained in the ELF® 97 Endogenous Phosphatase Detection Kit (E6601). This kit's ELF® substrate yields a green-fluorescent precipitate at the site of endogenous phosphatase activity. A partially digested brine shrimp, which also contains endogenous phosphatase activity, can be seen in the bottom right corner of this micrograph. The tissue was counterstained with propidium iodide (P1304MP, P3566, P21493).

Figure 6.3.18 Endogenous alkaline phosphatase enzyme of osteosarcoma cells localized with the ELF® 97 Endogenous Phosphatase Detection Kit (E6601). Unlike other phosphatase substrates, the unique ELF® 97 phosphatase substrate forms a fluorescent precipitate at the site of enzymatic activity. The blue-fluorescent nucleic acid stain Hoechst 33342 (H1399, H3570, H21492) was used as a counterstain to the green fluorescence of the ELF® 97 alcohol precipitate. The double-exposure image was acquired using a bandpass filter set appropriate for ELF® 97 alcohol and a longpass filter set appropriate for DAPI.

Figure 6.3.19 A cryostat section of lightly fixed adult zebrafish gills that have been incubated with the ELF® 97 substrate in our ELF® 97 Endogenous Phosphatase Detection Kit (E6601). This kit's novel ELF® 97 phosphatase substrate yields a yellow-green-fluorescent precipitate at the site of endogenous phosphatase activity. This staining pattern is identical to that seen when employing the conventional Gomori method for detecting phosphatase activity.

Figure 6.3.20 A cryostat section through adult zebrafish kidney that was incubated with the ELF® 97 phosphatase substrate in our ELF® 97 Endogenous Phosphatase Detection Kit (E6601) and counterstained with propidium iodide (P1304MP, P3566, P21493). The ELF® 97 alcohol signal, which is ordinarily green fluorescent, appears yellow in this section because the phosphatase activity is in close proximity to the nuclei, which are stained red by the propidium iodide. This double-exposure image was obtained using longpass filter sets appropriate for ELF® 97 alcohol product and tetramethylrhodamine.

Figure 6.3.22 Endogenous phosphatase activity in a zebra fish ovary cross-section, stained with the BCIP (B6492) and NBT (N6495) reagents. These reagents are also available in the NBT/BCIP Reagent Kit (N6547).

to the patterns of black precipitate produced by the conventional Gomori technique, but show much higher spatial resolution. The ELF® 97 Endogenous Phosphatase Detection Kit has also been used to monitor and quantitate alkaline phosphatase activity in marine phytoplankton³⁴ and bacteria.³⁵

Each ELF® 97 Endogenous Phosphatase Detection Kit (E6601) provides:

- ELF® 97 phosphatase substrate solution
- ELF® detection buffer
- ELF® mounting medium
- Easy-to-follow protocol

Sufficient materials are provided for staining 50–250 tissue sections.

ELF® Spin Filters

Like many enzyme substrates, the ELF® 97 developing solution should be filtered before use for optimal staining. The ELF® spin filters (E6606)—spin-filtration devices with a pore size of 0.2 μm —are both convenient and efficient, permitting a very small volume to be filtered without significant loss. These spin filters are recommended for use with all of our ELF® 97 Kits. These filters are equally suitable for rapid filtration of aqueous solutions of other probes.

Alkaline Phosphatase Conjugates for Secondary Detection

For use in signal amplification of antibody- or biotin-labeled targets, we offer the alkaline phosphatase conjugates of:

- Streptavidin (S921, Section 7.6)
- Goat anti-mouse IgG antibody (G21060)
- Goat anti-mouse F(ab')₂ fragment (F21452)
- Goat anti-rabbit IgG antibody (G21079)
- Goat anti-rabbit F(ab')₂ fragment (F21456)
- Goat anti-rat IgG antibody (A10546)
- Rabbit anti-goat IgG antibody (R21458)

A more thorough discussion of our secondary antibodies can be found in Section 7.2 (Table 7.1). We also offer the Zenon® Alkaline Phosphatase Rabbit IgG Labeling Kit (Z25350) for creating alkaline phosphatase conjugates of primary rabbit IgG antibodies. Our Zenon® antibody labeling technology (Section 7.3, Table 7.7) permits the rapid and quantitative formation of dye

Figure 6.3.21 Principle of enzyme-linked detection using the reagents in our NBT/BCIP Reagent Kit (N6547). Phosphatase hydrolysis of BCIP is coupled to reduction of NBT, yielding a formazan and an indigo dye that together form a black-purple-colored precipitate.

and enzyme complexes with the Fc portion of an intact antibody. The alkaline phosphatase–antibody complexes formed with our Zenon® Alkaline Phosphatase Antibody Labeling Kit can be used in combination with the ELF® 97 Kits described above or with other applications for alkaline phosphatase–conjugated antibodies such as ELISAs.

Chromogenic Phosphatase Substrate

NBT/BCIP Reagent Kit

5-Bromo-4-chloro-3-indolyl phosphate (BCIP) is commonly used with a number of different chromogens in various histological and molecular biology techniques. Hydrolysis of this indolyl phosphate, followed by oxidation, produces a blue-colored precipitate at the site of enzymatic activity. For convenience, we offer the NBT/BCIP Reagent Kit (N6547), which provides 1 g samples of BCIP as well as its co-precipitant NBT.

NBT: A Co-Precipitant for the BCIP Reaction

Nitro blue tetrazolium (NBT, N6495) is the most commonly used electron-transfer agent and co-precipitant for the BCIP reaction, forming a dark blue, precisely localized precipitate in the presence of alkaline phosphatase^{36,37} (Figure 6.3.21, Figure 6.3.22).

CSPD® and CDP-Star® Chemiluminescent ELISA Detection

The Chemiluminescent Alkaline Phosphatase ELISA Kits employ CSPD® or CDP-Star® 1,2-dioxetane substrates for alkaline phosphatase with Sapphire™-II or Emerald-II enhancer in a system designed for rapid and ultrasensitive analyte detection in enzyme-linked immunoassays.³⁸ Maximum light emission from alkaline phosphatase–activated CSPD® or CDP-Star® substrate is reached in 5 to 60 minutes, depending

on the temperature and the substrate chosen. Enzymatic dephosphorylation of substrate occurs at a constant rate proportional to enzyme concentration; the resulting phenolate anion decomposes with a finite half-life (Figure 6.3.23). Light emission can be quantitated with a variety of luminometers without the need for solution injection.

Enzyme-linked immunosorbent assays (ELISAs) can be formatted in several configurations on a variety of solid supports including microplate wells, tubes, polystyrene beads or ferrite particles. The high sensitivity obtained with 1,2-dioxetane substrates is demonstrated in a sandwich immunoassay format that employs a biotinylated detector antibody and streptavidin alkaline phosphatase conjugate for quantitating recombinant human IL-6 (rhIL-6). The results obtained with CSPD® substrate/Sapphire™-II enhancer (Figure 6.3.24) show a significant improvement in signal-to-noise performance at all concentrations of rhIL-6 and a much wider assay dynamic range compared to those obtained with the fluorescent substrate 4-methylumbelliferyl phosphate (MUP, M6491; Section 10.3), and the colorimetric substrate *p*-nitrophenyl phosphate³⁸ (pNPP).

We offer four different Chemiluminescent Alkaline Phosphatase ELISA Kits, as well as a Chemiluminescent Alkaline Phosphatase ELISA Sampler Kit. Each kit provides concentrated assay buffer and blocking reagent, as well as one of the following substrate/enhancer solutions:

- CSPD® substrate/Sapphire™-II enhancer (in Kit #1, C10552)
- CSPD® substrate/Emerald-II™ enhancer (in Kit #2, C10553)
- CDP-Star® substrate/Sapphire™-II enhancer (in Kit #3, C10554)
- CDP-Star® substrate/Emerald-II™ enhancer (in Kit #4, C10555)

The Chemiluminescent Alkaline Phosphatase ELISA Sampler Kit (C10556) provides assay buffer, blocking reagent and sample sizes of all four substrate/enhancer solutions. All five kits provide sufficient reagents for 1000 assays based on the provided protocol.

Figure 6.3.23 Mechanism of phosphatase-dependent chemiluminescence generation by CDP-Star® substrate. Luminescence emission is shifted to 461 nm or 542 nm respectively by the Sapphire™-II or Emerald-II™ enhancers.

Figure 6.3.24 Comparison of detection sensitivities for the ELISA quantitation of recombinant human IL-6 (rhIL-6) using the chemiluminescent phosphatase substrate/enhancer in the Chemiluminescent Alkaline Phosphatase ELISA Kit #1 (CSPD® substrate/Sapphire™-II enhancer; C10552), the fluorescent phosphatase substrate 4-methylumbelliferyl phosphate (MUP, M6491) and the colorimetric phosphatase substrate *p*-nitrophenyl phosphate (pNPP).

DATA TABLE 6.3 PHOSPHATASE-BASED SIGNAL AMPLIFICATION TECHNIQUES

Cat. No.	MW	Storage	Soluble	Abs	EC	Em	Solvent	Notes
E6578	307.14	L	DMSO	345	ND	530	pH 8	1, 2, 3
E6588	431.08	F,L	H ₂ O	289	12,000	see Notes	pH 10	2, 4, 5
E6589	431.08	F,L	H ₂ O	289	12,000	see Notes	pH 10	2, 4, 5
N6495	817.65	D,L	H ₂ O, DMSO	256	64,000	see Notes	MeOH	6

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. ND = not determined.
2. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
3. ELF® 97 alcohol is insoluble in water. Spectral maxima listed are for an aqueous suspension; for this reason, the value of EC cannot be determined.
4. Enzymatic cleavage of this substrate yields E6578.
5. Fluorescence of the unhydrolyzed substrate is very weak.
6. Phosphatase hydrolysis of BCIP (B6492) is coupled to reduction of NBT (N6495), yielding a water-insoluble indigo dye (Abs ~615 nm) and a water-insoluble formazan (Abs ~605 nm), respectively.

Cat. No.	Product	Quantity
C10552	Chemiluminescent Alkaline Phosphatase ELISA Kit #1 *with CSPD® Substrate/ Sapphire-II™ enhancer* *1000 assays*	1 kit
C10553	Chemiluminescent Alkaline Phosphatase ELISA Kit #2 *with CSPD® Substrate/ Emerald-II™ enhancer* *1000 assays*	1 kit
C10554	Chemiluminescent Alkaline Phosphatase ELISA Kit #3 *with CDP-Star® Substrate/ Sapphire-II™ enhancer* *1000 assays*	1 kit
C10555	Chemiluminescent Alkaline Phosphatase ELISA Kit #4 *with CDP-Star® Substrate/ Emerald-II™ enhancer* *1000 assays*	1 kit
C10556	Chemiluminescent Alkaline Phosphatase ELISA Sampler Kit *1000 assays*	1 kit
E6578	ELF® 97 alcohol *1 mM solution in DMSO*	1 mL
E6603	ELF® 97 Cytological Labeling Kit *with streptavidin, alkaline phosphatase conjugate* *50 assays*	1 kit
E6601	ELF® 97 Endogenous Phosphatase Detection Kit	1 kit
E6600	ELF® 97 Immunohistochemistry Kit	1 kit
E6604	ELF® 97 mRNA <i>In Situ</i> Hybridization Kit #1 *50 assays*	1 kit
E6605	ELF® 97 mRNA <i>In Situ</i> Hybridization Kit #2 *with streptavidin, alkaline phosphatase conjugate* *50 assays*	1 kit
E6588	ELF® 97 phosphatase substrate (ELF® 97 phosphate) *5 mM in water* *0.2 µm filtered*	1 mL
E6589	ELF® 97 phosphatase substrate (ELF® 97 phosphate) *5 mM in water* *contains 2 mM azide*	1 mL
E6606	ELF® spin filters *20 filters*	1 box
N6547	NBT/BCIP Reagent Kit	1 kit
N6495	nitro blue tetrazolium chloride (NBT)	1 g

6.4 Phycobiliproteins

Phycobiliproteins are a family of highly soluble and reasonably stable fluorescent proteins derived from cyanobacteria and eukaryotic algae. These proteins contain covalently linked tetrapyrrole groups that play a biological role in collecting light and, through fluorescence resonance energy transfer, conveying it to a special pair of chlorophyll molecules located in the photosynthetic reaction center.¹ Because of their role in light collection, phycobiliproteins have evolved to maximize both absorption and fluorescence and to minimize the quenching caused either by internal energy transfer or by external factors such as changes in pH or ionic composition.^{2,3} Phycobiliproteins have several advantages when used as fluorescent probes, including:

- Intense long-wavelength excitation and emission to provide fluorescence that is relatively free of interference from other biological materials
- Relatively large Stokes shifts with extremely high emission quantum yields
- Fluorescence that is not quenched by external agents because the fluorophores are protected by covalent binding to the protein backbone
- Very high water solubility
- Homogeneous structure with defined molecular weights
- Multiple sites for stable conjugation to many biological and synthetic materials

Spectral Characteristics of Phycobiliproteins

B-Phycoerythrin, R-Phycoerythrin and Allophycocyanin

The phycobiliproteins B-phycoerythrin (B-PE), R-phycoerythrin (R-PE) and allophycocyanin (APC) are among the preferred dyes for applications that require either high sensitivity or simultaneous multicolor detection.^{4–6} Quantum yields up to 0.98 and extinction coefficients up to 2.4 million $\text{cm}^{-1}\text{M}^{-1}$ have been reported for these fluorescent proteins (Table 6.2). On a molar basis, the fluorescence yield is equivalent to at least 30 unquenched fluorescein or 100 rhodamine molecules at comparable wavelengths. The fluorescence of a single molecule of B-PE has been detected.^{7,8} B-PE is reportedly more photostable than R-PE, but photostability of R-PE conjugates can be improved by adding 1-propyl gallate.⁹

In practical applications such as flow cytometry and immunoassays,^{10,11} the sensitivity of B-PE- and R-PE-conjugated antibodies is usually 5 to 10 times greater than that of the corresponding fluorescein conjugate.^{12,13} Using R-PE-conjugated streptavidin, researchers have detected fewer than 100 receptor-bound biotinylated antibodies per cell by flow cytometry.¹⁴ A multistep amplification method utilizing

a fluoresceinated opioid, biotinylated anti-fluorescein/Oregon Green[®] antibody (A982, Section 7.4) and a phycoerythrin conjugate of avidin (A2660) was required to detect low-abundance κ -opioid receptors by flow cytometry. In imaging applications, APC and its conjugates are both brighter and more photostable than Cy[®]5 conjugates (Figure 6.4.1).

Tandem Conjugates of Phycobiliproteins

A phycoerythrin-labeled detection reagent can be used in combination with a green-fluorescent detection reagent to detect two different signals using simultaneous excitation with the 488 nm spectral line of the argon-ion laser.¹⁵ By conjugating R-PE to longer-wavelength light-emitting fluorescence acceptors, an energy transfer cascade is established wherein excitation of the R-PE produces fluorescence of the acceptor dye by the process of fluorescence resonance energy transfer (FRET) (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). This process, which occurs naturally within single molecules and assemblies of phycobiliproteins (phycobilisomes), can be quite efficient, resulting in almost total transfer of energy from the phycobiliprotein to the acceptor dye of these “tandem conjugates.” Thus, it is possible to combine a green-fluorescent antibody conjugate with an R-PE conjugate, as mentioned above, and then to add tandem conjugates of R-PE with either our Alexa Fluor[®] 610, Alexa Fluor[®] 647, Alexa Fluor[®] 680 or

Figure 6.4.1 A comparison of the photobleaching rates of APC and Cy[®]5 conjugates. The microtubules of bovine pulmonary artery endothelial cells were stained with mouse anti- α -tubulin antibody (A11126) in combination with goat anti-mouse IgG labeled antibody with either crosslinked APC (A865, top series) or the Cy[®]5 dye (bottom series). The samples were exposed to continuous illumination, and the images were acquired at 30-second intervals with a Quantex cooled CCD camera (Photometrics[®]) using filter sets appropriate for both APC and Cy[®]5 dye.

Table 6.2 Spectral data for B-PE, R-PE and APC.

Cat. No.	Phycobiliprotein	Molecular Weight	Absorption Max (nm)	EC ($\text{cm}^{-1}\text{M}^{-1}$)	Emission Max (nm)	Fluorescence QY
P800	B-phycoerythrin	240,000	546, 565	2,410,000	575	0.98
P801	R-phycoerythrin	240,000	496, 546, 565	1,960,000	578	0.82
A803, A819	Allophycocyanin	104,000	650	700,000	660	0.68

EC = extinction coefficient. QY = quantum yield.

Figure 6.4.2 Normalized fluorescence emission spectra of 1) Alexa Fluor® 488 goat anti-mouse IgG antibody (A11001), 2) R-phycoerythrin goat anti-mouse IgG antibody (P852), 3) Alexa Fluor® 610-R-phycoerythrin goat anti-mouse IgG antibody (A20980), 4) Alexa Fluor® 647-R-phycoerythrin goat anti-mouse IgG antibody (A20990) and 5) Alexa Fluor® 680-R-phycoerythrin goat anti-mouse IgG antibody (A20983). The tandem conjugates permit simultaneous multicolor labeling and detection of up to five targets with excitation by a single excitation source—the 488 nm spectral line of the argon-ion laser.

Figure 6.4.3 Fluorescence emission spectra of Alexa Fluor® 610-R-phycoerythrin streptavidin (S20982; red) and Texas Red®-R-phycoerythrin streptavidin (blue) tandem conjugates. Panel A shows a comparison of the spectra on a relative fluorescence intensity scale for samples prepared with equal absorbance at the excitation wavelength (488 nm). Panel B shows the same data normalized to the same peak intensity value to facilitate comparison of the spectral profiles.

Figure 6.4.4 Fluorescence emission spectra of Alexa Fluor® 647-R-phycoerythrin streptavidin (S20992; red) and Cy®5-R-phycoerythrin streptavidin (blue) tandem conjugates. Panel A shows a comparison of the spectra on a relative fluorescence intensity scale for samples prepared with equal absorbance at the excitation wavelength (488 nm). Panel B shows the same data normalized to the same peak intensity value to facilitate comparison of the spectral profiles.

Alexa Fluor® 750 dyes for simultaneous detection of up to five targets using only 488 nm excitation (Figure 6.4.2).

Phycoerythrin has previously been conjugated to our Texas Red® dye to provide a third signal that is excitable at 488 nm; however, our Alexa Fluor® 610 tandem conjugates of R-PE (A20980, A20981, S20982) have emission properties superior to those of commercially available Texas Red® tandem conjugates of R-PE. Not only are the Alexa Fluor® 610-R-PE tandem conjugates more fluorescent than the commercially available Texas Red®-R-PE tandem conjugates, but also the fluorescence emission of Alexa Fluor® 610-R-PE tandem conjugates is shifted to somewhat longer wavelengths than is the emission of Texas Red®-R-PE conjugates, resulting in better separation from the emission of R-PE (Figure 6.4.3). Our Alexa Fluor® 647 (A20990, A20991, S20992) and Alexa Fluor® 680 (A20983, A20984, S20985) tandem conjugates of R-PE have emission spectra almost identical to those of Cy®5-R-PE and Cy®5.5-R-PE tandem conjugates but tend to have more intense long-wavelength emission and to require less compensation in the R-PE channel than the Cy® dye-R-PE tandem conjugates (Figure 6.4.4, Figure 6.4.5). Our Alexa Fluor® 750 tandem conjugate of R-PE (S32363) emits at 771 nm.

We have also conjugated APC to our Alexa Fluor® 680 (A21000, A21001MP, S21002), Alexa Fluor® 700 (A21005) and Alexa Fluor® 750 (A21006, S21008) dyes to provide tandem conjugates that can be excited by the He-Ne laser at 633 nm or by the krypton-ion laser at 647 nm. These Alexa Fluor® dye-APC tandem conjugates can potentially be combined with direct APC conjugates for simultaneous three- or four-color applications (Figure 6.4.6).

As the absorption and emission maxima of the acceptor dye move to longer wavelengths, the energy transfer efficiency from the R-PE to the

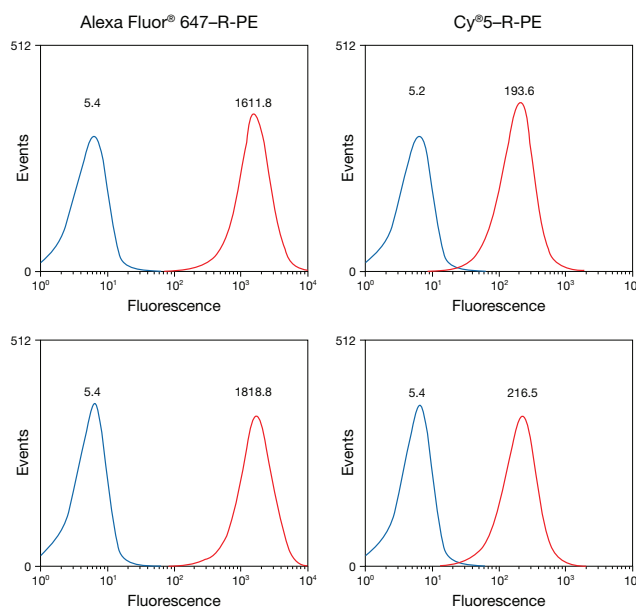

Figure 6.4.5 Comparison of immunofluorescent staining by R-phycoerythrin-dye tandem conjugates. EL4 cells labeled with a biotinylated anti-CD44 monoclonal antibody were detected with streptavidin conjugates of Alexa Fluor® 647-R-PE (S20992) or Cy®5-R-PE (Serotec). The cells were analyzed by flow cytometry on a Coulter® XL cytometer using excitation at 488 nm. Data were obtained using an bandpass emission filter (675 ± 20 nm; upper panels) or a longpass emission filter (>650 nm; lower panels). In each histogram, unstained and stained cells are represented by the blue and red lines, respectively. The numbers above each peak represent mean channel fluorescence intensities. Data provided by William Telford, NCI-NIH, Bethesda, MD.

bound dyes tends to decrease; also, the quantum yields of the longer-wavelength acceptor dyes in the tandem conjugates tend to be lower than those of the shorter-wavelength dyes and to decrease further at high degrees of substitution. Consequently, the preparation of tandem conjugates necessarily involves careful optimization of both the energy transfer efficiency from the R-PE to the longer-wavelength-emitting acceptor dye and the total brightness of the tandem conjugate. For our Alexa Fluor® 647 and Alexa Fluor® 680 tandem conjugates of R-PE, the energy transfer efficiency from R-PE to the attached dye is about 99% and 98%, respectively, as determined from their fluorescence at 575 nm relative to unconjugated R-PE. The residual signal that overlaps the unquenched R-PE emission can be compensated by methods familiar to flow cytometrists.

Pure Phycobiliproteins

We were the first company to make the phycobiliproteins available for research, and we can supply bulk quantities of B-PE (P800), R-PE (P801), APC (A803) and chemically crosslinked APC (A819); more information is available at www.invitrogen.com/handbook/custombioconjugates.

Phycobiliproteins may undergo some loss of fluorescence upon freezing. The pure proteins are shipped in an ammonium sulfate suspension and are stable for at least one year when stored at 4°C. The conjugates and modified derivatives are shipped in solutions containing sodium azide to inhibit bacterial growth and typically have a useful life of more than six months. *All phycobiliproteins and their derivatives should be stored refrigerated, never frozen.*

Phycobiliprotein Conjugates

Reactive Phycobiliprotein Derivative

Conjugates of R-PE with other proteins are generally prepared from the pyridyldisulfide derivative of R-PE (P806). This derivative can be directly reacted with thiolated antibodies, enzymes and other biomolecules to form a disulfide linkage. More commonly, however, the pyridyldisulfide groups in this derivative are first reduced to thiols, which are then reacted with maleimide-derivatized proteins (Figure 6.4.7). Because the pyridyldisulfide derivative of R-PE is somewhat unstable, we recommend using it within three months of receipt. Phycobiliproteins can be conveniently crosslinked to other proteins using the reagents and protocol provided in our Protein-Protein Crosslinking Kit (P6305, Section 5.2).

Phycobiliprotein-Labeled Secondary Detection Reagents

We prepare R-PE conjugates of the goat anti-mouse IgG (P852) and goat anti-rabbit IgG (P2771MP) antibodies and NeutrAvidin™ biotin-binding protein (A2660), as well as both the R-PE (SAPE, S866) and B-PE (S32350) conjugates of streptavidin. R-PE conjugates of anti-mouse IgG₁, IgG_{2a} and IgG_{2b} antibodies are also available (P21129, P21139, P21149). Our streptavidin conjugates of R-PE and B-PE have been purified to help ensure that all unconjugated streptavidin has been removed (Figure 6.4.8), making them useful for multicolor flow cytometry and

Figure 6.4.6 Normalized fluorescence emission spectra of 1) allophycocyanin goat anti-mouse IgG antibody (A865), 2) Alexa Fluor® 680-allophycocyanin goat anti-mouse IgG antibody (A21000) and 3) Alexa Fluor® 750-allophycocyanin goat anti-mouse IgG antibody (A21006). The tandem conjugates permit simultaneous multicolor labeling and detection of up to three targets with excitation by a single excitation source—the 633 nm spectral line of the He-Ne laser.

Figure 6.4.8 Analytical size-exclusion chromatograms of free streptavidin (S888; red curve, detected by absorption at 280 nm) and R-phycoerythrin streptavidin (SAPE; S866, S21388; blue curve, detected by absorption at 565 nm), demonstrating that the R-phycoerythrin conjugate is substantially free of unconjugated streptavidin.

Figure 6.4.7 SPDP derivatization reactions. SPDP (S1531) reacts with an amine-containing biomolecule at pH 7 to 9, yielding a pyridyldithiopropionyl mixed disulfide. The mixed disulfide can then be reacted with a reducing agent such as DTT (D1532) or TCEP (T2556) to yield a 3-mercaptopropionyl conjugate or with a thiol-containing biomolecule to form a disulfide-linked tandem conjugate. Either reaction can be quantitated by measuring the amount of 2-pyridinethione chromophore released during the reaction.

Figure 6.4.9 R-phycoerythrin used to detect DNA on a microarray. A DNA microarray containing a decreasing dilution of calf thymus DNA was hybridized with a biotinylated DNA probe and then incubated with R-phycoerythrin–streptavidin (SAPE; S866, S21388). After washing, the fluorescence signal was detected on a Packard ScanArray® 5000 using three different detection configurations: 488 nm excitation (argon-ion laser)/570 nm emission filter (left); 543.5 nm excitation (He-Ne laser)/570 nm emission filter (middle); 543.5 nm excitation (He-Ne laser)/592 nm emission filter (right).

microarray assays^{16–23} (Figure 6.4.9). In addition, biotinylated R-PE (P811) can be used with standard avidin/streptavidin bridging techniques to detect biotinylated molecules.²⁴

Because APC tends to dissociate into subunits when highly diluted or treated with chaotropic agents, we prepare all APC conjugates—including APC tandem conjugates, APC conjugates of the goat anti–mouse IgG (A865) and goat anti–rabbit IgG (A10931) antibodies and APC-labeled streptavidin (S868)—from chemically crosslinked APC (A819), a protein complex that does not dissociate even in strongly chaotropic salts.^{25–27} We also prepare premium-grade R-PE and APC conjugates of streptavidin (S21388, S32362), which represent an even further fractionation of our R-PE streptavidin (S866) and APC streptavidin (S868), respectively.

Secondary Detection Reagents Labeled with Alexa Fluor® Dye–Phycobiliprotein Tandem Conjugates

We have conjugated R-PE with four of our Alexa Fluor® dyes—Alexa Fluor® 610, Alexa Fluor® 647, Alexa Fluor® 680 and Alexa Fluor® 750 dyes—and then conjugated these fluorescent proteins to antibodies or streptavidin to yield secondary detection reagents that can be excited with the 488 nm spectral line of the argon-ion laser (Table 6.3). The long-wavelength emission maxima are 628 nm for the Alexa Fluor® 610–R-PE conjugates, 668 nm for the Alexa Fluor® 647–R-PE conjugates, 702 nm for the Alexa Fluor® 680–R-PE conjugates (Figure 6.4.2) and 771 nm for the Alexa Fluor® 750–R-PE conjugates. Emission of the Alexa Fluor® 610–R-PE conjugates is shifted to longer wavelengths by about 13 nm relative to that of Texas Red® conjugates of R-PE (Figure 6.4.3). This slightly longer-wavelength emission maximum significantly improves the resolution that can be obtained when using the Alexa Fluor® 610–R-PE tandem conjugates in place of Texas Red®–R-PE tandem conjugates for multicolor flow cytometry. The Alexa Fluor® 647–R-PE tandem conjugates have spectra virtually identical to those of Cy®5 conjugates of R-PE but are about three-fold brighter (Figure 6.4.4). These tandem conjugates can potentially be used for simultaneous three-, four- or five-color labeling with a single excitation (Figure 6.4.2, Figure 6.4.10, Figure 6.4.11).

In addition, we have conjugated crosslinked APC (A819) to our Alexa Fluor® 680, Alexa Fluor® 700 and Alexa Fluor® 750 dyes, and then conjugated these fluorescent proteins to antibodies or streptavidin to yield secondary detection reagents that can be excited with the He-Ne laser

Table 6.3 Tandem conjugates of R-phycoerythrin (R-PE).

Acceptor Dye (Ex/Em) *	Conjugate		
	Anti–Mouse IgG †	Anti–Rabbit IgG †	Streptavidin
Alexa Fluor® 610 (565/628)	A20980	A20981	S20982
Alexa Fluor® 647 (565/668)	A20990	A20991	S20992
Alexa Fluor® 680 (565/702)	A20983	A20984	S20985

* Fluorescence excitation and emission maxima, in nm. † Host = goat.

Figure 6.4.10 Simultaneous detection of three cell surface markers using an Alexa Fluor® 610–R-phycoerythrin tandem conjugate, Alexa Fluor® 488 dye and R-phycoerythrin labels. Lymphocytes from ammonium chloride RBC-lysed whole blood were labeled with a biotinylated mouse anti–human CD3 monoclonal antibody, washed with 1% BSA in PBS and then incubated with Alexa Fluor® 610–R-phycoerythrin tandem dye-labeled streptavidin (S20982). Cells were again washed and then labeled with directly conjugated primary antibodies against the CD8 and CD4 markers (Alexa Fluor® 488 dye-labeled mouse anti–human CD8 antibody and R-phycoerythrin–conjugated mouse anti–human CD4 antibody (A21337)). After a further wash in 1% BSA/PBS, labeling was analyzed on a Becton Dickinson FACScan™ flow cytometer using excitation at 488 nm. CD8 was detected in the green channel (525 ± 10 nm), CD4 in the orange channel (575 ± 10 nm) and CD3 in the red channel (>650 nm). The bivariate scatter plots show the expected mutually exclusive populations of CD4 and CD8 positive cells (A), together with co-positive CD3/CD4 (B) and CD3/CD8 (C) populations.

at 633 nm with emission beyond 700 nm (Table 6.4). The long-wavelength emission maxima are 702 nm for the Alexa Fluor® 680-APC conjugates, 719 nm for the Alexa Fluor® 700-APC conjugates and 779 nm for the Alexa Fluor® 750-APC conjugates (Figure 6.4.2). Our Alexa Fluor® dye-APC tandem conjugates can potentially be combined with direct APC conjugates for simultaneous three-color applications (Figure 6.4.6).

R-Phycoerythrin Anti-Fluorescein/Oregon Green® Antibody

The R-PE conjugate of the rabbit anti-fluorescein/Oregon Green® antibody (A21250) has the unique ability both to shift the green-fluorescent emission of fluorescein-labeled probes to longer wavelengths and to greatly intensify the signal (Figure 6.4.12). Anti-fluorescein antibodies strongly cross-react with our Oregon Green® dye conjugates, suggesting the possibility of amplifying the signal from nucleic acid probes labeled by our ULYSIS® Oregon Green® 488 Nucleic Acid Labeling Kit (U21659, Section 8.2) or for further amplifying the signal of Oregon Green® 488 tyramide, which is used in one of our TSA™ Kits (Section 6.2, Table 6.1).

Phycobiliprotein Conjugates of Annexin V

In collaboration with Nexins Research BV, we offer the highly fluorescent APC and R-PE conjugates of annexin V (A35110, A35111), in addition to several other fluorescent annexin V conjugates (Section 15.5). Highly fluorescent annexin V conjugates provide quick and reliable detection methods for studying the externalization of phosphatidylserine, an indicator of intermediate stages of apoptosis (Section 15.5).²⁸ Several of Molecular Probes® apoptosis assay kits (V35112, V35113, V35114; Section 15.5; Table 15.4) contain either R-PE-annexin V or APC-annexin V conjugates as well as SYTOX® Green nucleic acid stain to characterize mixed populations of apoptotic and non-apoptotic cells by flow cytometry.

Custom Phycobiliprotein Conjugates

We have carried out hundreds of successful conjugations with phycobiliproteins, beginning soon after their use was disclosed in 1982.⁶ We are experts in doing custom conjugations of phycobiliproteins to antibodies and other proteins and welcome inquiries for specific conjugates (www.invitrogen.com/handbook/custombioconjugates).

Figure 6.4.12 Color-shifting using a labeled anti-fluorescein/Oregon Green® antibody. Jurkat cells were first stained with a primary mouse anti-human CD3 antibody, followed by fluorescein goat anti-mouse IgG antibody (F2761), with the resultant fluorescence detected in the R-phycoerythrin (red-orange fluorescence) channel of a flow cytometer (blue curve). The weak signal was then shifted to better suit the R-phycoerythrin channel by the addition of an R-phycoerythrin conjugate of anti-fluorescein/Oregon Green® antibody (A21250). The resulting signal intensity is approximately two orders of magnitude greater (red curve) than the direct fluorescence from the first staining step (blue curve).

Figure 6.4.11 Simultaneous detection of three cell surface markers using an Alexa Fluor® 647-R-phycoerythrin tandem conjugate, Alexa Fluor® 488 dye and R-phycoerythrin labels. Lymphocytes from ammonium chloride RBC-lysed whole blood were labeled with a mouse anti-human CD3 monoclonal antibody, washed with 1% BSA in PBS and then incubated with a goat anti-mouse IgG antibody labeled with the Alexa Fluor® 647-R-phycoerythrin tandem dye (A20990). Cells were again washed and then labeled with directly conjugated primary antibodies against the CD8 and CD4 markers (Alexa Fluor® 488 dye-labeled mouse anti-human CD8 antibody and R-phycoerythrin-conjugated mouse anti-human CD4 antibody). After a further wash in 1% BSA/PBS, labeling was analyzed on a Becton Dickinson FACScan™ flow cytometer using excitation at 488 nm. CD8 was detected in the green channel (525 ± 10 nm), CD4 in the orange channel (575 ± 10 nm) and CD3 in the red channel (>650 nm). The bivariate scatter plots show the expected mutually exclusive populations of CD4 and CD8 positive cells (A), together with co-positive CD3/CD4 (B) and CD3/CD8 (C) populations.

Figure 6.4.13 Labeling scheme utilized in the Zenon® Antibody Labeling Kits. An unlabeled IgG antibody is incubated with the Zenon® labeling reagent, which contains a fluorophore-labeled, Fc-specific anti-IgG Fab fragment (A). This labeled Fab fragment binds to the Fc portion of the IgG antibody (B). Excess Fab fragment is then neutralized by the addition of a nonspecific IgG (C), preventing crosslabeling by the Fab fragment in experiments where primary antibodies of the same type are present. Note that the Fab fragment used for labeling need not be coupled to a fluorophore, but could instead be coupled to an enzyme (such as HRP) or to biotin.

Zenon® Antibody Labeling Technology

Chemical conjugation of phycobiliproteins to antibodies and other proteins is a moderately difficult and relatively low-yield process that cannot be done on very small quantities of proteins. The Protein–Protein Crosslinking Kit (P6305, Section 5.2) provides the reagents and a protocol for conjugating phycobiliproteins using our recommended procedure. However, instead of labeling each primary antibody, researchers typically use labeled secondary antibodies to detect their primary antibodies. Our exceptional Zenon® immunolabeling technology (Section 7.3) provides an easy, versatile and unique method of labeling antibodies with phycobiliproteins, as well as with many other premier dyes, haptens and enzymes. This enabling technology not only eliminates the need for secondary detection reagents in many applications, but also simplifies immunolabeling applications that were previously time consuming or impractical, including the use of multiple antibodies derived from the same species in the same protocol, as well as the detection of antibody binding in tissues when both the antibody and the tissue are derived from the same species.

Zenon® immunolabeling technology allows the rapid and quantitative preparation of antibody complexes from a purified antibody fraction or from a crude antibody preparation such as serum, ascites fluid or a hybridoma supernatant. The Zenon® antibody labeling procedure (Figure 6.4.13) has numerous advantages, particularly when preparing phycobiliprotein-labeled antibodies:

- Conjugations can be done on submicrogram quantities of a primary antibody.
- The reactions are usually quantitative with respect to the primary antibody.
- Labeling and purification of the complex can be completed in only minutes.
- Labeling is essentially irreversible under conditions of use.
- Multiple antibodies derived from the same species can be used in the same experiment.
- The fluorescence intensity of the cells can be adjusted by changing the ratio of labeling reagent to primary antibody, which even permits using identical dyes to detect multiple targets in cells by flow cytometry.
- Antibody complexes prepared from the Zenon® Antibody Labeling Kits can be combined with direct conjugates for multicolor labeling.
- Labeling is possible with a wide variety of fluorophores, including R-PE and APC as well as most of our Alexa Fluor® dyes (Table 7.7).
- Zenon® Antibody Labeling Kits with Alexa Fluor® dye–phycobiliprotein tandem conjugates are also available (Table 7.7), increasing the possible combinations of detection wavelengths in a multicolor experiment.

6.5 Microspheres

Figure 6.5.1 A photomicrograph of a multicolor mixture of Molecular Probes® FluoSpheres® fluorescent microspheres overlaid with a differential interference contrast (DIC) image of the same field. Molecular Probes® proprietary fluorescent dye technology produces a range of intensely fluorescent FluoSpheres® microspheres labeled with biotin, streptavidin and NeutrAvidin™ biotin-binding protein, providing important tools for improving the sensitivity of flow cytometry applications and immunodiagnostic assays.

Figure 6.5.2 A positively charged membrane containing an approximately equal number of TransFluoSpheres® fluorescent microspheres per slot. Our proprietary TransFluoSpheres® polystyrene beads are designed to be excited with a common wavelength and then detected at a variety of longer wavelengths with minimal spectral overlap. This nylon membrane was excited with 365 nm epillumination and photographed through a 400 nm longpass optical filter.

Although low molecular weight reactive dyes are versatile and easy to use, they are not without limitations. For example, the fluorescence output of the dye-biomolecule conjugate is often limited by the number of dyes that can be attached to the biomolecule without disrupting its function. Our highly fluorescent microspheres—both the FluoSpheres® (Figure 6.5.1) and TransFluoSpheres® (Figure 6.5.2) beads—provide a means of overcoming this limitation. Moreover, our TransFluoSpheres® beads are designed to facilitate multicolor detection, particularly in applications that use lasers with their inherent limited number of excitation wavelengths. TransFluoSpheres® beads contain a series of two or more proprietary dyes that have been carefully chosen to ensure excited-state energy transfer between the dyes. This strategy enables fine-tuning of both the excitation and emission wavelengths of the microspheres so that they match a particular instruments, excitation source and detection sensitivity, and complement the spectra of other fluorophores in a multicolor experiment.

Properties of Molecular Probes® Fluorescent and Nonfluorescent Microspheres

Fluorescent FluoSpheres® and TransFluoSpheres® Microspheres

Molecular Probes® FluoSpheres® and TransFluoSpheres® beads are manufactured using high-quality, ultraclean polystyrene microspheres. These microspheres are internally labeled with Molecular Probes® dyes, making them among the brightest fluorescent microspheres available (Table 6.5). We employ methods to help ensure that each bead is heavily loaded with dye. The protective environment within the bead matrix shields the dyes from many of the environmental effects that cause photobleaching of exposed fluorophores. Not only are our yellow-green-fluorescent beads more photostable, but their emission spectra are not affected by changes in pH, as are conventional fluorescein-labeled microspheres. Fluorescent microspheres can be fixed in formalin and embedded in paraffin if care is used to avoid extraction of the noncovalently associated dyes from the microspheres.¹ The stability, uniformity and reproducibility of our fluorescent beads, as well as the extensive selection of colors available, make our microspheres the preferred tools for research and diagnostic assays that use fluorescence.

In addition to the microspheres described in this section, we have developed several important microsphere-based products for calibrating and aligning fluorescence microscopes (Section 23.1) and flow cytometers (Section 23.2). Custom preparation of microspheres with other colors, sizes and surface coatings is available; please go to www.invitrogen.com/handbook/customparticles for more information.

Table 6.5 Molecular Probes® yellow-green-fluorescent FluoSpheres® beads compared with other commercially available yellow-green-fluorescent microspheres.

Brand/Supplier	Size (µm)	Fluorescence Intensity *	CV for Intensity †
Molecular Probes® F8852	1.02	1998	4.40%
Molecular Probes® F8853	2.07	8998	3.26%
Company A	0.84	3.7	30.28%
Company A	1.55	5.2	11.69%
Company B	1.01	12.6	2.49%
Company B	1.94	595	2.91%
Company C	0.93	116	4.62%
Company C	1.48	434	1.92%
Company D	0.85	17	5.19%
Company D	1.84	119	3.08%

* Median value for fluorescence intensity (in arbitrary units), measured for 10,000 individual beads per sample excited at 488 nm using flow cytometry. Values may vary slightly between batches of these products. † CV = coefficient of variation.

Colored and Unstained Microspheres

We also offer a wide selection of colored and unstained microspheres for research applications as well as for water- and air-flow testing and other bead-based applications. Through the acquisition of Interfacial Dynamics Corporation (IDC), we provide milliliter to 500-liter quantities of ultraclean microspheres with diameters from 20 nm to 10.0 μm and with more than 20 different surface functionalities; see www.invitrogen.com/handbook/latex for a complete listing of the microspheres available. IDC pioneered the commercial development of surfactant-free polymer particles used in bead-based assay systems and has been a key supplier of beads for Molecular Probes® fluorescent microspheres. Our outstanding capabilities in microsphere manufacturing allow a high level of control of the colloid engineering employed in the particle synthesis, providing excellent batch-to-batch consistency. Other microsphere manufacturers often use surfactants to prevent aggregation. However, standards of surfactant purity are generally not very high, leading to an undefined particle surface and variable protein attachment. In the manufacturing of our ultraclean microspheres, no surfactants are required to prevent aggregation, taking much of the guesswork out of stability and adsorption experiments. We can tailor-make colored and unstained microspheres of many sizes, surface chemistries, densities and volumes to meet the diverse needs of customers, including academic, industrial and government laboratories, as well as major global diagnostic companies; please go to www.invitrogen.com/handbook/customparticles for more information.

Applications for Fluorescent Microspheres

Fluorescent microspheres have been used as immunofluorescent reagents,^{2–4} retrograde neuronal tracers,^{5–7} microinjectable cell tracers^{8,9} (Section 14.6) and standardization reagents for microscopy (Section 23.1) and flow cytometry¹⁰ (Section 23.2). Suspension arrays of fluorescent microspheres that differ in intensity, size or excited-state lifetime are extensively used for simultaneous assays to determine multiple analytes in a single sample.^{11–18} In addition, fluorescent microspheres are potentially more sensitive than colorimetric methods in most, if not all, of the major microsphere-based test systems presently in use, including latex-agglutination tests, filter-separation tests, particle-capture ELISA

Figure 6.5.3 Normalized fluorescence emission spectra of our FluoSpheres® beads, named according to their excitation/emission maxima (nm): 1) blue (365/415), 2) blue (350/440), 3) yellow-green (505/515), 4) orange (540/560), 5) red-orange (565/580), 6) red (580/605), 7) crimson (625/645), 8) dark red (660/680) and 9) infrared (715/755) FluoSpheres® beads.

methods and two-particle sandwich techniques. Applications of our fluorescent microspheres for assessing tissue blood perfusion¹⁹ are described in Section 14.6.

FluoSpheres® Fluorescent Microspheres

A Wide Array of Fluorescent Colors

Molecular Probes® FluoSpheres® fluorescent microspheres contain dyes with excitation and emission wavelengths that cover the entire spectrum from the near UV to the near-infrared. Figure 6.5.3 shows the normalized emission spectra for 9 fluorescent colors of FluoSpheres® beads. Because long-wavelength (>680 nm) light can penetrate tissues, our infrared-fluorescent microspheres may allow researchers to conduct experiments that were not previously possible with beads that emit at shorter wavelengths. We would like to highlight the following FluoSpheres® products:

- Blue-fluorescent FluoSpheres® beads with excitation/emission maxima of 350/440 nm contain an improved blue-fluorescent dye that has exceptional brightness and a long shelf life. We also offer blue-fluorescent FluoSpheres® beads with slightly shorter-wavelength fluorescence spectra (excitation/emission maxima ~365/415 nm).
- Yellow-green-fluorescent FluoSpheres® beads have excitation/emission maxima of 505/515 nm and thus are excited very efficiently using the 488 nm spectral line of the argon-ion laser, resulting in exceptionally intense fluorescence (Table 6.5).
- Orange-, red-orange- and red-fluorescent FluoSpheres® beads have excitation maxima of 540 nm, 565 nm and 580 nm, respectively.
- Nile red-fluorescent FluoSpheres® beads have broad excitation/emission bandwidths at 535/575 nm, making them compatible with filter sets appropriate for fluorescein, rhodamine and Texas Red® dyes.
- Crimson- and dark red-fluorescent FluoSpheres® beads with excitation/emission maxima of 625/645 nm and 660/680 nm, respectively, are efficiently excited by the 633 nm spectral line of the He-Ne laser. Although the dark red-fluorescent beads are significantly less fluorescent than the crimson-fluorescent particles, they fluoresce at wavelengths that are longer than, and clearly distinguishable from, those of the crimson-fluorescent particles.
- Infrared-fluorescent FluoSpheres® beads with excitation/emission maxima of 715/755 nm are the longest-wavelength fluorescent microspheres currently available from any source. These beads absorb and emit at wavelengths at which most tissues are almost optically transparent.
- Europium luminescent and platinum luminescent FluoSpheres® beads have excitation/emission maxima of 340–370/610 nm (Figure 6.5.4) and ~390/650 nm (Figure 6.5.5), respectively, and decay times of >40 microseconds for the platinum microspheres and >100 microseconds for the europium microspheres, far longer than those of conventional fluorescent probes and autofluorescent samples. These beads should be useful as standards for time-resolved microscopy and for tracing applications in highly autofluorescent samples.

Table 6.6 Fluorescein equivalents in Molecular Probes® yellow-green–fluorescent FluoSpheres® beads.

Microsphere Diameter (µm)	Fluorescein Equivalents per Microsphere *
0.02	1.8×10^2
0.04	3.5×10^2
0.1	7.4×10^3
0.2	1.1×10^5
0.5	2.0×10^6
1.0	1.3×10^7
2.0	3.1×10^7
10	1.1×10^{10}
15	3.7×10^{10}

* Values may vary slightly between batches of these products. These data were obtained by taking known numbers of beads and totally dissolving the polystyrene to release the dye. The fluorescence of the released dye was then compared to a fluorescein standard curve. The relationship of fluorescence (fluorescein equivalents) to bead size scales as the cube of the bead radius, as it should for a spherical bead where the dye fills the full volume (as opposed to only being on the surface).

Our FluoSpheres® beads are many times brighter than fluorescent microspheres from other companies (Table 6.5). Table 6.6 shows the approximate number of unquenched fluorescein equivalents in our yellow-green–fluorescent FluoSpheres® beads. The intensity of the beads is sufficient to allow visualization of single particles, even for our smallest microspheres, which appear as point sources; see the description of the PS-Speck™ Microscope Point Source Kit (P7220) in Section 23.1. Our FluoSpheres® beads show little or no photobleaching, even when excited with the intense illumination required for fluorescence microscopy.

Although some of our FluoSpheres® beads are available in limited sizes, colors and surface functions, we will prepare custom orders upon request (www.invitrogen.com/handbook/customparticles). We also have considerable experience developing standards, including microsphere-based standards for companies selling fluorescence instrumentation. FluoSpheres® beads can also be prepared with intensities that are *lower* than those of our regular products—a desirable feature in some multicolor applications. FluoSpheres® beads with calibrated intensities are already available in our InSpeck™ Microscope Intensity Calibration Kits (Section 23.1) and LinearFlow™ Flow Cytometry Intensity Calibration Kits (Section 23.2).

A Wide Range of Sizes

To meet the diverse needs of academic and industry laboratories, we offer FluoSpheres® beads in a variety of sizes (Table 6.7). The smallest microspheres are currently about 0.02 µm in diameter, with a coefficient of variation (CV) of about 20% as determined by electron microscopy. The size uniformity improves with increasing size, with the CV decreasing from ~5% for 0.1 µm FluoSpheres® beads to ~1% for those with 10–15 µm diameters. The sizes

Table 6.7 Summary of FluoSpheres® fluorescent microspheres.

* Excitation (Ex) and emission (Em) maxima in nm. FluoSpheres® beads are supplied as aqueous suspensions containing 2% solids and 2 mM sodium azide, except for the 0.04 µm microspheres (†), which are supplied as aqueous suspensions containing 5% solids without preservatives; the 1 µm microspheres for tracer studies (‡), which are supplied as aqueous suspensions containing 10¹⁰ microspheres per mL and 0.02% thimerosal; and the europium luminescent microspheres, which are supplied as aqueous suspensions containing 0.5% solids and 2 mM sodium azide. All sizes fall within a narrow range as discussed in Section 6.5. Sizes indicated in the above tables are nominal and may vary from batch to batch. Actual sizes, as determined by electron microscopy, are specified on the product labels.

specified in the product names are nominal bead diameters; because of batch-to-batch variation in the undyed microspheres, the actual mean diameters shown on the product labels may differ from the nominal diameters, especially for the smaller microspheres. Because of their small size, 0.02–0.04 μm microspheres are effectively transparent to light in aqueous suspensions and behave very much like true solutions.

Four Different Surface Functional Groups

We prepare FluoSpheres® beads with four different surface functional groups, making them compatible with a variety of conjugation strategies. Our fluorescent dyes have negligible effect on the surface properties of the polystyrene beads or on their protein adsorption. We caution, however, that the surface properties have an important role in the functional utility of the microspheres; we cannot guarantee the suitability of a particular bead type for all applications.

- Carboxylate-modified FluoSpheres® beads have pendent carboxylic acids, making them suitable for covalent coupling of proteins and other amine-containing biomolecules using water-soluble carbodiimide reagents such as EDAC (E2247, Section 3.4). In order to both decrease nonspecific binding and provide additional functional groups for conjugation, these FluoSpheres® beads have a high density of carboxylic acids on their surfaces.
- Sulfate FluoSpheres® beads are relatively hydrophobic particles that will passively and nearly irreversibly adsorb almost any protein, including albumin, IgG, avidin and streptavidin.
- Aldehyde–sulfate FluoSpheres® beads, which are sulfate microspheres that have been modified to add surface aldehyde groups, are designed to react with proteins and other amines under very mild conditions.
- Amine-modified FluoSpheres® beads can be coupled to a wide variety of amine-reactive molecules, including the succinimidyl esters and isothiocyanates of haptens and drugs or the carboxylic acids of proteins, using a water-soluble carbodiimide. The amine surface groups can also be reacted with SPDP (S1531, Section 5.2) to yield (after reduction) microspheres with pendent sulfhydryl groups.

Fluorescent Microspheres Conjugated to Biotin, Avidin and Streptavidin

We offer yellow-green–fluorescent FluoSpheres® microspheres conjugated to biotin or streptavidin, and yellow-green–fluorescent,

red-fluorescent, europium luminescent and nonfluorescent microspheres conjugated to NeutrAvidin™ biotin-binding protein (Table 6.8). NeutrAvidin™ biotin-binding protein has been specially processed to remove carbohydrates and lower the isoelectric point, resulting in a near-neutral protein that has significantly lower nonspecific binding than conventional avidin. These microsphere conjugates provide valuable tools for improving the sensitivity of flow cytometry applications and immunochemical assays.^{2,20} They are also useful as tracers that can be detected with standard enzyme-mediated avidin/streptavidin methods.²¹ Additional sizes and colors of these microspheres can be custom-ordered through Invitrogen Custom Services.

Fluorescent Microspheres Coated with Collagen

Fibroblasts phagocytose and then intracellularly digest collagen. These activities play an important role in the remodeling of the extracellular matrix during normal physiological turnover of connective tissues, in development, in wound repair and aging and in various disorders. A well-established procedure for observing collagen phagocytosis by either flow cytometry or fluorescence microscopy involves the use of collagen-coated fluorescent microspheres, which attach to the cell surface and become engulfed by fibroblasts.^{22,23} We offer yellow-green–fluorescent FluoSpheres® collagen I–labeled microspheres in either 1.0 μm or 2.0 μm diameter (F20892, F20893) for use in these applications. These microspheres have collagen I from calf skin attached covalently to their surface.

Europium and Platinum Luminescent Microspheres for Time-Resolved Fluorometry

Detecting low levels of protein or DNA targets in a tissue sample or on a membrane using classic fluorochromes is sometimes difficult and prone to errors because specific fluorescence signals tend to be low and are usually mixed with nonspecific signals and autofluorescence. One approach to improve detectability is the use of time-resolved luminescence reagents, such as our FluoSpheres® europium luminescent microspheres and FluoSpheres® platinum luminescent microspheres. The FluoSpheres® europium luminescent beads contain Eu^{3+} coordination complexes with luminescence decay times of >100 microseconds²⁴—much longer than the nanosecond decay times of conventional fluorophores and autofluorescence. The luminescence of the Pt^{2+} chelate in the FluoSpheres® platinum luminescent microspheres has a decay time of

Table 6.8 Summary of biotin-, streptavidin- and NeutrAvidin™ biotin-binding protein–labeled FluoSpheres® microspheres.

Microspheres (Ex/Em) *	0.04 μm	0.2 μm	1.0 μm
Biotin-Labeled Microspheres			
Yellow-green (505/515)	F8766 (0.4 mL)	F8767 (0.4 mL)	F8768 (0.4 mL)
Nonfluorescent			F8769 (0.4 mL)

Nonfluorescent	F8772 (0.4 mL)		F8777 (0.4 mL)

* Excitation (Ex) and emission (Em) maxima in nm. The streptavidin-labeled FluoSpheres® beads are supplied as aqueous suspensions containing 0.5% solids and 5 mM sodium azide. The NeutrAvidin™ biotin-binding protein–labeled europium luminescent FluoSpheres® are supplied as aqueous suspensions containing 0.5% solids and 5 mM azide. Other NeutrAvidin™ biotin-binding protein– and biotin-labeled FluoSpheres® beads are supplied as aqueous suspensions containing 1% solids, 5 mM sodium azide and 0.02% Tween®. All sizes fall within a narrow range as discussed in this section. Sizes indicated in the above tables are nominal and may vary from batch to batch. Actual sizes, as determined by electron microscopy, are specified on the product label.

Figure 6.5.4 Luminescence excitation and emission spectra of the FluoSpheres® europium luminescent microspheres (F20880, F20881).

Figure 6.5.5 Luminescence excitation and emission spectra of the FluoSpheres® platinum luminescent microspheres (F20886).

Figure 6.5.6 Luminescent microsphere products provide an extensive range of sizes and fluorescent colors, illustrated by a sample of our Constellation™ microspheres for imaging (C14837).

>40 microseconds. Thus, time-gated fluorescence detection using these microspheres results in complete rejection of autofluorescence signals. In addition, both the europium luminescent and platinum luminescent microspheres feature long-wavelength emissions (610–650 nm) that are well separated from their excitation peaks (340–390 nm) (Figure 6.5.4, Figure 6.5.5). Because of this exceptionally large Stokes shift, filter combinations can be chosen that effectively isolate the desired luminescence signal.

These microspheres are available uncoated (F20880, F20881, F20886) or conjugated to NeutrAvidin™ biotin-binding protein (F20883, F20884), with nominal diameters of 0.04 μm or 0.2 μm . Beads labeled with NeutrAvidin™ biotin-binding protein can be used for the indirect detection of antigens and DNA targets in many biotin/avidin-based assays.

Fluorescent Microsphere Starter Kits

For applications requiring several different microsphere colors or sizes, we offer three types of fluorescent microsphere starter kits:

- The FluoSpheres® Fluorescent Color Kit (F10720) consists of 1 mL samples of yellow-green-, orange-, red- and dark red-fluorescent, carboxylate-modified 0.04 μm FluoSpheres® beads packaged as high-density, azide-free suspensions for microinjection.
- The FluoSpheres® Size Kits contain 1 mL samples of carboxylate-modified FluoSpheres® beads in 0.02, 0.1, 0.2, 0.5, 1.0 and 2.0 μm sizes. These beads are available in yellow-green- (F8888) or red- (F8887) fluorescent colors.
- The FluoSpheres® Blood Flow Determination Fluorescent Color Kits provide several different fluorescent colors of 10 μm (F8890) or 15 μm (F8891, F8892, F21015) FluoSpheres® microspheres; see Section 14.6 for a description of these kits.

Fluorescent Microspheres for Educational Purposes

Constellation™ microspheres for imaging (C14837) can be used to demonstrate hands-on techniques with a fluorescence microscope. Constellation™ microspheres consist of a selected mixture of beads in assorted sizes and colors (Figure 6.5.6) that can be used to practice adjusting the focus and switching filters on a fluorescence microscope. These microspheres are stable at room temperature, so they can be conveniently stored.

TransFluoSpheres® Fluorescent Microspheres: Tools for Multicolor Detection

Advantages of TransFluoSpheres® Fluorescent Microspheres

TransFluoSpheres® fluorescent microspheres (Table 6.9; Figure 6.5.7, Figure 6.5.2) are specially designed to overcome the limitations imposed by modern fluorescence instrumentation. Many flow cytometers, confocal laser-scanning microscopes and laser scanners incorporate the argon-ion laser as the excitation source, thereby limiting the available excitation wavelengths to the laser's 488 nm and 514 nm spectral lines and severely restricting simultaneous multicolor detection. Ideally, it would be useful to have a series of fluorescent dyes with absorption maxima close to the argon-ion laser's spectral lines, but with emission maxima at a variety of longer wavelengths. This approach would require that some of the dyes exhibit large Stokes shifts—defined as the separation of the absorption and emission maxima. Unfortunately, very few low molecular weight dyes have a combination of a large Stokes shift and a high molar absorptivity. For example, the Texas Red® fluorophore—often used in combination with fluorescein—has particularly weak absorption at 488 nm and 514 nm. In applications that employ the argon-ion laser as an excitation source, Texas Red® conjugates have a low fluorescence output that is easily obscured by the more intense fluorescein fluorescence, even when detected past 600 nm.

Our TransFluoSpheres® beads, which incorporate two or more fluorescent dyes that undergo excited-state energy transfer, exhibit Stokes shifts that can be extremely large. Each microsphere contains a dye with an excitation peak that maximally overlaps the spectral output

of a commonly used excitation source (for example, the 488 nm spectral line of the argon-ion laser; Figure 6.5.8). In addition, each microsphere contains one or more longer-wavelength dyes that are carefully chosen to create a relay series that can efficiently transfer the energy from the initially excited dye to the longest-wavelength acceptor dye. The proprietary dyes used in the TransFluoSpheres® beads are optimally loaded to help ensure that the excitation energy is efficiently transferred from dye to dye so that essentially only the longest-wavelength dye in the series exhibits significant fluorescence. Because these TransFluoSpheres® beads fluoresce at a considerably longer wavelength than the excitation wavelength, they provide a signal that can be detected in samples with significant Rayleigh or Raman scattering or with endogenous fluorescent compounds such as bilins, flavins and certain drugs. Also, the large Stokes shifts exhibited by the TransFluoSpheres® beads allow the use of broadband filters, both to excite the sample and to detect the emission, resulting in a greater fluorescent signal (Figure 6.5.7).

TransFluoSpheres® Beads to Match Different Excitation Sources

We offer TransFluoSpheres® beads compatible with two different laser excitation sources. The argon-ion laser–excitable TransFluoSpheres® beads have an excitation maximum near 488 nm but emit at 560 nm (T8864, T8872, T8880) or 645 nm (T8883). The red He-Ne laser–excitable TransFluoSpheres® beads have excitation/emission maxima of 633/720 nm (T8870). TransFluoSpheres® beads can also be combined with our more traditional FluoSpheres® beads or with low molecular weight dyes for multicolor detection.²⁵

Using carbodiimide reagents such as EDAC (E2247, Section 3.4), researchers can couple protein or other amine-containing molecules to our carboxylate-modified TransFluoSpheres® beads, making these microspheres suitable for a wide range of applications. TransFluoSpheres® beads can be used in the major microsphere-based test systems and in experiments that currently employ standard fluorescent microspheres to measure regional blood flow (Section 14.6), to study phagocytosis (Section 16.1), to detect cell-surface antigens and to trace neurons.^{6,26–30}

In addition, we offer TransFluoSpheres® microspheres with excitation/emission maxima of 488/605 nm (T8860, T8861) conjugated to NeutrAvidin™ biotin-binding protein, as well as TransFluoSpheres® beads with excitation/emission maxima of 488/645 nm (T10711) conjugated to streptavidin. Flow cytometry studies demonstrate that the sensitivity of our 40 nm TransFluoSpheres® beads conjugated to streptavidin is superior to that of fluorescein streptavidin and comparable to that of R-phycoerythrin–streptavidin for detecting biotinylated epidermal growth factor (EGF) bound to EGF receptors.²⁵ In multicolor experiments, the long-wavelength fluorescence emission of these TransFluoSpheres® beads permits their use simultaneously with fluorescein- and R-phycoerythrin–labeled probes. For all applications requiring protein-coated microspheres, we strongly recommend using our BlockAid™ blocking solution (B10710) to reduce nonspecific binding.

If wavelength or bead-size requirements are not met by our current selection of products, we invite inquiries about custom synthesis by contacting Invitrogen Custom Services at www.invitrogen.com/handbook/customparticles. We can fine-tune the excitation and emission to match a particular excitation source or detection wavelength. In addition, we can covalently conjugate our TransFluoSpheres® beads to other target-specific proteins to provide detection reagents that have potentially greater sensitivity in flow cytometry applications and immunochemical assays.

Table 6.9 Summary of TransFluoSpheres® fluorescent microspheres.

Excitation/Emission (nm) *	Size		
	0.04 μm	0.1 μm	1.0 μm
488/560	T8864	T8872	T8880
488/605 NeutrAvidin™-labeled	T8860	T8861	
488/645			T8883
488/645 Streptavidin-labeled	T10711		
633/720	T8870		

* All TransFluoSpheres® beads are based on carboxylate-modified polystyrene microspheres and are supplied as 0.5 mL of an aqueous suspension containing 2% solids and 2 mM sodium azide, except the TransFluoSpheres® beads labeled with NeutrAvidin™ biotin-binding protein, which are supplied as 0.4 mL of an aqueous suspension containing 1% solids and 2 mM sodium azide, and the streptavidin-labeled beads, which are supplied as 0.4 mL of an aqueous suspension containing 0.5% solids and 2 mM sodium azide.

Figure 6.5.7 Schematic diagram of the advantages of the large Stokes shift exhibited by our TransFluoSpheres® beads. A1 and E1 represent the absorption and emission bands of a typical TransFluoSpheres® bead. The large separation of the absorption and emission maxima (Stokes shift) is characteristic of our TransFluoSpheres® beads. Unlike most low molecular weight fluorescent dyes, which show considerable overlap of their absorption and emission spectra, the TransFluoSpheres® beads can be excited (EX) across the entire absorption band A1 and the resulting fluorescence can be detected across the full emission band E1, thereby allowing the researcher to maximize the signal (S1). Moreover, because of the large Stokes shifts of the TransFluoSpheres® beads, researchers can often avoid problems associated with autofluorescence. The absorption and emission bands of a typical autofluorescent component are represented in this figure by A2 and E2. Although the endogenous fluorescent species will be excited simultaneously with the TransFluoSpheres® beads, the resulting emission (E2) does not coincide with E1 and is therefore readily rejected by suitably chosen optical filters.

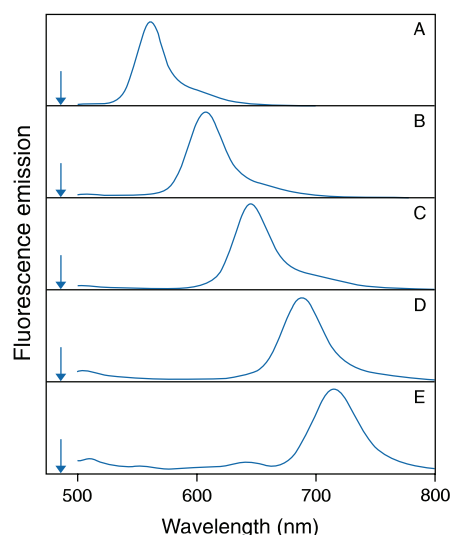

Figure 6.5.8 Fluorescence emission spectra of our five 488 nm light-excitable TransFluoSpheres® beads, named according to their excitation/emission maxima (nm): A) 488/560, B) 488/605, C) 488/645, D) 488/685 and E) 488/720. The arrow in each spectrum represents the 488 nm spectral line of the argon-ion laser. The beads shown in panels B, D and E are no longer routinely available; please inquire through Invitrogen Custom Services.

BlockAid™ Blocking Solution

The intensely fluorescent and highly photostable FluoSpheres® and TransFluoSpheres® microspheres have significant potential for applications requiring probes that can deliver a strong signal. Unfortunately, microspheres conjugated to proteins have hydrophobic regions that may cause them to bind to nontarget surfaces in some experimental systems. This nonspecific binding can often be relieved by the use of a blocking solution. However, we have found that microspheres require a stronger blocking solution than those in common use, and therefore we have developed the BlockAid™ blocking solution (B10710).

The BlockAid™ reagent is a protein-based blocking solution designed for use with FluoSpheres and TransFluoSpheres® microspheres conjugated to biotin, streptavidin, NeutrAvidin™ biotin-binding protein or other proteins. In our tests, BlockAid™ blocking solution has been found to be effective in flow cytometry applications with the NIH 3T3, A431, RAW and Jurkat cell lines; however, with the HMC-1 cell line, it did not appear to offer any advantages over standard blocking solutions. The BlockAid™ blocking solution has proven useful for reducing the nonspecific binding of protein-coated or other macromolecule-coated microspheres in a wide variety of flow cytometry, microscopy and microarray applications.^{20,31,32}

PRODUCT LIST 6.5 MICROSPHERES

Cat. No.	Product	Quantity
B10710	BlockAid™ blocking solution *for use with microspheres*	50 mL
C14837	Constellation™ microspheres for imaging *mixture of assorted sizes and colors*	3 mL
F8760	FluoSpheres® aldehyde-sulfate microspheres, 0.02 µm, yellow-green fluorescent (505/515) *2% solids*	10 mL
F8762	FluoSpheres® aldehyde-sulfate microspheres, 1.0 µm, yellow-green fluorescent (505/515) *2% solids*	10 mL
F8763	FluoSpheres® amine-modified microspheres, 0.2 µm, red fluorescent (580/605) *2% solids*	5 mL
F8764	FluoSpheres® amine-modified microspheres, 0.2 µm, yellow-green fluorescent (505/515) *2% solids*	5 mL
F8765	FluoSpheres® amine-modified microspheres, 1.0 µm, yellow-green fluorescent (505/515) *2% solids*	5 mL
F8766	FluoSpheres® biotin-labeled microspheres, 0.04 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
F8767	FluoSpheres® biotin-labeled microspheres, 0.2 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
F8769	FluoSpheres® biotin-labeled microspheres, 1.0 µm, nonfluorescent *1% solids*	0.4 mL
F8768	FluoSpheres® biotin-labeled microspheres, 1.0 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
F8781	FluoSpheres® carboxylate-modified microspheres, 0.02 µm, blue fluorescent (365/415) *2% solids*	10 mL
F8782	FluoSpheres® carboxylate-modified microspheres, 0.02 µm, crimson fluorescent (625/645) *2% solids*	2 mL
F8783	FluoSpheres® carboxylate-modified microspheres, 0.02 µm, dark red fluorescent (660/680) *2% solids*	2 mL
F8784	FluoSpheres® carboxylate-modified microspheres, 0.02 µm, Nile red fluorescent (535/575) *2% solids*	10 mL
F8786	FluoSpheres® carboxylate-modified microspheres, 0.02 µm, red fluorescent (580/605) *2% solids*	10 mL
F8787	FluoSpheres® carboxylate-modified microspheres, 0.02 µm, yellow-green fluorescent (505/515) *2% solids*	10 mL
F8789	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, dark red fluorescent (660/680) *5% solids, azide free*	1 mL
F20880	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, europium luminescent (365/610) *0.5% solids*	2 mL
F8792	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, orange fluorescent (540/560) *5% solids, azide free*	1 mL
F20886	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, platinum luminescent (390/650) *0.5% solids*	2 mL
F8793	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, red fluorescent (580/605) *5% solids, azide free*	1 mL
F8794	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, red-orange fluorescent (565/580) *5% solids, azide free*	1 mL
F8795	FluoSpheres® carboxylate-modified microspheres, 0.04 µm, yellow-green fluorescent (505/515) *5% solids, azide free*	1 mL
F8797	FluoSpheres® carboxylate-modified microspheres, 0.1 µm, blue fluorescent (350/440) *2% solids*	10 mL
F8799	FluoSpheres® carboxylate-modified microspheres, 0.1 µm, infrared fluorescent (715/755) *2% solids*	1 mL
F8800	FluoSpheres® carboxylate-modified microspheres, 0.1 µm, orange fluorescent (540/560) *2% solids*	10 mL
F8801	FluoSpheres® carboxylate-modified microspheres, 0.1 µm, red fluorescent (580/605) *2% solids*	10 mL
F8803	FluoSpheres® carboxylate-modified microspheres, 0.1 µm, yellow-green fluorescent (505/515) *2% solids*	10 mL
F8805	FluoSpheres® carboxylate-modified microspheres, 0.2 µm, blue fluorescent (365/415) *2% solids*	10 mL
F8806	FluoSpheres® carboxylate-modified microspheres, 0.2 µm, crimson fluorescent (625/645) *2% solids*	2 mL

PRODUCT LIST 6.5 MICROSPHERES—continued

Cat. No.	Product	Quantity
F8807	FluoSpheres® carboxylate-modified microspheres, 0.2 µm, dark red fluorescent (660/680) *2% solids*	2 mL
F20881	FluoSpheres® carboxylate-modified microspheres, 0.2 µm, europium luminescent (365/610) *0.5% solids*	2 mL
F8809	FluoSpheres® carboxylate-modified microspheres, 0.2 µm, orange fluorescent (540/560) *2% solids*	10 mL
F8810	FluoSpheres® carboxylate-modified microspheres, 0.2 µm, red fluorescent (580/605) *2% solids*	10 mL
F8811	FluoSpheres® carboxylate-modified microspheres, 0.2 µm, yellow-green fluorescent (505/515) *2% solids*	10 mL
F8812	FluoSpheres® carboxylate-modified microspheres, 0.5 µm, red fluorescent (580/605) *2% solids*	10 mL
F8813	FluoSpheres® carboxylate-modified microspheres, 0.5 µm, yellow-green fluorescent (505/515) *2% solids*	10 mL
F8815	FluoSpheres® carboxylate-modified microspheres, 1.0 µm, blue fluorescent (350/440) *2% solids*	10 mL
F8814	FluoSpheres® carboxylate-modified microspheres, 1.0 µm, blue fluorescent (365/415) *2% solids*	10 mL
F8816	FluoSpheres® carboxylate-modified microspheres, 1.0 µm, crimson fluorescent (625/645) *2% solids*	2 mL
F8819	FluoSpheres® carboxylate-modified microspheres, 1.0 µm, Nile red fluorescent (535/575) *2% solids*	10 mL
F8820	FluoSpheres® carboxylate-modified microspheres, 1.0 µm, orange fluorescent (540/560) *2% solids*	10 mL
F8821	FluoSpheres® carboxylate-modified microspheres, 1.0 µm, red fluorescent (580/605) *2% solids*	10 mL
F8823	FluoSpheres® carboxylate-modified microspheres, 1.0 µm, yellow-green fluorescent (505/515) *2% solids*	10 mL
F8824	FluoSpheres® carboxylate-modified microspheres, 2.0 µm, blue fluorescent (365/415) *2% solids*	2 mL
F8825	FluoSpheres® carboxylate-modified microspheres, 2.0 µm, Nile red fluorescent (535/575) *2% solids*	2 mL
F8826	FluoSpheres® carboxylate-modified microspheres, 2.0 µm, red fluorescent (580/605) *2% solids*	2 mL
F8827	FluoSpheres® carboxylate-modified microspheres, 2.0 µm, yellow-green fluorescent (505/515) *2% solids*	2 mL
F20892	FluoSpheres® collagen I-labeled microspheres, 1.0 µm, yellow-green fluorescent (505/515) *0.5% solids*	0.4 mL
F20893	FluoSpheres® collagen I-labeled microspheres, 2.0 µm, yellow-green fluorescent (505/515) *0.5% solids*	0.4 mL
F10720	FluoSpheres® Fluorescent Color Kit, carboxylate-modified microspheres, 0.04 µm *four colors, 1 mL each* *5% solids, azide free*	1 kit
F20883	FluoSpheres® NeutrAvidin™ labeled microspheres, 0.04 µm, europium luminescent (365/610) *0.5% solids*	0.4 mL
F8772	FluoSpheres® NeutrAvidin™ labeled microspheres, 0.04 µm, nonfluorescent *1% solids*	0.4 mL
F8770	FluoSpheres® NeutrAvidin™ labeled microspheres, 0.04 µm, red fluorescent (580/605) *1% solids*	0.4 mL
F8771	FluoSpheres® NeutrAvidin™ labeled microspheres, 0.04 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
F20884	FluoSpheres® NeutrAvidin™ labeled microspheres, 0.2 µm, europium luminescent (365/610) *0.5% solids*	0.4 mL
F8774	FluoSpheres® NeutrAvidin™ labeled microspheres, 0.2 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
F8777	FluoSpheres® NeutrAvidin™ labeled microspheres, 1.0 µm, nonfluorescent *1% solids*	0.4 mL
F8775	FluoSpheres® NeutrAvidin™ labeled microspheres, 1.0 µm, red fluorescent (580/605) *1% solids*	0.4 mL
F8776	FluoSpheres® NeutrAvidin™ labeled microspheres, 1.0 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
F13080	FluoSpheres® polystyrene microspheres, 1.0 µm, blue-green fluorescent (430/465) *for tracer studies* *1.0x10 ¹⁰ beads/mL*	5 mL
F13082	FluoSpheres® polystyrene microspheres, 1.0 µm, orange fluorescent (540/560) *for tracer studies* *1.0x10 ¹⁰ beads/mL*	5 mL
F13083	FluoSpheres® polystyrene microspheres, 1.0 µm, red fluorescent (580/605) *for tracer studies* *1.0x10 ¹⁰ beads/mL*	5 mL
F13081	FluoSpheres® polystyrene microspheres, 1.0 µm, yellow-green fluorescent (505/515) *for tracer studies* *1.0x10 ¹⁰ beads/mL*	5 mL
F8887	FluoSpheres® Size Kit #1, carboxylate-modified microspheres, red fluorescent (580/605) *six sizes, 1 mL each* *2% solids*	1 kit
F8888	FluoSpheres® Size Kit #2, carboxylate-modified microspheres, yellow-green fluorescent (505/515) *six sizes, 1 mL each* *2% solids*	1 kit
F8780	FluoSpheres® streptavidin-labeled microspheres, 0.04 µm, yellow-green fluorescent (505/515) *0.5% solids*	0.4 mL
F8845	FluoSpheres® sulfate microspheres, 0.02 µm, yellow-green fluorescent (505/515) *2% solids*	10 mL
F8848	FluoSpheres® sulfate microspheres, 0.2 µm, yellow-green fluorescent (505/515) *2% solids*	10 mL
F8851	FluoSpheres® sulfate microspheres, 1.0 µm, red fluorescent (580/605) *2% solids*	10 mL
F8852	FluoSpheres® sulfate microspheres, 1.0 µm, yellow-green fluorescent (505/515) *2% solids*	10 mL
F8853	FluoSpheres® sulfate microspheres, 2.0 µm, yellow-green fluorescent (505/515) *2% solids*	2 mL
F8854	FluoSpheres® sulfate microspheres, 4.0 µm, blue fluorescent (365/415) *2% solids*	2 mL
F8858	FluoSpheres® sulfate microspheres, 4.0 µm, red fluorescent (580/605) *2% solids*	2 mL
F8859	FluoSpheres® sulfate microspheres, 4.0 µm, yellow-green fluorescent (505/515) *2% solids*	2 mL
T8864	TransFluoSpheres® carboxylate-modified microspheres, 0.04 µm (488/560) *2% solids*	0.5 mL
T8870	TransFluoSpheres® carboxylate-modified microspheres, 0.04 µm (633/720) *2% solids*	0.5 mL
T8872	TransFluoSpheres® carboxylate-modified microspheres, 0.1 µm (488/560) *2% solids*	0.5 mL
T8880	TransFluoSpheres® carboxylate-modified microspheres, 1.0 µm (488/560) *2% solids*	0.5 mL
T8883	TransFluoSpheres® carboxylate-modified microspheres, 1.0 µm (488/645) *2% solids*	0.5 mL
T8860	TransFluoSpheres® NeutrAvidin™ labeled microspheres, 0.04 µm (488/605) *1% solids*	0.4 mL
T8861	TransFluoSpheres® NeutrAvidin™ labeled microspheres, 0.1 µm (488/605) *1% solids*	0.4 mL
T10711	TransFluoSpheres® streptavidin-labeled microspheres, 0.04 µm (488/645) *0.5% solids*	0.4 mL

Figure 6.6.1 Structure of a Qdot® nanocrystal. A) Qdot® nanocrystals containing core and shell components only are shown in this transmission electron microscope image (200,000× magnification). B) In this schematic of the overall structure of a Qdot® nanocrystal conjugate, the layers represent the distinct structural elements and are roughly to scale.

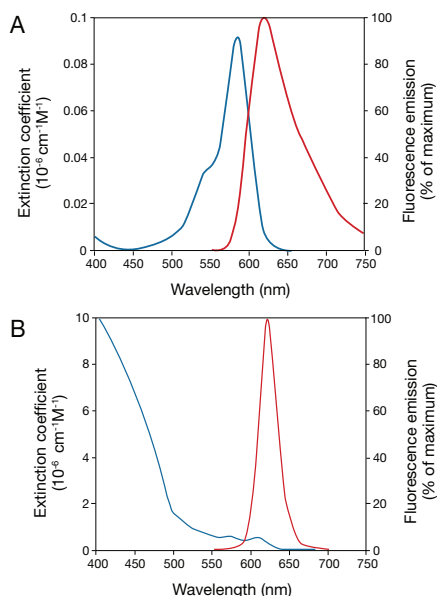

Figure 6.6.3 Absorption and fluorescence emission spectra of A) an organic dye (Alexa Fluor® 594 dye) and B) a quantum dot nanocrystal (Qdot® 625 nanocrystal). Absorption spectra are plotted in terms of molar extinction coefficient to illustrate the 100-fold larger values of this parameter typically exhibited by quantum dot nanocrystals relative to organic dyes. Comparison of the emission spectra illustrates the narrower bandwidths typical of quantum dot nanocrystals. In particular, Alexa Fluor® 594 dye exhibits significant emission intensity at wavelengths >700 nm whereas Qdot® 625 nanocrystal exhibits essentially none (note that the emission peak positions of the two fluorophores are almost identical). Overlay comparisons of Qdot® nanocrystal spectra with those of organic dyes and fluorescent proteins can be generated using our online Fluorescence SpectraViewer utility (www.invitrogen.com/handbook/spectraviewer). Note that molar extinction coefficients in $\text{cm}^{-1} \text{M}^{-1}$ have been multiplied by a constant (1×10^{-6}) for scaling purposes.

6.6 Qdot® Nanocrystals

Properties of Qdot® Nanocrystals

Structural Properties

Qdot® nanocrystals are nanometer-scale atom clusters comprising a core, shell and surface coating (Figure 6.6.1). The core is made up of a few hundred to a few thousand atoms of a semiconductor material (cadmium selenide (CdSe) or cadmium telluride (CdTe)). A semiconductor shell (typically zinc sulfide (ZnS)) surrounds and stabilizes the core, improving both the optical and physical properties of the material.

The core-shell assembly as initially prepared is extremely hydrophobic. An amphiphilic polymer coating is then applied, serving two purposes. Firstly, it incorporates ionizable functional groups that confer water solubility essential for bioanalytical applications. Secondly, it provides a platform for covalent functionalization of the Qdot® nanocrystal with antibodies, streptavidin, oligonucleotides and other affinity reagents (denoted as “biomolecule” in Figure 6.6.1) that confer targeting specificity for biomolecular detection. As depicted in Figure 6.6.1, Qdot® nanocrystal conjugates typically incorporate multiple copies of the affinity reagent—the inverse of the situation encountered in dye-labeled conjugates in which multiple dyes are attached to a single affinity reagent.

In most of our Qdot® nanocrystal conjugates, the affinity reagent is coupled to the amphiphilic polymer coating via a functionalized polyethylene glycol (PEG) linker. PEG linkers have been shown to reduce nonspecific binding in flow cytometry¹ and imaging assays,² thereby improving signal-to-noise ratios. Qdot® primary and secondary antibody conjugates, Qdot® streptavidin conjugates, Qtracker® non-targeted quantum dots, and Qdot® ITK™ amino (PEG) quantum dots, as well as the reactive nanocrystals provided in the Qdot® Antibody Conjugation Kits, all utilize this PEG linker chemistry.

The overall size of functionalized Qdot® nanocrystals, in a spherical approximation, is around 20 nm in diameter (Figure 6.6.2). This is much larger than an organic dye and comparable to the size of a large (molecular weight >500 kDa) protein or our smallest FluoSpheres® fluorescent microspheres (Section 6.5). The novel physical properties of Qdot® nanocrystals coupled to the fact that they contain cadmium³ gives rise to concerns regarding toxicity in applications involving live cells or *in vivo* administration. These concerns have prompted much investigation.^{3–5} It is difficult to draw general conclusions from these studies due to the influence of the cellular, tissue or animal context on the results. Toxicity concerns, however, are generally mitigated by the extraordinarily high fluorescence output of Qdot® nanocrystals, which enables the use of very low (often nanomolar) working concentrations. The extent to which the size of Qdot® nanocrystals may cause perturbations of molecular interactions has also been subjected to detailed scrutiny.⁶

Figure 6.6.2 Relative size of Qdot® nanocrystals.

Spectroscopic Properties

Although Qdot® nanocrystals are composed of semiconductor materials, their small size results in spectroscopic properties that are radically different from those of bulk semiconductors. Absorption of a photon causes an electron to move from the semiconductor valence band to the conduction band, creating an exciton (electron-hole pair). Absorption occurs as long as the energy of the incident photons is higher than the semiconductor bandgap energy; thus, excitons can be created over a wide range of energies within the nanocrystal core. The higher-energy excitons relax to the lowest bandgap energy before they recombine and emit a photon. Therefore, the wavelength range of the absorption spectrum is broad, whereas that of the emission spectrum is narrow (Figure 6.6.3, Figure 6.6.4, Figure 6.6.5).

Due to the small size of the nanocrystal, the electron-hole separation is confined to be smaller than the Bohr radius of the semiconductor. As the nanocrystal core is made progressively smaller, more energy is required to confine the exciton, and the energy of the emitted photons increases. Therefore, smaller nanocrystals exhibit shorter-wavelength emission. By controlled variation of the core size, we have developed a range of nanocrystals with distinctively different emission spectral characteristics (Figure 6.6.5) but largely overlapping absorption spectra (Figure 6.6.4) and generally similar physical properties. Currently, we offer eight Qdot® nanocrystal types identified by 3-digit numerals representing the peak emission wavelength in nanometers (e.g., Qdot® 655 nanocrystal, emission peak = 655 nm).

The spectral characteristics of Qdot® nanocrystals offer some distinctive advantages over those of organic dyes and fluorescent proteins,⁷ particularly with regard to implementation of spectral multiplex detection schemes. The broad absorption spectra facilitate single-source (e.g., 405 nm) excitation of multiple Qdot® nanocrystal types. Furthermore, Qdot® nanocrystals lack the ubiquitous red-edge “tail” of organic dye and fluorescent protein emission spectra (Figure 6.6.3), reducing the likelihood of detection channel crosstalk. Qdot® nanocrystals have been extensively characterized and utilized as donors in fluorescence resonance energy transfer (FRET) assays (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2) of molecular proximity.^{8–11} Their utility as FRET acceptors is limited by their absorption spectral characteristics (Figure 6.6.4), making it difficult to avoid direct, proximity-independent fluorescence excitation. However, they work well as acceptors from lanthanide chelate donors in time-resolved FRET (TR-FRET) assays, in which fluorescence originating from direct excitation is eliminated by time-gating of the detection system.^{12,13}

Another distinctive property of Qdot® nanocrystals relative to organic dyes and fluorescent proteins is their prodigious fluorescence output, which principally derives from their extraordinarily large extinction coefficients for absorption (Table 6.10, Figure 6.6.3). Organic dye and fluorescent protein extinction coefficients do not often exceed $10^5 \text{ cm}^{-1}\text{M}^{-1}$, whereas those of Qdot® nanocrystals are often $>10^6 \text{ cm}^{-1}\text{M}^{-1}$, particularly in the blue visible and ultraviolet wavelength regions (Figure 6.6.3, Figure 6.6.4). Because their fluorescence quantum yields are high and comparable to those of organic dyes and fluorescent proteins,¹⁴ the large capacity for photon absorption represented by the extinction coefficient is propagated into emission of fluorescence photons. The fluorescence lifetimes of Qdot® nanocrystals are typically in the 10–30 nanosecond range as compared to 1–10 nanoseconds for most organic dyes.⁸ They also have very large two-photon absorption cross-sections,¹⁵ resulting

Figure 6.6.4 Absorption spectra of Qdot® nanocrystals plotted in terms of molar extinction coefficient.

Figure 6.6.5 Normalized fluorescence emission spectra of Qdot® nanocrystals: 1) Qdot® 525, 2) Qdot® 565, 3) Qdot® 585, 4) Qdot® 605, 5) Qdot® 625, 6) Qdot® 655, 7) Qdot® 705, 8) Qdot® 800 nanocrystals.

Table 6.10 Extinction coefficients of Qdot® nanocrystal streptavidin conjugates at ultraviolet and visible wavelengths.

Product	Extinction Coefficient (EC) *			
	350 nm	405 nm	488 nm	532 nm
Qdot® 525 nanocrystals	710,000	360,000	130,000	NA
Qdot® 565 nanocrystals	1,900,000	1,100,000	290,000	139,000
Qdot® 585 nanocrystals	3,500,000	2,200,000	530,000	305,000
Qdot® 605 nanocrystals	4,400,000	2,800,000	1,100,000	580,000
Qdot® 625 nanocrystals	14,700,000	9,900,000	2,700,000	870,000
Qdot® 655 nanocrystals	9,100,000	5,700,000	2,900,000	2,400,000
Qdot® 705 nanocrystals	12,900,000	8,300,000	3,000,000	2,100,000
Qdot® 800 nanocrystals	15,800,000	10,600,000	4,100,000	2,100,000

* Molar extinction coefficient in $\text{cm}^{-1}\text{M}^{-1}$ determined at the corresponding wavelength. NA = Not applicable.

in exceptional performance in two-photon excitation microscopy applications^{8,16,17} (Fluorescent Probes for Two-Photon Microscopy—Note 1.5). Qdot® nanocrystals are much less susceptible to photobleaching than organic dyes and fluorescent proteins.^{18,19} This feature is particularly beneficial in protocols involving repeated image captures on a single field of view such as confocal z-stack²⁰ or longitudinal time-lapse acquisitions.

Furthermore, Qdot® nanocrystals exhibit fluorescence intermittency, commonly referred to as blinking, whereby continuously excited single fluorophores will spontaneously alternate between emitting and non-emitting states across timescales from milliseconds to many seconds.^{21–24} By its nature, blinking does not significantly impact ensemble measurements. Instead, it is most readily observable in single molecule detection trajectories where the binary nature of the “on” and “off” emission levels provides a useful confirmatory indication that the signals represent single fluorophores rather than clustered multiples.

Qdot® nanocrystals are intrinsically electron dense due to the tightly packed atomic lattice of the core–shell assembly, making them directly detectable by electron microscopy (EM).²⁵ They can therefore be used as dual-mode contrast agents for correlated fluorescence and EM without the diaminobenzidine photoconversion and subsequent osmification processing steps required for EM level visualization of organic dyes^{26,27} (Fluorescent Probes for Photoconversion of Diaminobenzidine Reagents—Note 14.2). Furthermore, particle size and shape differences can be used as identifying characteristics in EM in the same way that emission spectra are used in fluorescence microscopy.²⁶

Since the first reported applications of quantum dot nanocrystals for biomolecular detection in 1998,^{28,29} many reviews have been published that may be consulted for further information on their properties and applications, both actual and prospective.^{30–33}

Qdot® Nanocrystal Products and Applications

Qdot® Streptavidin Conjugates

Streptavidin conjugates provide access to a wide range of biomolecular functionality via high-affinity avidin–biotin coupling (Chapter 4), making them perhaps the most versatile subset in our range of Qdot® nanocrystal labeling reagents:

- Qdot® 525 streptavidin conjugate (Q10141MP)
- Qdot® 565 streptavidin conjugate (Q10131MP)
- Qdot® 585 streptavidin conjugate (Q10111MP)
- Qdot® 605 streptavidin conjugate (Q10101MP)
- Qdot® 625 streptavidin conjugate (A10196)
- Qdot® 655 streptavidin conjugate (Q10121MP)
- Qdot® 705 streptavidin conjugate (Q10161MP)
- Qdot® 800 streptavidin conjugate (Q10171MP)
- Qdot® Streptavidin Sampler Kit *1 μM solutions* (Q10151MP)

For example, nucleic acid hybridization can be detected by complexation of terminally biotinylated oligonucleotides with Qdot® streptavidin conjugates^{34–37} (Figure 6.6.6). Qdot® streptavidin conjugates in combination with biotinylated antibodies provide increased multiplexing capacity for immunodetection of proteins on both imaging^{38–42} and flow cytometry^{1,43} platforms. Single-particle tracking of molecular motion is a particularly compelling application of Qdot® streptavidin conjugates that takes advantage of their extraordinary fluorescence output capacity.⁴⁴ The principal subjects for these measurements are cell-surface receptors^{44–50} and molecular motors such as myosin.^{51,52} Single-molecule detection uncovers details of molecular

Figure 6.6.6 Multiplex mRNA *in situ* hybridization and immunofluorescence localization of tyrosine hydroxylase in mouse brain using Qdot® 525 and Qdot® 605 streptavidin conjugates (Q10141MP, Q10101MP). A) Vmat2 mRNA-positive neurons in substantia nigra were probed with a biotinylated oligonucleotide and labeled with Qdot® 525 streptavidin conjugate. B) The same cell was labeled with anti-tyrosine hydroxylase (TH) antibody in conjunction with biotinylated secondary antibody and Qdot® 605 streptavidin conjugate. The Vmat2 mRNA signal is restricted to the cytoplasm, whereas the labeling of TH is extended to the whole cell body and processes (arrow). C) Cell nuclei were labeled with DAPI. D) Overlay of all three stained images shows the different subcellular distributions of Vmat2 mRNA and TH immunoreactivity. Scale bar = 15 μm. Images contributed by Stuart Sealfon, Mount Sinai School of Medicine, and reprinted with permission from *Nucleic Acids Res* (2005) 33:e161.

Figure 6.6.7 Multicolor immunofluorescence imaging with Qdot® secondary antibody conjugates. Actin in a mouse intestine section was detected with mouse anti-actin antibody and Qdot® 655 goat F(ab')₂ anti-mouse IgG antibody (red; Q11021MP, Q11022MP), laminin was detected with rabbit anti-laminin antibody and Qdot® 525 goat F(ab')₂ anti-rabbit IgG antibody (green, Q11441MP), and nuclei were stained with Hoechst 33342 (blue). Image contributed by Thomas Deerinck and Mark Ellisman, The National Center for Microscopy and Imaging Research, San Diego, California, USA.

Figure 6.6.8 Multicolor immunofluorescence imaging with Qdot® secondary antibody conjugates. Laminin in a mouse kidney section was labeled with a rabbit anti-laminin primary antibody and visualized using green-fluorescent Qdot® 565 F(ab')₂ anti-rabbit IgG secondary antibody (Q11431MP, Q11432MP). PECAM-1 (platelet/endothelial cell adhesion molecule-1, CD31) was labeled with a rat anti-PECAM-1 primary antibody and visualized using red-fluorescent Qdot® 655 F(ab')₂ anti-rat IgG secondary antibody (Q11621MP). Nuclei were counterstained with blue-fluorescent Hoechst 33342. Image contributed by Stuart Shand, Center for Biologic Imaging, University of Pittsburgh.

motion and assembly that are obscured by the averaging effects of bulk measurements. Qdot® nanocrystals are quite essential in such applications as fluorescence photon output ultimately propagates into the spatial and temporal resolution of the measurements. Typically, labeling is accomplished using biotinylated ligands such as biotin EGF (E3477, Section 4.3) and biotin-XX α -bungartoxin (B1196, Section 4.3) to couple Qdot® streptavidin conjugates to the receptor of interest. Because these conjugates incorporate multiple streptavidins (typically 5–10 per Qdot® nanocrystal), careful attention must be paid to the streptavidin:ligand stoichiometry to avoid receptor crosslinking mediated by the Qdot® streptavidin–biotinylated ligand complex.^{49,53} A molar excess of Qdot® streptavidin conjugate over the biotinylated ligand biases the complex stoichiometry towards the desired outcome of one ligand per nanocrystal. Qdot® streptavidin conjugates are supplied as 1 μ M solutions in 50 mM borate, pH 8.3 containing 0.05% sodium azide and 1 M betaine cryoprotectant in 200 μ L units. The Qdot® Streptavidin Sampler Kit (Q10151MP) provides 50 μ L units of six different Qdot® streptavidin conjugates in a single package.

We also offer Qdot® ITK™ streptavidin quantum dots, in which streptavidin is directly attached to the inner amphiphilic coating without a PEG linker:

- Qdot® 525 ITK™ Streptavidin Conjugate Kit (Q10041MP)
- Qdot® 565 ITK™ Streptavidin Conjugate Kit (Q10031MP)
- Qdot® 585 ITK™ Streptavidin Conjugate Kit (Q10011MP)
- Qdot® 605 ITK™ Streptavidin Conjugate Kit (Q10001MP)
- Qdot® 655 ITK™ Streptavidin Conjugate Kit (Q10021MP)
- Qdot® 705 ITK™ Streptavidin Conjugate Kit (Q10061MP)
- Qdot® 800 ITK™ Streptavidin Conjugate Kit (Q10071MP)

This formulation results in a smaller overall particle size and an increase in the number of streptavidins per nanocrystal relative to PEG-linked conjugates. These characteristics are advantageous in fluorescence resonance energy transfer (FRET) assays for detecting hybridization of target nucleic acid sequences to biotinylated oligonucleotides captured on the Qdot® nanocrystal surface.^{11,54,55} Qdot® ITK™ streptavidin conjugates are supplied in 250 μ L units of 2 μ M solution in kits that also provide Qdot® incubation buffer (50 mM borate buffer, pH 8.3, containing 2% BSA and 0.05% sodium azide). Qdot® incubation buffer is also available in separately packaged 30 mL units (Q20001MP).

Biotinylated Qdot® Nanocrystals

The Qdot® 605 and Qdot® 655 Biotin Conjugate Kits (Q10301MP, Q10321MP) provide Qdot® nanocrystals that have been functionalized with biotin on their surface via carbodiimide-mediated coupling. The resulting conjugates typically incorporate 5–7 biotin groups per Qdot® nanocrystal. In addition to biotinylated Qdot® nanocrystals, these kits also provide Qdot® incubation buffer, which is formulated specifically to achieve improved signal-to-noise ratios in immunohistochemical applications. Biotinylated Qdot® nanocrystals have been used alongside biotinylated microspheres for analysis of the effects of fluorescent label size on ligand–receptor binding dynamics and equilibria by fluorescence correlation spectroscopy⁶ (Fluorescence Correlation Spectroscopy (FCS)—Note 1.3).

WesternDot™ Western Blot Kits

The WesternDot™ 625 Goat Anti-Mouse and Goat Anti-Rabbit Western Blot Kits (W10132, W10142) provide Qdot® nanocrystal secondary reagents for the detection of subnanogram amounts of protein on western blots without the complications of time-dependent signal development imposed by enzyme-amplified chemiluminescence detection systems. These kits provide Qdot® 625 streptavidin conjugates and biotinylated secondary antibodies for use in combination with user-supplied mouse or rabbit primary antibodies against the protein of interest. In other respects, immunodetection of proteins immobilized on nitrocellulose (NC) or polyvinylidene difluoride (PVDF) membranes follows standard western blotting protocols. Detection of the fluorescence signal can be accomplished using standard UV- or blue light-based gel and blot imaging systems and does not require specialized emission filters.

Qdot® Secondary Antibody Conjugates

Qdot® secondary antibody conjugates (Table 6.11) combine the spectral characteristics of Qdot® nanocrystals with the selective binding of F(ab')₂ fragments from affinity-purified secondary antibodies, enabling a wide range of immunocytochemical and immunohistochemical applications^{56,57} (Figure 6.6.7, Figure 6.6.8). Some examples include immunolabeling of GABA_A receptor α 1 and γ 2 subunits for colocalization analysis in HEK 293 cells⁵⁸ and immunodetection of EGFR, E-cadherin and cytokeratin on formalin-fixed, paraffin-embedded (FFPE) tissue array slides.⁵⁹

Table 6.11 Qdot® nanocrystal secondary antibody conjugates.

Antibody	Host	Qdot® 525	Qdot® 565	Qdot® 585	Qdot® 605	Qdot® 625	Qdot® 655	Qdot® 705	Qdot® 800

Anti-human IgG	Goat				Q11201MP		Q11221MP		
Anti-chicken IgY	Goat						Q14421MP		
Anti-goat IgG	Rabbit						Q11821MP		

All Qdot® nanocrystal secondary antibody conjugates are prepared from affinity-purified F(ab')₂ fragments and are supplied as 1 μ M solutions in 200 μ L units unless specified otherwise (* denotes 100 μ L units).

Figure 6.6.9 Antigen detection in human peripheral blood lymphocytes. Cells were incubated with **A**) Qdot® 655 mouse anti-human CD3 antibody (Q10012) or **B**) Qdot® 605 mouse anti-human CD4 antibody (Q10008). Samples were then subjected to flow cytometric analysis using LSR II flow cytometers and FACSDiva software (BD Biosciences) or FlowJo software (Tree Star, Inc.). The gray overlay peaks represent a sample of unstained cells.

Qmount® Qdot® Mounting Media

Qmount® Qdot® mounting media (Q10336) is a specialized mountant that preserves the fluorescence signal of Qdot® nanocrystals with little to no quenching of the initial signal intensity. The formulation cures within 12 hours and is provided in a convenient and easy-to-use dropper bottle. This mounting medium offers excellent compatibility with Qdot® secondary antibody and streptavidin conjugates in immunocytochemical and immunohistochemical detection applications, as well with Qnuclear™ Deep Red stain (Q10363, Section 12.5), which is the recommended nuclear counterstain for these applications.

Anti-Human CD Antibodies

Immunophenotyping of leukocytes based on expression of cell-surface CD (cluster of differentiation) markers is a mainstream flow cytometry application in both clinical and research settings.⁶⁰ Our Qdot® nanocrystal-conjugated mouse monoclonal anti-human CD antibodies (Table 6.12) bring extended multiplexing capacity and unmatched fluorescence output to enhance conventional leukocyte immunophenotyping protocols⁶¹ (Figure 6.6.9). The large selection of Invitrogen™ anti-human CD antibodies labeled with Alexa Fluor® dyes, phycobiliproteins and phycobiliprotein tandem fluorophores⁶² can be surveyed using our online primary antibody search utility at www.invitrogen.com/handbook/antibodies.

Qdot® Antibody Conjugation Kits

Qdot® Antibody Conjugation Kits provide reagents and protocols for researchers to prepare Qdot® nanocrystal conjugates of independently sourced antibodies:

- Qdot® 525 Antibody Conjugation Kit (Q22041MP)
- Qdot® 565 Antibody Conjugation Kit (Q22031MP)
- Qdot® 585 Antibody Conjugation Kit (Q22011MP)
- Qdot® 605 Antibody Conjugation Kit (Q22001MP)
- Qdot® 625 Antibody Conjugation Kit (A10197)
- Qdot® 655 Antibody Conjugation Kit (Q22021MP)
- Qdot® 705 Antibody Conjugation Kit (Q22061MP)
- Qdot® 800 Antibody Conjugation Kit (Q22071MP)

The conjugation reaction involves reduction of antibody interchain disulfides followed by coupling of the resulting free thiols to amine-derivatized, PEG-coated Qdot® nanocrystals via the heterobifunctional crosslinker SMCC (S1534, Section 5.2). Primary antibodies labeled using these methods have demonstrated utility in applications as diverse as multiplexed immunodetection of

biomarkers in formalin-fixed, paraffin-embedded (FFPE) tissue sections^{41,63} and *in vivo* imaging of HER2-positive tumors in mice.⁶⁴

Other Qdot® Nanocrystal Conjugates

We offer Qdot® 565 and Qdot® 655 conjugates of goat anti-fluorescein antibody and a Qdot® 655 conjugate of rat anti-dinitrophenol (anti-DNP) antibody, which complement the Alexa Fluor® dye-labeled conjugates described in Section 7.4:

- Qdot® 565 goat anti-fluorescein conjugate (Q15431MP)
- Qdot® 655 goat anti-fluorescein conjugate (Q15421MP)
- Qdot® 655 rat anti-dinitrophenol conjugate (Q17421MP)

Fluorescein and DNP are excellent affinity tags that can be recognized by labeled primary antibodies, providing an alternative to the traditional biotin–streptavidin system in applications such as *in situ* hybridization,⁶⁵ enzyme-linked immunosorbent assays (ELISA) and western blot analysis. T

The Qdot® 655 wheat germ agglutinin (WGA) conjugate (Q12021MP) extends our selection of dye-labeled WGA conjugates (Section 7.7) for labeling of *N*-acetylglucosamine and *N*-acetylneuraminic acid (sialic acid) residues of glycoproteins on cell surfaces.⁵⁸ WGA conjugates are also useful for labeling of bacterial cell wall peptidoglycans, chitin and cartilage glycosaminoglycans.

Qtracker® Cell Labeling Kits

Qtracker® Cell Labeling Kits provide Qdot® nanocrystals that have been functionalized on their surface with polyarginine peptides to facilitate spontaneous uptake by live cells.⁶⁶

- Qtracker® 525 Cell Labeling Kit (Q25041MP)
- Qtracker® 565 Cell Labeling Kit (Q25031MP)
- Qtracker® 585 Cell Labeling Kit (Q25011MP)
- Qtracker® 605 Cell Labeling Kit (Q25001MP)
- Qtracker® 625 Cell Labeling Kit (A10198)
- Qtracker® 655 Cell Labeling Kit (Q25021MP)
- Qtracker® 705 Cell Labeling Kit (Q25061MP)
- Qtracker® 800 Cell Labeling Kit (Q25071MP)

Figure 6.6.10 Distribution of Qdot® nanocrystals in cytoplasmic vesicles after labeling cells with the Qtracker® 655 Cell Labeling Kit (Q25021MP). HeLa cells were labeled with the Qtracker® 655 Cell Labeling Kit and then observed using a Leica TCS SP2 confocal microscope (excitation at 488 nm). This representative image shows the Qdot® nanocrystals distributed in vesicles throughout the cytoplasm.

The mechanism whereby such cell-penetrating peptides induce the cellular uptake of cargoes—including oligonucleotides and proteins as well as Qdot® nanocrystals—remains a topic of active investigation and considerable debate.^{67,68} However, it is reasonably well established that the uptake is passive and does not require specific receptors or active transport processes. Therefore, labeling of live cells is a simple matter of adding the Qtracker® cell labeling reagents supplied in the kits to adherent or suspension cells in complete growth medium, incubating at 37°C for 45–60 minutes, followed by a wash step to remove the unincorporated labeling reagents. The Qdot® nanocrystals are stably incorporated in cytoplasmic vesicles (Figure 6.6.10) and are passed to daughter cells upon cell division but are not transferred to adjacent cells in mixed cultures or host tissues. Fluorescence is not impacted by complex and varying cellular environments such as changes in intracellular pH, temperature and metabolic activity. A wide range of applications for Qtracker® Cell Labeling Kits have been reported, including fiducial marking of cell populations for identification during or after downstream analysis,^{66,69} labeling of mouse cerebral vascular tissue for visualization of explantation,⁷⁰ imaging the assembly of cultured pulmonary artery adventitial fibroblasts and endothelial cells into three-dimensional structures⁷¹ and tracking embryonic and mesenchymal stem cells.^{72–74}

Qtracker® Non-Targeted Quantum Dots

Qtracker® non-targeted quantum dots are designed for small animal *in vivo* imaging, and especially for studying vascular structure after microinjection^{75,76} (Figure 6.6.11). Our selection of Qtracker® non-targeted quantum dots includes:

- Qtracker® 565 non-targeted quantum dots (Q21031MP)
- Qtracker® 655 non-targeted quantum dots (Q21021MP)
- Qtracker® 705 non-targeted quantum dots (Q21061MP)
- Qtracker® 800 non-targeted quantum dots (Q21071MP)

These nanocrystals exhibit intense red or near-infrared fluorescence emission, enabling maximum transmission through tissues while avoiding interference from background autofluorescence. Qtracker®

Figure 6.6.11 Chick embryo injected through the major vitelline vein with Qtracker® non-targeted quantum dots. Following a few minutes of circulation of the Qtracker® 705 non-targeted quantum dots (Q21061MP), fluorescence images of the embryo were captured at increasing magnification using 460 nm excitation and a digital imaging system equipped with appropriate emission filters. These Qtracker® reagents revealed highly detailed vascular structure at all levels of magnification. Images contributed by Greg Fisher, Carnegie Mellon University.

non-targeted quantum dots have polyethylene glycol (PEG) surface coatings to minimize nonspecific binding interactions and associated inflammatory responses.^{77,78} Because the PEG surface coating does not contain reactive functional groups, the Qtracker® non-targeted quantum dots are retained in circulation longer and can be imaged for up to 3 months without additional injections.⁷⁹ Qtracker® non-targeted quantum dots are supplied as 2 μM solutions in 50 mM borate buffer, pH 8.3 in units of 200 μL .

Qdot® ITK™ Quantum Dots

ITK™ (Innovator's Tool Kit) quantum dots enable researchers to equip Qdot® nanocrystals with customized functionalities by means of surface derivatization (Figure 6.6.12). Qdot® ITK™ quantum dots are available with three different surface chemistries—carboxyl groups, amino (PEG) groups and aliphatic hydrocarbon—and up to nine different fluorescent colors (525, 545, 565, 585, 605, 625, 655, 705 or 800 nm emission).

Qdot® ITK™ carboxyl quantum dots have a carboxyl-derivatized amphiphilic coating and can be coupled to amine groups of proteins and modified oligonucleotides in aqueous solution using EDAC-mediated condensation^{55,80,81} (Section 3.4). Our Qdot® ITK™ carboxyl quantum dots are provided as 8 μM solutions and include:

- Qdot® 525 ITK™ carboxyl quantum dots (Q21341MP)
- Qdot® 545 ITK™ carboxyl quantum dots (Q21391MP)
- Qdot® 565 ITK™ carboxyl quantum dots (Q21331MP)
- Qdot® 585 ITK™ carboxyl quantum dots (Q21311MP)
- Qdot® 605 ITK™ carboxyl quantum dots (Q21301MP)
- Qdot® 625 ITK™ carboxyl quantum dots (A10200)
- Qdot® 655 ITK™ carboxyl quantum dots (Q21321MP)
- Qdot® 705 ITK™ carboxyl quantum dots (Q21361MP)
- Qdot® 800 ITK™ carboxyl quantum dots (Q21371MP)

Qdot® ITK™ amino (PEG) quantum dots have amine-derivatized PEG covalently attached to the amphiphilic inner coating and react efficiently with succinimidyl ester derivatives and other amine-reactive compounds.^{68,82} Our Qdot® ITK™ amino (PEG) quantum dots are provided as 8 μM solutions and include:

- Qdot® 525 ITK™ amino (PEG) quantum dots (Q21541MP)
- Qdot® 545 ITK™ amino (PEG) quantum dots (Q21591MP)
- Qdot® 565 ITK™ amino (PEG) quantum dots (Q21531MP)
- Qdot® 585 ITK™ amino (PEG) quantum dots (Q21511MP)
- Qdot® 605 ITK™ amino (PEG) quantum dots (Q21501MP)
- Qdot® 655 ITK™ amino (PEG) quantum dots (Q21521MP)
- Qdot® 705 ITK™ amino (PEG) quantum dots (Q21561MP)
- Qdot® 800 ITK™ amino (PEG) quantum dots (Q21571MP)

Qdot® ITK™ organic quantum dots have an aliphatic hydrocarbon surface coating instead of an amphiphilic polymer coating. They are provided as a suspension in decane and are specifically designed for applications requiring organic solvents. Our Qdot® ITK™ organic quantum dots are provided as 1 μM solutions and include:

- Qdot® 545 ITK™ organic quantum dots (Q21791MP)
- Qdot® 565 ITK™ organic quantum dots (Q21731MP)
- Qdot® 585 ITK™ organic quantum dots (Q21711MP)
- Qdot® 605 ITK™ organic quantum dots (Q21701MP)
- Qdot® 655 ITK™ organic quantum dots (Q21721MP)
- Qdot® 705 ITK™ organic quantum dots (Q21761MP)
- Qdot® 800 ITK™ organic quantum dots (Q21771MP)

Note: With the carboxyl material, there is typically no linker present between the protein and the nanocrystal after coupling.

Figure 6.6.12 Coupling of Qdot® ITK™ quantum dots. Qdot® ITK™ amino (PEG) quantum dots can be coupled to biomolecules using amine-reactive crosslinking chemistries. Qdot® ITK™ carboxyl quantum dots can be coupled to amine-containing biomolecules by amide linkages generated by EDAC-mediated condensation.

PRODUCT LIST 6.6 QDOT® NANOCRYSTALS

Cat. No.	Product	Quantity
Q10172	CD2, mouse anti-human, Qdot® 605 conjugate (clone S5.5) *1 µM solution*	100 µL
Q10054	CD3, mouse anti-human, Qdot® 605 conjugate (clone UCHT1) *1 µM solution*	100 µL
Q10012	CD3, mouse anti-human, Qdot® 655 conjugate (clone S4.1) *1 µM solution*	100 µL
Q10008	CD4, mouse anti-human, Qdot® 605 conjugate (clone S3.5) *1 µM solution*	100 µL
Q10007	CD4, mouse anti-human, Qdot® 655 conjugate (clone S3.5) *1 µM solution*	100 µL
Q10060	CD4, mouse anti-human, Qdot® 705 conjugate (clone S3.5) *1 µM solution*	100 µL
Q10152	CD8, mouse anti-human, Qdot® 565 conjugate (clone 3B5) *1 µM solution*	100 µL
Q10009	CD8, mouse anti-human, Qdot® 605 conjugate (clone 3B5) *1 µM solution*	100 µL
Q10055	CD8, mouse anti-human, Qdot® 655 conjugate (clone 3B5) *1 µM solution*	100 µL
Q10059	CD8, mouse anti-human, Qdot® 705 conjugate (clone 3B5) *1 µM solution*	100 µL
Q10153	CD10, mouse anti-human, Qdot® 605 conjugate (clone MEM-78) *2 µM solution*	100 µL
Q10154	CD10, mouse anti-human, Qdot® 800 conjugate (clone MEM-78) *1 µM solution*	100 µL
Q10013	CD14, mouse anti-human, Qdot® 605 conjugate (clone Tük4) *2 µM solution*	100 µL
Q10056	CD14, mouse anti-human, Qdot® 655 conjugate (clone Tük4) *1 µM solution*	100 µL
Q10064	CD14, mouse anti-human, Qdot® 800 conjugate (clone Tük4) *1 µM solution*	100 µL
Q10306	CD19, mouse anti-human, Qdot® 605 conjugate (clone SJ25-C1) *1 µM solution*	100 µL
Q10179	CD19, mouse anti-human, Qdot® 655 conjugate (clone SJ25-C1) *1 µM solution*	100 µL
Q10305	CD20, mouse anti-human, Qdot® 655 conjugate (clone HI47) *1 µM solution*	100 µL
Q10065	CD27, mouse anti-human, Qdot® 605 conjugate (clone CLB-27/1) *2 µM solution*	100 µL
Q10066	CD27, mouse anti-human, Qdot® 655 conjugate (clone CLB-27/1) *2 µM solution*	100 µL
Q10053	CD38, mouse anti-human, Qdot® 605 conjugate (clone HIT2) *2 µM solution*	100 µL
Q10057	CD38, mouse anti-human, Qdot® 655 conjugate (clone HIT2) *2 µM solution*	100 µL
Q10051	CD45, mouse anti-human, Qdot® 605 conjugate (clone HI30) *1 µM solution*	100 µL
Q10062	CD45, mouse anti-human, Qdot® 705 conjugate (clone HI30) *1 µM solution*	100 µL
Q10156	CD45, mouse anti-human, Qdot® 800 conjugate (clone HI30) *1 µM solution*	100 µL
Q10047	CD45RA, mouse anti-human, Qdot® 605 conjugate (clone MEM-56) *1 µM solution*	100 µL
Q10069	CD45RA, mouse anti-human, Qdot® 655 conjugate (clone MEM-56) *1 µM solution*	100 µL
Q10307	CD56, mouse anti-human, Qdot® 605 conjugate (clone MEM-188) *2 µM solution*	100 µL
Q10052	HLA-DR, mouse anti-human, Qdot® 605 conjugate (clone Tu36) *1 µM solution*	100 µL
Q10063	HLA-DR, mouse anti-human, Qdot® 800 conjugate (clone Tu36) *1 µM solution*	100 µL
Q10073	Mouse IgG ₁ , Qdot® 605 conjugate (isotype control) *1 µM solution*	100 µL
Q10298	Mouse IgG ₁ , Qdot® 800 conjugate (isotype control) *1 µM solution*	100 µL
Q10014	Mouse IgG _{2a} , Qdot® 605 conjugate (isotype control) *1 µM solution*	100 µL
Q10015	Mouse IgG _{2a} , Qdot® 655 conjugate (isotype control) *1 µM solution*	100 µL

SYTOX® Orange, Alexa Fluor® 488 phalloidin and Alexa Fluor® 350 concanavalin A.

7.1 Introduction to Antibodies, Avidins and Lectins

This chapter describes Molecular Probes® affinity reagents for protein detection. These reagents are primarily conjugated and unconjugated antibodies, augmented by avidin and streptavidin conjugates for detecting biotinylated proteins and lectin conjugates for detecting glycoproteins. Collectively, they represent the combination of our premium fluorophores with our bioconjugation expertise to produce an unsurpassed range of products for histochemical and cytochemical analysis.

Despite the advent of competing approaches such as recombinant peptide tagging and mass spectrometry, antibody-based detection remains the most broadly applicable means of localizing and quantitating specific proteins in complex samples.¹⁻³ Although the primary emphasis is on proteins, some of these reagents, particularly avidin and streptavidin conjugates, have important applications for the detection of nucleic acids^{4,5} and other biomolecules. Non-antibody based approaches for protein detection are discussed in Chapter 9. Within this chapter, Molecular Probes® affinity reagents for protein detection are subdivided as described below.

Secondary Immunoreagents—Section 7.2

Labeled secondary antibodies form stable and specific complexes with unlabeled primary antibodies (Figure 7.1.1), providing the foundation for most immunofluorescence microscopy protocols. Molecular Probes® secondary antibody offering provides an extensive selection of labels that include our superior Alexa Fluor® dyes, phycobiliproteins, Alexa Fluor® dye–phycobiliprotein tandem fluorophores, Qdot® nanocrystals, biotin and enzyme labels (horseradish peroxidase and alkaline phosphatase). We also offer many options in terms of immunoreactivity, an essential consideration in avoiding confounding cross-reactivity when performing simultaneous secondary immunodetection of two or more targets.⁶⁻⁸ Our labeled secondary antibody portfolio includes antibodies against IgG and IgM from several mammalian species, including various isotypes of mouse IgG, as well as against avian (chicken) IgY.

Zenon® Technology: Versatile Reagents for Immunolabeling—Section 7.3

Molecular Probes® Zenon® antibody labeling technology uses reagents that are technically secondary antibody conjugates in rapid immunolabeling protocols that would normally require preparation or purchase of directly labeled primary antibodies. Rapid processing enabled by elimination of the secondary reagent incubation step in conventional immunolabeling protocols is vital when identifying cells for mRNA extraction and downstream genomic analysis.⁹ Elimination of the secondary reagent incubation step also enables the use of multiple antibodies derived from the same species in the same immunolabeling protocol.^{10,11}

Anti-Dye and Anti-Hapten Antibodies—Section 7.4

Antibodies to fluorophores and other nonfluorescent labels provide unique opportunities for signal enhancement and for correlated fluorescence and electron microscopy studies.¹² For example, transplanted cells labeled with fluorescein-based tracers such as CFSE (C1157, V12883; Section 14.2) can be immunohistochemically detected using our anti-fluorescein/Oregon Green® antibodies in situations where the fluorescein fluorescence signal is undetectable due to cellular dissemination *in vivo*.¹³⁻¹⁵ Dye/anti-dye antibody affinity pairs can also be used as

alternatives to biotin/avidin detection methods in applications such as *in situ* hybridization and enzyme-linked immunosorbent assays (ELISAs).

Antibodies against Expression Tags—Section 7.5

This section presents a selected set of primary antibodies for detection of expression tags, including Green Fluorescent Protein (GFP) and Red Fluorescent Protein (RFP). The full range of Invitrogen™ primary antibodies can be surveyed using our online primary antibody search utility at www.invitrogen.com/handbook/antibodies. Direct labeling of primary antibodies can be accomplished via amine-reactive chemistry implemented in our comprehensive selection of convenient and easy-to-use protein labeling kits (Section 1.2). Alternatively, Zenon® immunolabeling technology (Section 7.3) can fulfill the same purposes and is less demanding in terms of antibody quantity and purity requirements.

Avidin and Streptavidin Conjugates—Section 7.6

Molecular Probes® fluorophore-conjugated avidins and streptavidins are extensively used in conjunction with biotinylated oligonucleotides or biotinylated antibodies for nucleic acid hybridization analysis,^{4,16} immunohistochemistry^{6,17} and multicolor flow cytometry.¹⁸ Qdot® nanocrystal–streptavidin conjugates used for the same purposes are described in Section 6.6. Section 7.6 also features our enzyme-labeled avidins and streptavidins, NeutrAvidin™-coated microspheres and affinity matrices for capture and isolation of biotinylated proteins and nucleic acids. Biotin conjugates and the reagents and methods used for their preparation are described in Chapter 4.

Figure 7.1.1 Schematic diagram of primary and secondary detection reagents. **A**) In primary detection methods, the target-specific molecule includes one or more detectable moieties, shown here as radiant orbs. **B**) In secondary detection methods, the target-specific molecule contains binding sites or haptens that can be selectively recognized by secondary detection reagents. For example, these sites might be antigenic epitopes that bind antibodies. Alternatively, the target-specific molecule might be conjugated to either biotin or fluorescent dyes, thereby creating a molecule that can be detected with any of our avidin and streptavidin conjugates or our anti-fluorescent dye antibodies. As shown here, the target-specific molecule may contain multiple sites for binding the secondary detection reagent, thereby providing a simple system for amplifying the signal.

Lectins and Other Carbohydrate-Binding Proteins— Section 7.7

Lectins and certain other carbohydrate-binding proteins that bind to specific glycans are versatile primary detection reagents for histochemical and cytochemical analysis of glycoproteins and glycolipids.^{19–21} Complementary detection methods for glycoproteins based on Molecular Probes® Click-iT® labeling technology are described in Section 3.1 and Section 9.4.

7.2 Secondary Immunoreagents

We provide an extensive selection of Molecular Probes® secondary immunoreagents for use in fluorescence microscopy, flow cytometry and microplate assays, as well as protein and nucleic acid blots and microarrays. Because of their brightness and photostability, the Alexa Fluor® conjugates are superior to most conventional fluorescent secondary reagents (Figure 7.2.1, Figure 7.2.2, Figure 7.2.3) and are the detection reagents of choice for many immunofluorescence microscopy, *in situ* hybridization and bead-based applications. Properties of the organic fluorophores we use to prepare our conjugates are described in detail in Chapter 1. We also offer Qdot® secondary antibody conjugates (Table 6.11), which combine the fluorescence characteristics of Qdot® nanocrystals with the selective binding of F(ab')₂ fragments

from affinity-purified secondary antibodies; the physical and spectroscopic properties of Qdot® nanocrystals are discussed in Section 6.6. In addition to our extensive line of species-specific antibodies, isotype-specific antibodies and F(ab')₂ fragments (Antibody Structure and Classification—Note 7.1), we prepare fluorescent conjugates of protein A and protein G—bacterial proteins that bind with high affinity to the Fc portion of various classes and subclasses of immunoglobulins from many species.

The next section of this chapter is devoted to our Zenon® antibody labeling technology (Section 7.3). The Zenon® antibody labeling technology uses affinity-purified dye- or enzyme-labeled Fab fragments of Fc-specific anti-IgG antibodies for the rapid and quantitative labeling

Figure 7.2.1 Brightness comparison of Molecular Probes® Alexa Fluor® 488 goat anti-mouse IgG antibody with Cy®2 goat anti-mouse IgG antibody from Jackson ImmunoResearch. Human blood was blocked with normal goat serum and incubated with an anti-CD3 mouse monoclonal antibody; cells were washed, resuspended and incubated with either Alexa Fluor® 488 or Cy®2 goat anti-mouse IgG antibody at equal concentrations. Red blood cells were lysed, and the samples were analyzed with a flow cytometer equipped with a 488 nm argon-ion laser and a 525 ± 10 nm bandpass emission filter.

Figure 7.2.2 Brightness comparison of Molecular Probes® Alexa Fluor® 555 goat anti-mouse IgG antibody with Cy®3 goat anti-mouse IgG antibody conjugates commercially available from several other companies. Human blood was blocked with normal goat serum and incubated with an anti-CD3 mouse monoclonal antibody; cells were washed, resuspended and incubated with either the Alexa Fluor® 555 or Cy®3 goat anti-mouse IgG antibody at equal concentrations. Red blood cells were lysed and the samples were analyzed with a flow cytometer equipped with a 488 nm argon-ion laser and a 585 ± 21 nm bandpass emission filter.

Figure 7.2.3 Brightness comparison of Molecular Probes® Alexa Fluor® 647 goat anti-mouse IgG antibody with Cy®5 goat anti-mouse IgG antibody conjugates commercially available from other companies. Human blood was blocked with normal goat serum and incubated with an anti-CD3 mouse monoclonal antibody; cells were washed, resuspended and incubated with either Alexa Fluor® 647 or Cy®5 goat anti-mouse IgG antibody at equal concentrations. Red blood cells were lysed and the samples were analyzed with a flow cytometer equipped with a 633 nm He-Ne laser and a longpass emission filter (>650 nm).

NOTE 7.1**Antibody Structure and Classification**

The basic structural unit of most mammalian antibodies is a glycoprotein (MW ~150,000 daltons) comprising four polypeptide chains—two light chains and two heavy chains, which are connected by disulfide bonds (Figure 1). Each light chain has a molecular weight of ~25,000 daltons and is composed of two domains, one variable domain (V_L) and one constant domain (C_L). There are two types of light chains, lambda (λ) and kappa (κ). In humans, 60% of the light chains are κ , and 40% are λ , whereas in mice, 95% of the light chains are κ and only 5% are λ . A single antibody molecule contains either κ light chains or λ light chains, but never both.

Each heavy chain has a molecular weight of ~50,000 daltons and consists of a constant and variable region. The heavy and light chains contain a number of homologous sections consisting of similar but not identical groups of amino acid sequences. These homologous units consist of about 110 amino acids and are called immunoglobulin domains. The heavy chain contains one variable domain (V_H) and either three or four constant domains (C_{H1} , C_{H2} , C_{H3} and C_{H4} , depending on the antibody class or isotype). The region between the C_{H1} and C_{H2} domains is called the hinge region and permits flexibility between the two Fab arms of the Y-shaped antibody molecule, allowing them to open and close to accommodate binding to two antigenic determinants separated by a fixed distance.

The heavy chain also serves to determine the functional activity of the antibody molecule. There are five antibody classes—IgG, IgA, IgM, IgE and IgD—which are distinguished by their heavy chains γ , α , μ , ϵ and δ , respectively (Table 1). The IgD, IgE and IgG antibody classes are each made up of a single structural unit, whereas IgA antibodies may contain either one or two units and IgM antibodies consist of five disulfide-linked structural units. IgG antibodies are further divided into four subclasses (often referred to as isotypes) although the nomenclature differs slightly depending on the species producing the antibody (Table 1).

Structure/function studies on IgG have been aided by the discovery that the proteolytic enzymes pepsin and papain cleave the molecule into specific fragments with specific biological properties. Treatment of an IgG molecule with pepsin generates the $F(ab')_2$ fragment, which broadly encompasses the two Fab regions linked by the hinge region. Because the $F(ab')_2$ molecule is bivalent, it is capable of precipitating an antigen. Papain cleaves the IgG molecule in the hinge region between the C_{H1} and C_{H2} domains to yield two identical Fab fragments, which retain their antigen-binding ability, and one non-antigen-binding fragment—the (Fc) region. The Fc region is glycosylated and has many effector functions (e.g., binding complement, binding to cell receptors on macrophages and monocytes), and serves to distinguish one class of antibody from another.

Figure 1 Schematic representation of an antibody molecule.

Table 1 Overview of antibody classes and subclasses.

Antibody	Human and Mouse					
	Light Chain	Subtype	Heavy Chain	Light Chain	Subtype	Heavy Chain
IgA	κ or λ κ or λ	IgA ₁ IgA ₂	α_1 α_2			
IgE	κ or λ	None	ϵ			
IgD	κ or λ	None	δ			
IgM	κ or λ	None	μ			
IgG	κ or λ κ or λ κ or λ κ or λ	IgG ₁ IgG ₂ IgG ₃ IgG ₄	γ_1 γ_2 γ_3 γ_4

**Figure 7.2.5** The primary cell walls in a 500 nm-thick apple leaf section identified with an antibody to the methyl-esterified regions of pectic polysaccharides or pectin, and visualized with green-fluorescent Alexa Fluor® 488 goat anti-rabbit IgG antibody (A11008). The orange regions inside the cells are due to the autofluorescent properties of chlorophyll localized in the chloroplasts. Image contributed by Paul Sutherland, EM Unit, Mount Albert Research Centre, Auckland, New Zealand.

of an intact mouse, rabbit, goat or human IgG antibody. The Zenon® labeling method has several advantages over use of the secondary antibodies discussed in this section, including:

- The Zenon® labeling method is suitable for quantitatively labeling submicrogram amounts of an antibody in a few minutes and is not affected by the presence of non-antibody proteins or amine-containing buffers in the sample.
- Multiple antibodies derived from the same species can be used in the same experiment.
- The conjugate's degree of substitution and brightness can be easily adjusted.
- The Zenon® labeled antibody complexes can be combined with labeled primary and secondary antibodies in most protocols.

The fluorescence intensity of the Zenon® labeled antibody complexes may be 2- to 3-fold less than that of labeled secondary antibodies.

Species-Specific Secondary Antibodies

Fluorescent Anti-IgG Antibodies

We offer fluorescent secondary antibody conjugates directed against IgG from a variety of species, including human, mouse, rabbit, rat, chicken, goat, guinea pig, hamster and sheep (Table 7.1). These anti-IgG antibodies are available with a wide selection of fluorophores, including our:

- Blue-fluorescent Alexa Fluor® 350 (Figure 7.2.4), Alexa Fluor® 405, Marina Blue®, Cascade Blue® and Pacific Blue™ dyes
- Green-fluorescent Alexa Fluor® 488 (Figure 7.2.5, Figure 7.2.6, Figure 7.2.7), Oregon Green® 488, Oregon Green® 514 (Figure 7.2.8), BODIPY® FL (Figure 7.2.9) and fluorescein dyes
- Yellow-green-fluorescent Alexa Fluor® 430 and Alexa Fluor® 514 dyes
- Yellow-fluorescent Alexa Fluor® 532 dye (Figure 7.2.10)
- Orange-fluorescent Pacific Orange™, Alexa Fluor® 546 (Figure 7.2.11), Alexa Fluor® 555, tetramethylrhodamine and R-phycoerythrin (R-PE) dyes
- Red-orange-fluorescent Alexa Fluor® 568 and Rhodamine Red™-X dyes
- Red-fluorescent Alexa Fluor® 594 (Figure 7.2.12), Alexa Fluor® 610, Texas Red® and Texas Red™-X dyes
- Far-red-fluorescent Alexa Fluor® 633, Alexa Fluor® 635, Alexa Fluor® 647 (Figure 7.2.13), Alexa Fluor® 660, Alexa Fluor® 680 and allophycocyanin dyes
- Infrared-fluorescent Alexa Fluor® 700 and Alexa Fluor® 750 dyes
- Alexa Fluor® dye-R-phycoerythrin (R-PE) tandem conjugates, which can each be excited with the 488 nm spectral line of the argon-ion laser, but exhibit long-wavelength emission maxima (627 nm for the Alexa Fluor® 610-R-PE conjugates, 667 nm for the Alexa Fluor® 647-R-PE conjugates and 702 nm for the Alexa Fluor® 680-R-PE conjugates)
- Alexa Fluor® dye-allophycocyanin (APC) tandem conjugates, which can each be excited by the He-Ne laser at 633 nm or 635 nm diode lasers with emission beyond 700 nm

**Figure 7.2.4** Live bovine pulmonary artery endothelial cells (BPAEC) loaded with red-fluorescent MitoTracker® Red CMXRos (M7512) (middle). After fixation and permeabilization, the cells were treated with a cocktail containing two mouse monoclonal antibodies to cytochrome oxidase (anti-OxPhos Complex IV subunit VIc and anti-OxPhos Complex IV subunit I antibodies), which were then detected using blue-fluorescent Alexa Fluor® 350 goat anti-mouse IgG antibody (A11045) (left). The image in the right panel is an overlay of the first two images.

Figure 7.2.6 Formation of the cephalic furrow in the anterior end of a developing *Drosophila melanogaster* embryo visualized with the help of several fluorescent stains. A primary antibody to neurotactin was visualized using a red-fluorescent Cy3 dye secondary antibody (Amersham Pharmacia® Biotech Ltd.). Primary antibodies to plasma membrane-bound myosin and to nuclear-localized even-skipped (Eve) protein were visualized with green-fluorescent Alexa Fluor® 488 goat anti-mouse IgG antibody (A11001) and Alexa Fluor® 488 goat anti-rabbit IgG antibody (A11008), respectively. The nuclei were stained with blue-fluorescent Hoechst 33342 (H1399, H3570, H21492). The sample was prepared by Eric Wieschaus, and the imaging was performed by Joe Goodhouse of Princeton University.

Figure 7.2.7 A 2.0 µm maize leaf section illustrating the immunolocalization of the enzyme ribulose biphosphate carboxylase (rubisco) in the chloroplasts of the bundle sheath cells surrounding the vascular bundles. Maize is a C4 plant and, as a result, spatially segregates components of the photosynthetic process between the leaf mesophyll and the bundle sheath. Rubisco was localized using a rabbit anti-rubisco antibody and visualized using the highly cross-adsorbed Alexa Fluor® 488 goat anti-rabbit IgG antibody (A11034). The remaining fluorescence is due to the autofluorescence of chlorophyll, which appears red and is localized to the mesophyll plastids; lignin, which appears dull green and is localized to the xylem of the vascular bundle; and cutin, which appears bright green and is localized to the cuticle outside the epidermis. Image contributed by Todd Jones, DuPont.

Figure 7.2.8 A bovine pulmonary artery endothelial cell (BPAEC) stained with mouse monoclonal anti-β-tubulin antibody in conjunction with Oregon Green® 514 goat anti-mouse IgG antibody (O6383), MitoTracker® Red CMXRos (M7512) and DAPI (D1306, D3571, D21490).

Figure 7.2.9 FluorCells® prepared slide #2 (F14781), which shows bovine pulmonary artery endothelial cells (BPAEC) that have been stained with a mouse monoclonal anti-β-tubulin antibody in conjunction with BODIPY® FL goat anti-mouse IgG antibody (B2752) for labeling microtubules, Texas Red®-X phalloidin (T7471) for labeling F-actin and DAPI (D1306, D3571, D21490) for labeling nuclei. This multiple-exposure image was acquired using bandpass optical filter sets appropriate for DAPI, fluorescein and Texas Red® dye.

Figure 7.2.10 A bovine pulmonary artery endothelial cell (BPAEC) labeled with mouse monoclonal anti-α-tubulin antibody (A11126) in combination with Alexa Fluor® 532 goat anti-mouse IgG antibody (A11002) to stain microtubules. The image was acquired using a bandpass filter set (excitation/emission 535 ± 17.5/590 ± 17.5 nm).

Figure 7.2.11 Microtubules of bovine pulmonary artery endothelial cells (BPAEC) tagged with mouse monoclonal anti-α-tubulin antibody (A11126) and subsequently probed with: Alexa Fluor® 488 goat anti-mouse IgG antibody (A11001, left), Alexa Fluor® 546 goat anti-mouse IgG antibody (A11003, middle) or Alexa Fluor® 594 goat anti-mouse IgG antibody (A11005, right). These images were acquired using a fluorescein bandpass optical filter set, a rhodamine bandpass optical filter set and a Texas Red® bandpass optical filter set, respectively.

Figure 7.2.12 The peripheral nervous system of a wild-type (Canton-S) *Drosophila melanogaster* embryo labeled with the monoclonal 22c10 antibody (which detects a microtubule-associated protein) and subsequently visualized using green-fluorescent Alexa Fluor® 488 rabbit anti-mouse IgG antibody (A11059). The actively dividing cells of the developing denticle bands were labeled with a rabbit anti-histone H3 antibody and visualized using red-fluorescent Alexa Fluor® 594 goat anti-rabbit IgG antibody (A11012). Finally, the nuclei, which are concentrated in the central nervous system, were counterstained with blue-fluorescent DAPI (D1306, D3571, D21490). Image contributed by Neville Cobbe, University of Edinburgh.

Figure 7.2.13 A zebrafish cryosection incubated with the biotin-XX conjugate of mouse monoclonal anti-α-tubulin antibody (A21371). The signal was amplified with TSA™ Kit #22, which includes a horseradish peroxidase–streptavidin conjugate and Alexa Fluor® 488 tyramide (T20932). The sample was then incubated with the mouse monoclonal FRET 6 antibody and was visualized with Alexa Fluor® 647 goat anti-mouse IgG antibody (A21235), which is pseudocolored magenta. Finally, the nuclei were counterstained with SYTOX® Orange nucleic acid stain (S11368).

More information on secondary antibodies is available at www.invitrogen.com/handbook/antibodies.

Our species-specific anti-IgG antibodies, which are raised against IgG heavy and light chains, are affinity purified and adsorbed against the sera of a number of species to minimize cross-reactivity. For multilabeling experiments in which cross-reactivity is critical, we offer highly cross-adsorbed goat anti-mouse IgG and goat anti-rabbit IgG antibodies. See the accompanying product information for a complete list of IgG and sera against which our anti-IgG antibodies have been cross-adsorbed.

Fluorescent Chicken IgY Antibodies

We also offer Alexa Fluor® conjugates of chicken IgY secondary antibodies, including anti-mouse IgG, -rabbit IgG, -rat IgG, -human IgG and -goat IgG antibodies. Chicken secondary antibodies have gained popularity because they demonstrate a lower level of nonspecific binding. Chicken IgY antibodies, which are functionally equivalent to mammalian IgG antibodies (and sometimes referred to as chicken IgG antibodies), lack a classical "Fc" domain and are not bound by protein A or protein G, nor do they bind to Fc receptors for mammalian IgG.

Fluorescent Anti-IgM Antibodies

Our anti-IgM conjugates are prepared from well-characterized antibodies that have been purified by IgM affinity chromatography. These anti-IgM conjugates react specifically with IgM heavy chains (μ chains) (Antibody Structure and Classification—Note 7.1). Due to their large

size, IgM antibodies do not diffuse well into tissue. In addition, because the IgM μ chain is more highly conserved across different species than are IgG, IgA, or light chains, anti-IgM antibodies may react with IgM from other species.

Isotype-Specific Antibodies

We offer isotype-specific antibodies to aid in multilabeling experiments (Table 7.2). The Alexa Fluor® goat anti-mouse IgG isotype-specific antibodies have been cross-adsorbed against mouse IgM, IgA, pooled human sera, purified human paraproteins and other isotypes to minimize cross-reactivity.

F(ab')₂ Fragments

Our range of anti-mouse IgG, -rabbit IgG, -rat IgG and -goat IgG antibodies has been expanded to include fluorescent dye-, alkaline phosphatase-, horseradish peroxidase- and biotin-labeled F(ab')₂ fragments (Table 7.1). These F(ab')₂ fragments are often preferred to whole antibody conjugates because they lack the Fc region (Antibody Structure and Classification—Note 7.1), thereby eliminating nonspecific interactions with Fc receptor-bearing cell membranes and allowing for better penetration into tissue. Please note that the rabbit Fc region may bind nonspecifically to human tissue; consequently, we recommend the F(ab')₂ fragment when using rabbit-derived secondary antibodies on human tissues.

Qdot® Secondary Antibody Conjugates

Because of their unique physical and spectroscopic properties, our Qdot® secondary antibody conjugates are discussed together with our complete line of Qdot® nanocrystal products in Section 6.6 (Table 6.11). The Qdot® nanocrystal secondary antibody conjugates exhibit the broad absorption spectra and intense fluorescence output characteristic of Qdot® nanocrystals along with the selective binding of F(ab')₂ fragments, enabling a wide range of immunocytochemical and immunohistochemical applications.^{1,2} Some examples include immunolabeling of GABA_A receptor $\alpha 1$ and $\gamma 2$ subunits for colocalization analysis in HEK 293 cells³ and immunodetection of EGFR, E-cadherin and cytokeratin on formalin-fixed, paraffin-embedded (FFPE) tissue array slides.⁴

Enzyme-Labeled and Biotinylated Secondary Antibodies

In addition to fluorescent secondary antibodies, we offer high-activity horseradish peroxidase and alkaline phosphatase conjugates of our species-specific secondary antibodies (Table 7.3), as well as several biotin conjugates, for enzyme-based signal amplification techniques. By using an avidin, streptavidin or NeutrAvidin™ biotin-binding protein bridge, the biotinylated secondary antibodies can be linked to a biotinylated enzyme—a method that is often preferred because it tends to reduce nonspecific staining. Enzyme and hapten conjugates of secondary antibodies are also commonly used in histochemical amplification schemes such as the tyramide signal amplification (TSA™) technology and Enzyme-Labeled Fluorescence (ELF®) technology, as well as in enzyme-linked immunosorbent assays (ELISAs) (Section 6.2, Section 6.3). The Zenon® Alkaline Phosphatase and Horseradish Peroxidase Antibody Labeling Kits (Section 7.3, Table 7.7) permit the formation of enzyme-labeled antibodies using submicrogram quantities of a primary antibody.

More information on secondary antibodies is available at www.invitrogen.com/handbook/antibodies.

Image-iT® FX Signal Enhancer

By efficiently blocking nonspecific electrostatic interactions of anionic fluorescent dyes with cationic cell and tissue constituents, the Image-iT® FX signal enhancer (I36933) dramatically improves the signal-to-noise ratio of immunolabeled cells and tissues,⁵⁻⁷ allowing clear visualization of targets that would normally be indistinguishable due to background fluorescence (Figure 7.2.14). Background staining seen with fluorescent conjugates of streptavidin (Table 7.4), goat anti-mouse IgG antibody or goat anti-rabbit IgG antibody is largely eliminated when Image-iT® FX signal enhancer is applied to fixed and permeabilized cells prior to staining. Image-iT® FX signal enhancer is particularly recommended for use with Alexa Fluor® secondary antibodies.

In addition to the stand-alone reagent, we offer the Image-iT® FX signal enhancer bundled with our Alexa Fluor® goat anti-mouse IgG or Alexa Fluor® goat anti-rabbit IgG secondary antibodies (either the standard or highly cross-adsorbed versions) in the Immunofluorescence SFX Detection Kits:

- Alexa Fluor® 488 Goat Anti-Mouse SFX Kit (standard, A31619; highly cross-adsorbed, A31620)
- Alexa Fluor® 555 Goat Anti-Mouse SFX Kit (standard, A31621; highly cross-adsorbed, A31622)
- Alexa Fluor® 594 Goat Anti-Mouse SFX Kit (standard, A31623; highly cross-adsorbed, A31624)
- Alexa Fluor® 647 Goat Anti-Mouse SFX Kit (standard, A31625; highly cross-adsorbed, A31626)
- Alexa Fluor® 488 Goat Anti-Rabbit SFX Kit (standard, A31627; highly cross-adsorbed, A31628)
- Alexa Fluor® 555 Goat Anti-Rabbit SFX Kit (standard, A31629; highly cross-adsorbed, A31630)
- Alexa Fluor® 594 Goat Anti-Rabbit SFX Kit (standard, A31631; highly cross-adsorbed, A31632)
- Alexa Fluor® 647 Goat Anti-Rabbit SFX Kit (standard, A31633; highly cross-adsorbed, A31634)

Figure 7.2.14 Golgi in fixed and permeabilized HeLa cells labeled with anti-golgin-97 antibody (A21270) and visualized with green-fluorescent Alexa Fluor® 488 goat anti-mouse IgG antibody (A11001). Actin was stained with red-fluorescent Alexa Fluor® 594 phalloidin (A12381); nuclei were stained with blue-fluorescent DAPI (D1306, D3571, D21490). Treatment with Image-iT® FX signal enhancer (I36933) largely eliminates nonspecific dye binding (right) as compared to untreated slide (left).

Figure 7.2.16 Demonstration of the amplification obtained with the Alexa Fluor® 488 Signal Amplification Kit for Fluorescein- and Oregon Green® Dye-Conjugated Probes (A11053). Bovine pulmonary artery endothelial cells were labeled with anti- α -tubulin antibody (A11126) in combination with fluorescein goat anti-mouse IgG antibody (F2761) (top). The center panel shows the cells after treatment with Alexa Fluor® 488 rabbit anti-fluorescein/Oregon Green® antibody (A11090), and the bottom panel show the cells after additional labeling with the Alexa Fluor® 488 goat anti-rabbit IgG antibody (A11008). The images were acquired using identical exposure times, and a bandpass filter set appropriate for fluorescein.

Alexa Fluor® Signal Amplification Kits

Alexa Fluor® Signal Amplification Kits for Mouse Antibodies

The Alexa Fluor® Signal Amplification Kits for Mouse Antibodies provide a method for enhancing the detection of mouse primary antibodies using Alexa Fluor® 488, Alexa Fluor® 568 and Alexa Fluor® 594 dye conjugates, which yield green, red-orange and red fluorescence, respectively. These kits provide two Alexa Fluor® antibody conjugates to detect antibodies derived from mouse:

- The Alexa Fluor® 488 Signal Amplification Kit (A11054) provides Alexa Fluor® 488 rabbit anti-mouse IgG and Alexa Fluor® 488 goat anti-rabbit IgG antibodies and is compatible with fluorescein filter sets.
- The Alexa Fluor® 568 Signal Amplification Kit (A11066) provides Alexa Fluor® 568 rabbit anti-mouse IgG and Alexa Fluor® 568 goat anti-rabbit IgG antibodies and is compatible with tetramethylrhodamine filter sets.
- The Alexa Fluor® 594 Signal Amplification Kit (A11067) provides Alexa Fluor® 594 rabbit anti-mouse IgG and Alexa Fluor® 594 goat anti-rabbit IgG antibodies and it compatible with Texas Red® dye filter sets.

An Alexa Fluor® rabbit anti-mouse IgG antibody conjugate is first used to bind to the mouse-derived primary antibody. The fluorescence is then dramatically enhanced by the addition of an Alexa Fluor® goat anti-rabbit IgG antibody (Figure 7.2.15). The Alexa Fluor® 488, Alexa Fluor® 568 and Alexa Fluor® 594 Signal Amplification Kits for Mouse Antibodies can be used for both fluorescence microscopy and flow cytometry applications and contain sufficient materials for 60–300 assays.

Alexa Fluor® 488 Signal Amplification Kit for Fluorescein- and Oregon Green® Dye-Conjugated Probes

The Alexa Fluor® 488 Signal Amplification Kit for Fluorescein-Conjugated Probes (A11053) is designed to simultaneously enhance the fluorescence and the photostability of virtually any fluorescein- or Oregon Green® dye-containing probe (Figure 7.2.16, Figure 7.2.17). This kit takes advantage of the superior spectral properties of Alexa Fluor® 488 conjugates. Alexa Fluor® 488 conjugates are considerably brighter and more photostable than fluorescein-labeled probes. In addition, the fluorescence of Alexa Fluor® 488 conjugates is not sensitive to pH over a wide pH range, unlike the fluorescence of fluorescein conjugates.

Figure 7.2.15 Antibody amplification scheme provided in the Alexa Fluor® 488 Signal Amplification Kits for Mouse Antibodies (A11054). The analogous amplification scheme is used in the Alexa Fluor® 568 (A11066) and Alexa Fluor® 594 (A11067) Signal Amplification Kits for Mouse Antibodies. An Alexa Fluor® rabbit anti-mouse IgG antibody conjugate is first used to bind to the mouse primary antibody. The fluorescence signal is then dramatically enhanced by the addition of an Alexa Fluor® goat anti-rabbit IgG antibody.

The Alexa Fluor® 488 Signal Amplification Kit for Fluorescein- and Oregon Green® Dye-Conjugated Probes uses Alexa Fluor® 488 conjugates of two different antibodies to amplify the signals from fluorescein-labeled probes. Alexa Fluor® 488 anti-fluorescein/Oregon Green® antibody, which is prepared from a rabbit IgG fraction, is first used to bind to the fluorescein- or Oregon Green® dye-labeled target. The fluorescence signal is then dramatically enhanced by addition of the Alexa Fluor® 488 goat anti-rabbit IgG antibody. Because the spectra of Alexa Fluor® 488 conjugates are remarkably similar to those of fluorescein conjugates (Figure 7.2.18), this kit can be used with optical filters or instrument settings appropriate for fluorescein. The Alexa Fluor® 488 Signal Amplification Kit for Fluorescein-Conjugated Probes can be used for fluorescence microscopy, flow cytometry or other applications that employ fluorescein-conjugated probes; it contains sufficient reagents for 60–120 assays by microscopy or flow cytometry.

Fluorescence- and Chemiluminescence-Based ELISA Kits

Amplex® ELISA Development Kits for Mouse IgG and for Rabbit IgG

The Amplex® ELISA Development Kits for Mouse IgG and for Rabbit IgG (A33851, A33852; Section 6.2) provide a comprehensive set of components for creating fluorescence-based ELISAs using horseradish peroxidase conjugates of mouse and rabbit detection antibodies, respectively.⁸ This assay is based on the Amplex® UltraRed reagent, a fluorogenic substrate for horseradish peroxidase (HRP) that reacts with H₂O₂ in a 1:1 stoichiometric ratio to produce a brightly fluorescent and strongly absorbing reaction product (excitation/emission maxima ~568/581 nm).

With a high extinction coefficient, good quantum efficiency and resistance to autooxidation, the fluorescence-based Amplex® UltraRed reagent allows for better sensitivity and a broader assay range than

colorimetric reagents. In a sandwich ELISA format using C-reactive protein, we can routinely detect 75 pg of antigen using goat anti-mouse IgG antibody and 1 pg using goat anti-rabbit IgG antibody; these detection limits are 25-fold lower than those obtained from the same sandwich ELISA format using the common colorimetric reagent TMB. The Amplex® ELISA Development Kits for Mouse IgG and for Rabbit IgG are described in detail in Section 6.2.

Chemiluminescent Alkaline Phosphatase ELISA Kits

We offer four different Chemiluminescent Alkaline Phosphatase ELISA Kits, as well as a Chemiluminescent Alkaline Phosphatase ELISA Sampler Kit. These enzyme-linked immunoassays are based on the CSPD® or CDP-Star® 1,2-dioxetane substrates for alkaline phosphatase with Sapphire™-II or Emerald-II™ enhancer in a system designed for rapid and ultrasensitive analyte detection.⁹ Each kit provides concentrated assay buffer and blocking reagent, as well as one of the following substrate/enhancer solutions:

- CSPD® substrate/Sapphire™-II enhancer (in Kit #1, C10552)
- CSPD® substrate/Emerald-II™ enhancer (in Kit #2, C10553)
- CDP-Star® substrate/Sapphire™-II enhancer (in Kit #3, C10554)
- CDP-Star® substrate/Emerald-II™ enhancer (in Kit #4, C10555)

The Chemiluminescent Alkaline Phosphatase ELISA Sampler Kit (C10556) provides assay buffer, blocking reagent and sample sizes of all four substrate/enhancer solutions. All five kits are described in detail in Section 6.3.

Fluorescence-Based Western Blot Kits

DyeChrome™ Double Western Blot Stain Kit

The DyeChrome™ Double Western Blot Stain Kit (D21887) provides a method for the simultaneous trichromatic detection of multiple

Figure 7.2.17 An example of flow cytometry results obtained using the Alexa Fluor® 488 Signal Amplification Kit for Fluorescein- and Oregon Green® Dye-Conjugated Probes (A11053). Human T-cell leukemia cells (Jurkat) were stained with fluorescein (FITC) mouse anti-CD4 antibody and, as indicated, with Alexa Fluor® 488 rabbit anti-fluorescein/Oregon Green® antibody (A11090) and Alexa Fluor® 488 goat anti-rabbit IgG antibody (A11008). The fluorescence values of the negative controls, in which the FITC anti-CD4 antibody was omitted, are shown (black) together with the fluorescence values of the experimental samples (green). The fluorescence values represent the average signals from the population of cells analyzed.

Figure 7.2.18 Absorption and fluorescence emission spectra of fluorescein goat anti-mouse IgG antibody (F2761, (-)) and Alexa Fluor® 488 goat anti-mouse IgG antibody (A11001, (- -)). The fluorescence intensity of the Alexa Fluor® 488 conjugate was significantly higher than that of the fluorescein conjugate. The data are normalized to show the spectral similarity.

Figure 7.2.19 A total-protein profile and two specific protein bands visualized on a blot using the DyeChrome™ Double Western Blot Stain Kit. A 2-fold dilution series of a protein mixture containing bovine serum albumin (BSA), tubulin, ovalbumin, carbonic anhydrase and soybean trypsin inhibitor (from 1 µg to 0.24 ng each) was separated by electrophoresis through a 13% SDS-polyacrylamide gel and blotted onto a PVDF membrane. The DyeChrome™ Double Western Blot Stain Kit (D21887) was used, together with two primary antibodies, to stain all proteins and to visualize two specific proteins. A) The total-protein profile was stained with the blue-fluorescent dye MDPF. B) Tubulin was detected using mouse monoclonal anti- α -tubulin antibody followed by an alkaline phosphatase conjugate of goat anti-mouse IgG antibody, along with DDAO phosphate (red fluorescence). C) BSA was detected using a rabbit IgG antibody against BSA followed by a horseradish peroxidase conjugate of goat anti-rabbit IgG antibody, along with the Amplex® Gold reagent (yellow fluorescence). The fluorescent signals were detected separately using appropriate excitation light and emission filters on either the Fluor-S MAX Multimager documentation system (Bio-Rad Laboratories) or the FLA3000G laser scanner (Fuji Photo Film Co.).

targets on the same blot using two different enzyme-conjugated secondary antibodies and a general protein stain (Figure 7.2.19).

The components of the DyeChrome™ Double Western Blot Stain Kit are:

- Horseradish peroxidase (HRP) conjugate of goat anti-rabbit IgG antibody and the Amplex® Gold reagent, for yellow-fluorescent detection of a rabbit antibody to a specific protein or proteins
- Alkaline phosphatase conjugate of goat anti-mouse IgG antibody and DDAO phosphate, for far-red-fluorescent detection of a mouse antibody to a specific protein or proteins
- MDPF (2-methoxy-2,4-diphenyl-3(2H)-furanone) for blue-fluorescent detection of the total-protein profile
- Appropriate solvents and buffers for the enzymatic reactions
- Detailed protocols

Each DyeChrome™ Double Western Blot Stain Kit contains sufficient materials to stain approximately 20 minigel blots (6 cm × 9 cm). The two antigens are developed and detected simultaneously, and staining is stable indefinitely on dried blots. The fluorescent signals can be visualized using UV or visible-light illumination.

WesternDot™ Western Blot Kits

The WesternDot™ 625 Goat Anti-Mouse and Goat Anti-Rabbit Western Blot Kits (W10132, W10142) provide Qdot® nanocrystal secondary reagents for the detection of subnanogram amounts of protein on western blots without the complications of time-dependent signal development imposed by enzyme-amplified chemiluminescence detection systems. These kits provide Qdot® 625 streptavidin conjugates and biotinylated secondary antibodies for use in combination with user-supplied mouse or rabbit primary antibodies against the protein of interest. In other respects, immunodetection of proteins immobilized on nitrocellulose (NC) or polyvinylidene difluoride (PVDF) membranes follows standard western blotting protocols. The components of these kits are:

- Biotin-XX goat anti-mouse IgG antibody (in W10132) or biotin-XX goat anti-rabbit IgG antibody (in W10142)
- Qdot® 625 streptavidin
- WesternDot™ blocking buffer
- Wash buffer
- WesternDot™ staining dish
- Detailed protocols

Each WesternDot™ 625 Western Blot Kit contains sufficient materials to stain approximately 20 minigel blots (8 cm × 8 cm). Detection of the fluorescence signal can be accomplished using standard UV- or blue light-based gel and blot imaging systems and does not require specialized emission filters.

Gold-Labeled Immunoreagents

NANOGOLD® and Alexa Fluor® FluoroNanogold™ Conjugates

In collaboration with Nanoprobe, Inc. (www.nanoprobe.com), we offer NANOGOLD® and Alexa Fluor® FluoroNanogold™ conjugates of antibodies and streptavidin to facilitate immunoblotting, light microscopy and electron microscopy applications. These reagents include

Table 7.5 NANOGOLD®, Alexa Fluor® FluoroNanogold™ and colloidal gold conjugates.

Conjugate	Label (Abs/Em) *			
	NANOGOLD®	Alexa Fluor® 488 FluoroNanogold™ (495/519)	Alexa Fluor® 488 Colloidal Gold (495/519)	Alexa Fluor® 594 FluoroNanogold™ (590/617)

Goat anti-rabbit IgG	N24916 †	A24922 †	A31565 ‡, A31566 §	A24923 †
Streptavidin	N24918	A24926	A32360 ‡, A32361 §	A24927

* Approximate absorption (Abs) and fluorescence emission (Em) maxima, in nm, for conjugates. † Fab' fragment. ‡ 5 nm colloidal gold. § 10 nm colloidal gold.

affinity-purified Fab' fragments of the goat anti-mouse IgG and anti-rabbit IgG antibodies, as well as of streptavidin (Section 7.6, Table 7.5). Also available is NANOGOLD® monomaleimide (N20345, Section 2.2), which can be conjugated to thiols in the same way that dyes are conjugated to proteins and nucleic acids.¹⁰

NANOGOLD® antibody conjugates are covalently conjugated to the 1.4 nm NANOGOLD® gold cluster label, whereas Alexa Fluor® FluoroNanogold™ antibody conjugates are coupled to both a NANOGOLD® label and either the Alexa Fluor® 488 or Alexa Fluor® 594 fluorophore, resulting in gold clusters with green or red fluorescence, respectively. Alexa Fluor® FluoroNanogold™ conjugates have all the advantages of the NANOGOLD® cluster, with the additional benefit that they may be used for correlative fluorescence, light and electron microscopy^{11,12} (Figure 7.2.20).

NANOGOLD® gold clusters have several advantages over colloidal gold. They develop better with silver than do most gold colloids and therefore provide higher sensitivity.¹³ Silver enhancement, such as the system provided in the LI Silver Enhancement Kit (L24919), is described below. Additionally, NANOGOLD® particles do not have as high affinity for proteins as do gold colloids, thereby reducing background due to nonspecific binding.

Several additional features of NANOGOLD® and Alexa Fluor® FluoroNanogold™ conjugates include:

- NANOGOLD® gold clusters are an extremely uniform (1.4 nm \pm 10% diameter) and stable compound, not a gold colloid.
- NANOGOLD® gold clusters are smaller than a complete IgG (H+L) antibody—approximately 1/15 the size of an Fab' fragment—and therefore will be able to better penetrate cells and tissues, reaching antigens that are inaccessible to conjugates of larger gold particles.
- NANOGOLD® conjugates contain no aggregates, as they are chromatographically purified through gel filtration columns. This feature is in sharp contrast to colloidal gold conjugates, which are usually prepared by centrifugation to remove the largest aggregates and frequently contain significantly smaller aggregates.
- The ratio of NANOGOLD® particle to Fab' fragment is nearly 1:1, making this product distinct from the 0.2–10 variable stoichiometry of most colloidal gold–antibody preparations.

Figure 7.2.20 Human prostate tissue with adenocarcinoma imaged using an Alexa Fluor® 488 FluoroNanogold™ conjugate. Tissues were labeled with an anti-cytokeratin antibody, followed by staining with the Alexa Fluor® 488 FluoroNanogold™ Fab' fragment of goat anti-mouse IgG antibody (A24920). The fluorescence image in the left panel was taken with optical filters appropriate for fluorescein. The right panel shows a bright-field image of the same system, processed with the LI Silver (LIS) Enhancement Kit (L24919) to visualize the gold distribution. Image courtesy of Nanoprobes, Inc.

NANOGOLD® and Alexa Fluor® FluoroNanogold™ products can be used in immunoblotting, light microscopy and electron microscopy (Figure 7.2.21). Standard immunostaining methodologies can be used successfully with NANOGOLD® and Alexa Fluor® FluoroNanogold™ immunoreagents. Also, because the concentration of antibody and gold is similar to most commercial preparations of colloidal gold antibodies, similar dilutions and blocking agents are appropriate.

Colloidal Gold Complexes

We also offer Alexa Fluor® 488 dye-labeled colloidal gold conjugates, including affinity-purified goat anti-mouse IgG and anti-rabbit IgG antibodies and streptavidin (Table 7.5). These conjugates, which have been adsorbed to 5 nm or 10 nm gold colloids, may be used as probes in immunoblotting, light microscopy, fluorescence microscopy or electron microscopy. The fluorescence of these conjugates can be easily detected by standard techniques, but visualization of colloidal gold can be greatly improved using silver-enhancement methods, such as those provided in the LI Silver Enhancement Kit (L24919) described below.

Combining fluorescent secondary detection reagents with colloidal gold to form functional complexes is difficult because the fluorescence of fluorophores such as fluorescein is significantly quenched by proximity to the colloidal gold.¹⁴ We prepare fluorescent colloidal gold complexes with our Alexa Fluor® 488 dye, a dye that has superior brightness and photostability. Our Alexa Fluor® 488 dye-labeled colloidal gold complexes of anti-IgG antibody and of streptavidin may be used to perform correlated immunofluorescence and electron microscopy in a two-step labeling procedure, rather than in the three-step indirect labeling procedure that is required with conventional nonfluorescent colloidal gold complexes of anti-IgG antibodies or streptavidin.¹⁵

LI Silver Enhancement Kit

The LI Silver Enhancement Kit (L24919) provides a convenient, light-insensitive silver-enhancement system for use with the NANOGOLD®, Alexa Fluor® FluoroNanogold™ and colloidal gold reagents that can be used with electron or light microscopy or for visualization on blots. LI silver is nucleated quickly by NANOGOLD® gold clusters or colloidal gold, resulting in the precipitation of metallic silver and the formation of a dark brown to black signal. The system

Figure 7.2.21 Spindle microtubules labeled with an anti-tubulin primary antibody followed by (left) goat anti-mouse IgG antibody colloidal gold or (right) NANOGOLD® Fab' fragment of goat anti-mouse IgG antibody (N24915). Micrographs (magnification = 1300x) were generated by D. Vandere and R. Burry, Ohio State University. Image courtesy of Nanoprobes, Inc.

PRODUCT LIST 7.2 SECONDARY IMMUNOREAGENTS

Cat. No.	Product	Quantity
A21081	Alexa Fluor® 350 donkey anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A10035	Alexa Fluor® 350 donkey anti-mouse IgG (H + L) *2 mg/mL*	0.5 mL
A10039	Alexa Fluor® 350 donkey anti-rabbit IgG (H + L) *2 mg/mL*	0.5 mL
A21097	Alexa Fluor® 350 donkey anti-sheep IgG (H+L) *2 mg/mL*	0.5 mL
A11068	Alexa Fluor® 350 F(ab') ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 µL
A11069	Alexa Fluor® 350 F(ab') ₂ fragment of goat anti-rabbit IgG (H+L) *2 mg/mL*	250 µL
A11045	Alexa Fluor® 350 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21049	Alexa Fluor® 350 goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21120	Alexa Fluor® 350 goat anti-mouse IgG ₁ (γ1) *2 mg/mL*	250 µL
A21130	Alexa Fluor® 350 goat anti-mouse IgG _{2a} (γ2a) *2 mg/mL*	250 µL
A21140	Alexa Fluor® 350 goat anti-mouse IgG _{2b} (γ2b) *2 mg/mL*	250 µL
A31552	Alexa Fluor® 350 goat anti-mouse IgM (μ chain) *2 mg/mL*	250 µL
A11046	Alexa Fluor® 350 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21068	Alexa Fluor® 350 goat anti-rabbit IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21093	Alexa Fluor® 350 goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A21062	Alexa Fluor® 350 rabbit anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A31553	Alexa Fluor® 405 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A31556	Alexa Fluor® 405 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A11063	Alexa Fluor® 430 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A11064	Alexa Fluor® 430 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21467	Alexa Fluor® 488 chicken anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A21200	Alexa Fluor® 488 chicken anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21441	Alexa Fluor® 488 chicken anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21470	Alexa Fluor® 488 chicken anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A11055	Alexa Fluor® 488 donkey anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A21202	Alexa Fluor® 488 donkey anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21206	Alexa Fluor® 488 donkey anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21208	Alexa Fluor® 488 donkey anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A11015	Alexa Fluor® 488 donkey anti-sheep IgG (H+L) *2 mg/mL*	0.5 mL
A11017	Alexa Fluor® 488 F(ab') ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 µL
A10684	Alexa Fluor® 488 F(ab') ₂ fragment of goat anti-mouse IgG, IgM (H+L) *2 mg/mL*	250 µL
A11070	Alexa Fluor® 488 F(ab') ₂ fragment of goat anti-rabbit IgG (H+L) *2 mg/mL*	250 µL
A21222	Alexa Fluor® 488 F(ab') ₂ fragment of rabbit anti-goat IgG (H+L) *2 mg/mL*	250 µL
A21204	Alexa Fluor® 488 F(ab') ₂ fragment of rabbit anti-mouse IgG (H+L) *2 mg/mL*	250 µL
A24920	Alexa Fluor® 488 FluoroNanogold™ Fab' fragment of goat anti-mouse IgG *80 µg protein/mL*	1 mL
A24922	Alexa Fluor® 488 FluoroNanogold™ Fab' fragment of goat anti-rabbit IgG *80 µg protein/mL*	1 mL
A11039	Alexa Fluor® 488 goat anti-chicken IgG (H+L) *2 mg/mL*	0.5 mL
A11073	Alexa Fluor® 488 goat anti-guinea pig IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21110	Alexa Fluor® 488 goat anti-hamster IgG (H+L) *2 mg/mL*	0.5 mL
A11013	Alexa Fluor® 488 goat anti-human IgG (H+L) *2 mg/mL*	0.5 mL
A21215	Alexa Fluor® 488 goat anti-human IgM (μ chain) *2 mg/mL*	250 µL
A11001	Alexa Fluor® 488 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A11029	Alexa Fluor® 488 goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A31561	Alexa Fluor® 488 goat anti-mouse IgG, 10 nm colloidal gold conjugate *30 µg protein/mL*	0.5 mL
A31560	Alexa Fluor® 488 goat anti-mouse IgG, 5 nm colloidal gold conjugate *30 µg protein/mL*	0.5 mL
A10667	Alexa Fluor® 488 goat anti-mouse IgG, IgA, IgM (H+L) *2 mg/mL*	250 µL
A10680	Alexa Fluor® 488 goat anti-mouse IgG, IgM (H+L) *2 mg/mL*	250 µL
A21121	Alexa Fluor® 488 goat anti-mouse IgG ₁ (γ1) *2 mg/mL*	250 µL
A21131	Alexa Fluor® 488 goat anti-mouse IgG _{2a} (γ2a) *2 mg/mL*	250 µL
A21141	Alexa Fluor® 488 goat anti-mouse IgG _{2b} (γ2b) *2 mg/mL*	250 µL
A21151	Alexa Fluor® 488 goat anti-mouse IgG ₃ (γ3) *2 mg/mL*	250 µL
A21042	Alexa Fluor® 488 goat anti-mouse IgM (μ chain) *2 mg/mL*	250 µL
A31619	Alexa Fluor® 488 Goat Anti-Mouse SFX Kit	1 kit
A31620	Alexa Fluor® 488 Goat Anti-Mouse SFX Kit *highly cross-adsorbed*	1 kit
A11008	Alexa Fluor® 488 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A11034	Alexa Fluor® 488 goat anti-rabbit IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A31566	Alexa Fluor® 488 goat anti-rabbit IgG, 10 nm colloidal gold conjugate *30 µg protein/mL*	0.5 mL
A31565	Alexa Fluor® 488 goat anti-rabbit IgG, 5 nm colloidal gold conjugate *30 µg protein/mL*	0.5 mL
A31627	Alexa Fluor® 488 Goat Anti-Rabbit SFX Kit	1 kit
A31628	Alexa Fluor® 488 Goat Anti-Rabbit SFX Kit *highly cross-adsorbed*	1 kit
A11006	Alexa Fluor® 488 goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL

PRODUCT LIST 7.2 SECONDARY IMMUNOREAGENTS—continued

Cat. No.	Product	Quantity
A21212	Alexa Fluor® 488 goat anti-rat IgM (μ chain) *2 mg/mL*	250 μ L
A10631	Alexa Fluor® 488 mouse anti-human IgG ₁ *1 mg/mL*	250 μ L
A11078	Alexa Fluor® 488 rabbit anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A11059	Alexa Fluor® 488 rabbit anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21210	Alexa Fluor® 488 rabbit anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A11053	Alexa Fluor® 488 Signal-Amplification Kit for Fluorescein- and Oregon Green® Dye-Conjugated Probes *60–120 assays*	1 kit
A11054	Alexa Fluor® 488 Signal-Amplification Kit for Mouse Antibodies *60–300 assays*	1 kit
A31555	Alexa Fluor® 514 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A31558	Alexa Fluor® 514 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A11002	Alexa Fluor® 532 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A11009	Alexa Fluor® 532 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A11056	Alexa Fluor® 546 donkey anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A10036	Alexa Fluor® 546 donkey anti-mouse IgG (H + L) *2 mg/mL*	0.5 mL
A10040	Alexa Fluor® 546 donkey anti-rabbit IgG (H + L) *2 mg/mL*	0.5 mL
A21098	Alexa Fluor® 546 donkey anti-sheep IgG (H+L) *2 mg/mL*	0.5 mL
A11018	Alexa Fluor® 546 F(ab') ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 μ L
A11071	Alexa Fluor® 546 F(ab') ₂ fragment of goat anti-rabbit IgG (H+L) *2 mg/mL*	250 μ L
A11040	Alexa Fluor® 546 goat anti-chicken IgG (H+L) *2 mg/mL*	0.5 mL
A11074	Alexa Fluor® 546 goat anti-guinea pig IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21111	Alexa Fluor® 546 goat anti-hamster IgG (H+L) *2 mg/mL*	0.5 mL
A21089	Alexa Fluor® 546 goat anti-human IgG (H+L) *2 mg/mL*	0.5 mL
A11003	Alexa Fluor® 546 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A11030	Alexa Fluor® 546 goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21123	Alexa Fluor® 546 goat anti-mouse IgG ₁ (γ 1) *2 mg/mL*	250 μ L
A21133	Alexa Fluor® 546 goat anti-mouse IgG _{2a} (γ 2a) *2 mg/mL*	250 μ L
A21143	Alexa Fluor® 546 goat anti-mouse IgG _{2b} (γ 2b) *2 mg/mL*	250 μ L
A21045	Alexa Fluor® 546 goat anti-mouse IgM (μ chain) *2 mg/mL*	250 μ L
A11010	Alexa Fluor® 546 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A11035	Alexa Fluor® 546 goat anti-rabbit IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A11081	Alexa Fluor® 546 goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A21085	Alexa Fluor® 546 rabbit anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A11060	Alexa Fluor® 546 rabbit anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21432	Alexa Fluor® 555 donkey anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A31570	Alexa Fluor® 555 donkey anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A31572	Alexa Fluor® 555 donkey anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21436	Alexa Fluor® 555 donkey anti-sheep IgG (H+L) *2 mg/mL*	0.5 mL
A21425	Alexa Fluor® 555 F(ab') ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 μ L
A21430	Alexa Fluor® 555 F(ab') ₂ fragment of goat anti-rabbit IgG (H+L) *2 mg/mL*	250 μ L
A21437	Alexa Fluor® 555 goat anti-chicken IgG (H+L) *2 mg/mL*	0.5 mL
A21435	Alexa Fluor® 555 goat anti-guinea pig IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21433	Alexa Fluor® 555 goat anti-human IgG (H+L) *2 mg/mL*	0.5 mL
A21422	Alexa Fluor® 555 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21424	Alexa Fluor® 555 goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21127	Alexa Fluor® 555 goat anti-mouse IgG ₁ (γ 1) *2 mg/mL*	250 μ L
A21137	Alexa Fluor® 555 goat anti-mouse IgG _{2a} (γ 2a) *2 mg/mL*	250 μ L
A21147	Alexa Fluor® 555 goat anti-mouse IgG _{2b} (γ 2b) *2 mg/mL*	250 μ L
A21426	Alexa Fluor® 555 goat anti-mouse IgM (μ chain) *2 mg/mL*	250 μ L
A31621	Alexa Fluor® 555 Goat Anti-Mouse SFX Kit	1 kit
A31622	Alexa Fluor® 555 Goat Anti-Mouse SFX Kit *highly cross-adsorbed*	1 kit
A21428	Alexa Fluor® 555 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21429	Alexa Fluor® 555 goat anti-rabbit IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL

A21046	Alexa Fluor® 633 goat anti-mouse IgM (μ chain) *2 mg/mL*	250 µL
A21070	Alexa Fluor® 633 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21071	Alexa Fluor® 633 goat anti-rabbit IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21094	Alexa Fluor® 633 goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A21086	Alexa Fluor® 633 rabbit anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A21063	Alexa Fluor® 633 rabbit anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A31574	Alexa Fluor® 635 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A31575	Alexa Fluor® 635 goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A31576	Alexa Fluor® 635 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A31577	Alexa Fluor® 635 goat anti-rabbit IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21469	Alexa Fluor® 647 chicken anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A21463	Alexa Fluor® 647 chicken anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21443	Alexa Fluor® 647 chicken anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21472	Alexa Fluor® 647 chicken anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A21447	Alexa Fluor® 647 donkey anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A31571	Alexa Fluor® 647 donkey anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A31573	Alexa Fluor® 647 donkey anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21448	Alexa Fluor® 647 donkey anti-sheep IgG (H+L) *2 mg/mL*	0.5 mL
A21237	Alexa Fluor® 647 F(ab') ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 µL
A21246	Alexa Fluor® 647 F(ab') ₂ fragment of goat anti-rabbit IgG (H+L) *2 mg/mL*	250 µL
A21449	Alexa Fluor® 647 goat anti-chicken IgG (H+L) *2 mg/mL*	0.5 mL
A21450	Alexa Fluor® 647 goat anti-guinea pig IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21451	Alexa Fluor® 647 goat anti-hamster IgG (H+L) *2 mg/mL*	0.5 mL
A21445	Alexa Fluor® 647 goat anti-human IgG (H+L) *2 mg/mL*	0.5 mL
A21249	Alexa Fluor® 647 goat anti-human IgM (μ chain) *2 mg/mL*	250 µL
A21235	Alexa Fluor® 647 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21236	Alexa Fluor® 647 goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21240	Alexa Fluor® 647 goat anti-mouse IgG ₁ (γ1) *2 mg/mL*	250 µL
A21241	Alexa Fluor® 647 goat anti-mouse IgG _{2a} (γ2a) *2 mg/mL*	250 µL
A21242	Alexa Fluor® 647 goat anti-mouse IgG _{2b} (γ2b) *2 mg/mL*	250 µL
A21238	Alexa Fluor® 647 goat anti-mouse IgM (μ chain) *2 mg/mL*	250 µL
A31625	Alexa Fluor® 647 Goat Anti-Mouse SFX Kit	1 kit
A31626	Alexa Fluor® 647 Goat Anti-Mouse SFX Kit *highly cross-adsorbed*	1 kit
A21244	Alexa Fluor® 647 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21245	Alexa Fluor® 647 goat anti-rabbit IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A31633	Alexa Fluor® 647 Goat Anti-Rabbit SFX Kit	1 kit
A31634	Alexa Fluor® 647 Goat Anti-Rabbit SFX Kit *highly cross-adsorbed*	1 kit
A21247	Alexa Fluor® 647 goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A21248	Alexa Fluor® 647 goat anti-rat IgM (μ chain) *2 mg/mL*	250 µL
A21446	Alexa Fluor® 647 rabbit anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A21239	Alexa Fluor® 647 rabbit anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A20990	Alexa Fluor® 647-R-phycoerythrin goat anti-mouse IgG (H+L) *1 mg/mL*	100 µL
A20991	Alexa Fluor® 647-R-phycoerythrin goat anti-rabbit IgG (H+L) *1 mg/mL*	100 µL
A21083	Alexa Fluor® 660 donkey anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A21054	Alexa Fluor® 660 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21055	Alexa Fluor® 660 goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21073	Alexa Fluor® 660 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21074	Alexa Fluor® 660 goat anti-rabbit IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21084	Alexa Fluor® 680 donkey anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A10038	Alexa Fluor® 680 donkey anti-mouse IgG (H + L) *2 mg/mL*	0.5 mL
A10043	Alexa Fluor® 680 donkey anti-rabbit IgG (H + L) *2 mg/mL*	0.5 mL
A21102	Alexa Fluor® 680 donkey anti-sheep IgG (H+L) *2 mg/mL*	0.5 mL

PRODUCT LIST 7.2 SECONDARY IMMUNOREAGENTS—continued

Cat. No.	Product	Quantity
A21059	Alexa Fluor® 680 F(ab') ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 µL
A21077	Alexa Fluor® 680 F(ab') ₂ fragment of goat anti-rabbit IgG (H+L) *2 mg/mL*	250 µL
A21057	Alexa Fluor® 680 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21058	Alexa Fluor® 680 goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A31562	Alexa Fluor® 680 goat anti-mouse IgG ₁ (γ1) *2 mg/mL*	250 µL

A21076	Alexa Fluor® 680 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21109	Alexa Fluor® 680 goat anti-rabbit IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
A21096	Alexa Fluor® 680 goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A21088	Alexa Fluor® 680 rabbit anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
A21065	Alexa Fluor® 680 rabbit anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21000	Alexa Fluor® 680-allophycocyanin goat anti-mouse IgG (H+L) *1 mg/mL*	100 µL
A21001MP	Alexa Fluor® 680-allophycocyanin goat anti-rabbit IgG (H+L) *1 mg/mL*	100 µL
A20983	Alexa Fluor® 680-R-phycoerythrin goat anti-mouse IgG (H+L) *1 mg/mL*	100 µL
A20984	Alexa Fluor® 680-R-phycoerythrin goat anti-rabbit IgG (H+L) *1 mg/mL*	100 µL
A21036	Alexa Fluor® 700 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21038	Alexa Fluor® 700 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21037	Alexa Fluor® 750 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A21039	Alexa Fluor® 750 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A21006	Alexa Fluor® 750-allophycocyanin goat anti-mouse IgG (H+L) *1 mg/mL*	100 µL
A10539	allophycocyanin, crosslinked, F(ab') ₂ fragment of goat anti-mouse (H+L) *1 mg/mL*	250 µL
A865	allophycocyanin, crosslinked, goat anti-mouse IgG (H+L) *1 mg/mL*	0.5 mL
A10541	allophycocyanin, crosslinked, goat anti-mouse IgG ₁ (γ1) *1 mg/mL*	250 µL
A10686	allophycocyanin, crosslinked, goat anti-mouse IgG _{2a} (γ2a) *1 mg/mL*	250 µL
A10688	allophycocyanin, crosslinked, goat anti-mouse IgM (μ chain) *1 mg/mL*	250 µL
A10931	allophycocyanin, crosslinked, goat anti-rabbit IgG (H+L) *1 mg/mL*	0.5 mL
A10540	allophycocyanin, crosslinked, goat anti-rat IgG (H+L) *1 mg/mL*	250 µL
B11027	biotin-XX F(ab') ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 µL
B21078	biotin-XX F(ab') ₂ fragment of goat anti-rabbit IgG (H+L) *2 mg/mL*	250 µL
B2763	biotin-XX goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A10676	biotin-XX goat anti-mouse IgG, IgA, IgM (H+L) *2 mg/mL*	250 µL
A10519	biotin-XX goat anti-mouse IgG ₁ (γ1) *2 mg/mL*	250 µL
B2770	biotin-XX goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A10517	biotin-XX goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A10650	biotin-XX mouse anti-human IgG ₁ *1 mg/mL*	250 µL
A10663	biotin-XX mouse anti-human IgG ₄ *1 mg/mL*	250 µL
A10518	biotin-XX rabbit anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
B2752	BODIPY® FL goat anti-mouse IgG (H+L)	1 mg
B2766	BODIPY® FL goat anti-rabbit IgG (H+L)	1 mg
C962	Cascade Blue® goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
C2764	Cascade Blue® goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A10521	Cy®3 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A10520	Cy®3 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A10522	Cy®3 goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A10524	Cy®5 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A10523	Cy®5 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A10525	Cy®5 goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A10691	Cy®5-R-phycoerythrin, F(ab') ₂ fragment of goat anti-rat IgG (H+L) *1 mg/mL*	100 µL
D22185	Diaminobenzidine (DAB) Histochemistry Kit #1 *with goat anti-mouse IgG-HRP*	1 kit
D20698	DSB-X™ biotin donkey anti-goat IgG (H+L) *2 mg/mL*	0.5 mL
D20701	DSB-X™ biotin goat anti-chicken IgG (H+L) *2 mg/mL*	0.5 mL
D20691	DSB-X™ biotin goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
D20693	DSB-X™ biotin goat anti-mouse IgM (μ chain) *2 mg/mL*	250 µL
D20697	DSB-X™ biotin goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
D21887	DyeChrome™ Double Western Blot Stain Kit *for mouse IgG, rabbit IgG and total protein detection* *20 minigel blots*	1 kit
A10534	F(ab') ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 µL
F21452	F(ab') ₂ fragment of goat anti-mouse IgG (H+L), alkaline phosphatase conjugate	0.5 mg
F21453	F(ab') ₂ fragment of goat anti-mouse IgG (H+L), horseradish peroxidase conjugate	0.5 mg
F21456	F(ab') ₂ fragment of goat anti-rabbit IgG (H+L), alkaline phosphatase conjugate	0.5 mg

PRODUCT LIST 7.2 SECONDARY IMMUNOREAGENTS—continued

Cat. No.	Product	Quantity
A10547	F(ab') ₂ fragment of goat anti-rabbit IgG (H+L), horseradish peroxidase conjugate	0.5 mg
A10548	F(ab') ₂ fragment of goat anti-rat IgG (H+L), horseradish peroxidase conjugate	0.5 mg
F11021	fluorescein F(ab') ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 µL
A10683	fluorescein F(ab') ₂ fragment of goat anti-mouse IgG, IgM (H+L) *2 mg/mL*	250 µL
A10526	fluorescein F(ab') ₂ fragment of goat anti-rabbit IgG (H+L) *2 mg/mL*	250 µL
A10527	fluorescein F(ab') ₂ fragment of goat anti-rat IgG (H+L) *2 mg/mL*	250 µL
F2761	fluorescein goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A10679	fluorescein goat anti-mouse IgG, IgM (H+L) *2 mg/mL*	250 µL
A10530	fluorescein goat anti-mouse IgG ₁ (γ1) *2 mg/mL*	250 µL
F2765	fluorescein goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A10528	fluorescein goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A10529	fluorescein rabbit anti-goat (H+L) *2 mg/mL*	0.5 mL
A10535	goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
A10516	goat anti-mouse IgG (H+L) agarose *sedimented bead suspension*	2 mL
G21060	goat anti-mouse IgG (H+L), alkaline phosphatase conjugate	1 mg
G21040	goat anti-mouse IgG (H+L), horseradish peroxidase conjugate	1 mg
G31567	goat anti-mouse IgG (H+L), β-lactamase TEM-1 conjugate *0.5 mg net protein*	0.5 mg
A10538	goat anti-mouse IgG ₁ (γ1) *2 mg/mL*	250 µL
A10551	goat anti-mouse IgG ₁ (γ1), horseradish peroxidase conjugate	0.5 mg
A10685	goat anti-mouse IgG _{2a} (γ2a), horseradish peroxidase conjugate	200 µg
A10666	goat anti-mouse IgG, IgA, IgM (H+L) *2 mg/mL*	250 µL
A10668	goat anti-mouse IgG, IgA, IgM (H+L), horseradish peroxidase conjugate	200 µg
A10677	goat anti-mouse IgG, IgM (H+L), horseradish peroxidase conjugate	200 µg
A10533	goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
G21079	goat anti-rabbit IgG (H+L), alkaline phosphatase conjugate	1 mg
G21234	goat anti-rabbit IgG (H+L), horseradish peroxidase conjugate	1 mg
G31568	goat anti-rabbit IgG (H+L), β-lactamase TEM-1 conjugate *0.5 mg net protein*	0.5 mg
A10536	goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
A10546	goat anti-rat IgG (H+L), alkaline phosphatase conjugate	0.5 mg
A10549	goat anti-rat IgG (H+L), horseradish peroxidase conjugate	0.5 mg
I36933	Image-iT [®] FX signal enhancer	10 mL
L24919	LI Silver (LIS) Enhancement Kit	1 kit
M10991	Marina Blue [®] goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
M10992	Marina Blue [®] goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
A10630	mouse anti-human IgG ₁ *1 mg/mL*	250 µL
A10648	mouse anti-human IgG ₁ , horseradish peroxidase conjugate	200 µg
A10651	mouse anti-human IgG ₄ *1 mg/mL*	250 µL
A10654	mouse anti-human IgG ₄ , horseradish peroxidase conjugate	200 µg
N24915	NANOGOLD [®] Fab' fragment of goat anti-mouse IgG *80 µg protein/mL*	1 mL
N24916	NANOGOLD [®] Fab' fragment of goat anti-rabbit IgG *80 µg protein/mL*	1 mL
O6380	Oregon Green [®] 488 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
O11033	Oregon Green [®] 488 goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
O6381	Oregon Green [®] 488 goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
O11038	Oregon Green [®] 488 goat anti-rabbit IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
O6382	Oregon Green [®] 488 goat anti-rat IgG (H+L) *2 mg/mL*	0.5 mL
O6383	Oregon Green [®] 514 goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
P31581	Pacific Blue [™] F(ab') ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 µL
P10993	Pacific Blue [™] goat anti-mouse IgG (H+L) *2 mg/mL*	0.5 mL
P31582	Pacific Blue [™] goat anti-mouse IgG (H+L) *highly cross-adsorbed* *2 mg/mL*	0.5 mL
P10994	Pacific Blue [™] goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
P31585	Pacific Orange [™] F(ab') ₂ fragment of goat anti-mouse IgG (H+L) *2 mg/mL*	250 µL
P31584	Pacific Orange [™] goat anti-rabbit IgG (H+L) *2 mg/mL*	0.5 mL
P11047	protein A, Alexa Fluor [®] 488 conjugate	1 mg
P11049	protein A, Alexa Fluor [®] 546 conjugate	1 mg
P21462	protein A, Alexa Fluor [®] 647 conjugate	1 mg
P11065	protein G, Alexa Fluor [®] 488 conjugate	1 mg
P21041	protein G, horseradish peroxidase conjugate	1 mg
Q11041MP	Qdot [®] 525 goat F(ab') ₂ anti-mouse IgG conjugate (H+L) *1 µM solution*	200 µL
Q11441MP	Qdot [®] 525 goat F(ab') ₂ anti-rabbit IgG conjugate (H+L) *1 µM solution*	200 µL
Q11031MP	Qdot [®] 565 goat F(ab') ₂ anti-mouse IgG conjugate (H+L) *1 µM solution*	200 µL
Q11032MP	Qdot [®] 565 goat F(ab') ₂ anti-mouse IgG conjugate (H+L) *1 µM solution* *in 1 M betaine, 50 mM borate, pH 8.3 with 0.05% sodium azide*	100 µL

PRODUCT LIST 7.2 SECONDARY IMMUNOREAGENTS—*continued*

Cat. No.	Product	Quantity
Q11431MP	Qdot® 565 goat F(ab') ₂ anti-rabbit IgG conjugate (H+L) *1 µM solution*	200 µL
Q11432MP	Qdot® 565 goat F(ab') ₂ anti-rabbit IgG conjugate (H+L) *1 µM solution* *in 1 M betaine, 50 mM borate, pH 8.3 with 0.05% sodium azide*	100 µL

7.3 Zenon® Technology: Versatile Reagents for Immunolabeling

Our exceptional Zenon® immunolabeling technology provides an easy, versatile and truly unique method of labeling antibodies with Molecular Probes® premier dyes, haptens and enzymes. This enabling technology not only eliminates the need for secondary detection reagents in many applications, but also simplifies immunolabeling applications that previously were time consuming or impractical, including the use of multiple antibodies derived from the same species in the same protocol,¹⁻⁴ as well as the detection of antibody binding in tissues when both the antibody and the tissue are derived from the same species. Moreover, Zenon® immunolabeling technology permits the rapid and quantitative preparation of antibody complexes from a purified antibody fraction or from a crude antibody preparation such as serum, ascites fluid or a hybridoma supernatant.

Figure 7.3.1 Labeling scheme utilized in the Zenon® Antibody Labeling Kits. **A)** An unlabeled IgG antibody is incubated with the Zenon® labeling reagent, which contains a fluorophore-labeled, Fc-specific anti-IgG Fab fragment. **B)** This labeled Fab fragment binds to the Fc portion of the IgG antibody. **C)** Excess Fab fragment is then neutralized by the addition of a nonspecific IgG, preventing crosslabeling by the Fab fragment in experiments where primary antibodies of the same type are present. Note that the Fab fragment used for labeling need not be coupled to a fluorophore, but could instead be coupled to an enzyme (such as HRP) or to biotin.

The Zenon® labeling method takes advantage of the immunoselectivity of the antibody binding reaction by forming a complex between an intact primary IgG antibody and a fluorophore-, biotin- or enzyme-labeled Fab fragment directed against the Fc portion of that IgG (Figure 7.3.1). Simple mixing of the labeled Fab fragment, which is supplied in the Zenon® Antibody Labeling Kits, with the corresponding primary antibody quantitatively produces the Fab-antibody complex in under 10 minutes, with no pre- or postlabeling purification required. This labeled Fab-antibody complex can be immediately used to stain cells, tissues^{1,4} and other targets in the same manner as a covalently labeled primary antibody.

Molecular Probes® Zenon® immunolabeling technology has many outstanding features that open several avenues for research and development. These features, which are discussed in detail later in this section, include:

- **Rapid antibody labeling.** The Zenon® antibody labeling protocol permits rapid and reproducible labeling of submicrogram quantities of a primary antibody. The Zenon® complex is ready for use in cell-labeling protocols in less than 10 minutes. In the absence of competing antibodies of the same species, the Zenon® complex can also be stored for later use.
- **Quantitative antibody labeling.** Labeling is quantitative with respect to the primary antibody, and the extent of antibody labeling (and thus the intensity of the fluorophore or activity of a conjugated enzyme) can be adjusted by changing the molar ratio of the dye- or enzyme-labeled Fab fragment to the primary antibody. In flow cytometry, this unique property of the Zenon® reagents permits use of the same fluorescent color to label two or more cell populations in the same sample.⁵
- **Affinity-purified Fab fragments.** The Zenon® dye- and enzyme-labeled Fab fragments have been affinity purified during their preparation to help ensure their high affinity and selectivity for the Fc portion of the corresponding primary antibody. Furthermore, our procedure for chemical labeling of the Fab fragments protects the Fc-binding site, resulting in more active labeling reagents.
- **Function like covalently labeled primary antibodies.** The Zenon® complexes formed with the Zenon® Antibody Labeling Kits can be used to label cells and tissues without introducing nonspecific background, which can often arise from secondary antibody detection. Moreover, these Zenon® complexes are much easier to prepare and more versatile than covalently labeled primary antibodies, and they show higher activity because only the Fc portion of the primary antibody is labeled, leaving the antigen-binding sites available for cell and tissue labeling. Furthermore, the Zenon® Labeling Kits permit easy and efficient labeling of antibodies that are not commercially available as direct conjugates.
- **Many fluorophore and enzyme labels available.** Zenon® immunolabeling technology makes it very easy to change fluorescent color combinations or detection methodologies by simply using a different dye- or enzyme-labeled Fab fragment from our extensive selection of Zenon® Antibody Labeling Kits (Table 7.7).

Features of Zenon® Antibody Labeling Technology

Zenon® Immunolabeling Is Rapid and Quantitative

Labeling of a suitable primary antibody with the Zenon® Antibody Labeling Kits is *very* fast. The Zenon® labeling reagent contains dye- or enzyme-labeled Fab fragments that have been affinity purified to help ensure their high affinity for the Fc portion of the corresponding primary antibody. We recommend incubation of the Zenon® labeling reagent with the appropriate primary antibody for 5 minutes, followed by a 5-minute blocking reaction of any remaining labeled Fab fragments with excess nonspecific IgG; however, the actual rates of the complex formation and IgG blocking steps are likely to be even faster and may occur within the mixing time of the components (Figure 7.3.2).

Fab–antibody complex formation can be quantitative with respect to the primary antibody (Figure 7.3.3). Furthermore, the degree of labeling (and thus the intensity of the fluorophore or activity of a conjugated enzyme) can be adjusted to some extent by changing the molar ratio of the labeled Fab fragment to the primary antibody. We find that approximately equal *weights* of a dye-labeled Fab fragment generated from a goat anti-Fc antibody (MW ~50,000 daltons) and the intact mouse primary antibody (MW ~150,000 daltons)—a 3:1 *molar* ratio of the labeled Fab fragment to the primary antibody—yields an Fab–antibody complex that is suitable for most applications. Thus, the 50 µg of labeled Fab fragments in the Zenon® labeling reagent provided in the organic dye-based Zenon® Antibody Labeling Kits is sufficient for labeling approximately 50 µg of the corresponding intact IgG antibody; we have defined “one labeling” in all of our Zenon® Antibody Labeling Kits as the amount of Zenon® labeling reagent required for labeling 1 µg of an intact primary antibody. Use of a 5:1 molar ratio of the Zenon® labeling reagent gives an apparent 100% conversion of the primary antibody to the labeling complex (Figure 7.3.3) and a somewhat brighter total fluorescence when compared with the fluorescence of Zenon® complexes prepared using a 3:1 ratio.

Increasing the molar (or weight) ratio of the Zenon® labeling reagent to the antibody can yield a somewhat brighter conjugate and allows for quantitative utilization of the primary antibody, whereas decreasing the ratio can yield a somewhat less fluorescent complex. The ability to adjust the fluorescence intensity (or enzymatic activity) of a labeled complex is a feature of the Zenon® technology that is not at all practical with direct chemical labeling of antibodies.⁵ This property also permits the researcher to rapidly optimize the *best* complex for their experiment, rather than depending on the quite variable degree of substitution that is typical of covalently labeled antibodies from different commercial sources or from chemical labeling in a research laboratory. A 3:1 molar ratio of Zenon® labeling reagent to primary antibody is also suitable for labeling with the phycobiliprotein- and enzyme-derived Zenon® labeling reagents. The Zenon® Antibody Labeling Kits containing a phycobiliprotein- or enzyme-labeled Fab fragment include sufficient reagents for labeling ~25 µg of an intact primary antibody; the Zenon® Antibody Labeling Kits containing an Alexa Fluor® dye–phycobiliprotein tandem conjugate include sufficient reagents for labeling ~10 µg of a primary antibody.

Zenon® Technology Simplifies the Use of Multiple Antibodies of the Same Isotype in the Same Protocol

Unlike detection with secondary antibodies, Zenon® immunolabeling technology allows staining of a cell or tissue sample with multiple antibodies of the same isotype. Our affinity purification of the Zenon® labeling reagent (which we perform subsequent to dye or enzyme conjugation) helps to ensure that the formation of the Fab–antibody complex is stable. Reversal of Zenon® complex formation by the excess of nonspecific IgG used to capture any uncomplexed Zenon® labeling reagent does occur, particularly at temperatures above room temperature. The stability of the Zenon® complex, however, is sufficient to allow sequential (or simultaneous) labeling of different targets in cells and tissues

Figure 7.3.2 Formation of antibody–Fab complexes. An anti-biotin mouse IgG₁ monoclonal antibody was mixed with the Zenon® Alexa Fluor® 488 labeling reagent (a component of Kit Z25002) for varying time intervals before the reaction was quenched by the addition of excess mouse IgG blocking reagent. The quenched reactions were then added to a microplate well containing biotinylated bovine serum albumin and incubated for 20 minutes. After washing, the fluorescence of the remaining bound signal was measured. Binding was found to be essentially complete in less than 5 minutes. Three trials are shown, along with a control (O) where no labeling reagent was added.

Figure 7.3.3 High-performance size-exclusion chromatographic analysis of the Zenon® Alexa Fluor® 488 labeling reagent (a component of Kit Z25002) binding to a mouse IgG₁ antibody. The Zenon® labeling reagent peak appears at 38 minutes; the mouse IgG₁ peak appears at 33 minutes. When combined at a molar ratio of ~5:1 (Zenon® labeling reagent: IgG₁), the IgG₁ antibody is quantitatively converted to a labeled complex, which appears as a peak at 29 minutes.

with multiple antibody complexes (Figure 7.3.4, Figure 7.3.5, Figure 7.3.6). Subsequent to staining, an aldehyde-based fixation step can permanently block the transfer of Zenon® labels between different primary antibodies and will preserve the staining pattern. Zenon® complexes can be used together with other Zenon® complexes, with directly labeled primary antibodies, with labeled secondary antibodies to primary antibodies derived from other species, with antibodies that lack an Fc fragment and with avidin–biotin techniques (Section 7.6) for multiplexed immunolabeling. Some cross-reactivity of the Zenon® labeling reagent with the Fc portion of antibodies from other species may occur unless the excess Zenon® labeling reagent is captured with the soluble nonspecific IgG included in the Zenon® Antibody Labeling Kits.

Zenon® Immunolabeling Is Reliable, Even with Very Small Quantities of Reagents

Formation of the Fab–antibody complex with the Zenon® Antibody Labeling Kits is extremely reliable and reproducible, even with very small (submicrogram) amounts of primary antibody. Successful chemical labeling of submicrogram quantities of an antibody with a succinimidyl ester or an isothiocyanate of a dye is typically not possible; chemical labeling and purification of proteins usually requires at least 100 µg of the carrier-free protein. Because submicrogram amounts of an immunolabeling complex may be all that are required for an experiment, there is absolutely no waste of expensive or difficult-to-obtain antibodies when using the Zenon® Antibody Labeling Kits. Additionally, optimization of the degree of labeling by a dye or an enzyme is trivial, as compared with any chemical labeling method. Although we define “one labeling” in the Zenon® Antibody Labeling Kits as the amount of Zenon® labeling reagent required for labeling 1 µg of the primary antibody, we routinely label about 0.4 µg of the primary antibody dissolved in 2 µL of a buffer.

Unfortunately, many providers of mouse monoclonal antibodies do not indicate how much of the pure antibody they provide in their

products. Furthermore, these antibodies are frequently supplied diluted with an albumin or other carrier protein, which precludes estimation of the antibody concentration from the optical density at 280 nm. However, the ease of preparing Zenon® complexes makes it practical to rapidly optimize the labeling reagent, even when the amount of primary antibody in the sample is unknown.

Zenon® Immunolabeling Does Not Require Antibody Pre-Purification

Unlike chemically modifying antibodies, labeling antibodies with the Zenon® Antibody Labeling Kits does not require removal of exogenous proteins such as serum albumin from the antibody. Serum albumin is frequently added to laboratory-derived or commercially supplied antibodies to help preserve the activity of dilute solutions of antibodies. Because the Zenon® labeling reagent selectively binds only to the Fc portion of the primary antibody, there should be limited or no effect of exogenous proteins that do not have an Fc fragment. The Zenon® labeling reagents function equally well when used to label a purified antibody or a crude antibody preparation such as serum, ascites fluid or a hybridoma supernatant. Zenon® labeling is usually quite successful with even dilute solutions of a primary antibody, as well as with antibodies that are dissolved in amine-containing buffers such as Tris.

Zenon® Immunolabeling Is Versatile

We currently offer Zenon® Antibody Labeling Kits containing a wide selection of different fluorescent labels (Table 7.7), with spectra that span ultraviolet, visible and near-infrared wavelengths. Zenon® immunolabeling technology makes it particularly easy to change fluorescent colors or detection methodologies by simply using a different Zenon® labeling reagent from our extensive selection of Zenon® Antibody Labeling Kits. There is no need to purchase multiple direct conjugates of the same mouse primary antibody (such as with the

Figure 7.3.4 Bovine pulmonary artery endothelial cell labeled with probes for tubulin and mitochondria. Tubulin was detected with an anti- α -tubulin mouse IgG_{2b} monoclonal antibody pre-labeled with the Zenon® Alexa Fluor® 488 Mouse IgG_{2b} Labeling Kit (Z25202), and mitochondria were labeled using an anti-OxPhos Complex V subunit a, mouse IgG_{2b} monoclonal antibody (A21350) pre-labeled with the Zenon® Alexa Fluor® 555 Mouse IgG_{2b} Labeling Kit (Z25205). The nucleus was stained with DAPI (D1306, D3571, D21490).

Figure 7.3.5 Bovine pulmonary artery endothelial cell labeled with probes for actin, mitochondria and the phosphorylated form of histone H3. Actin was labeled with blue-fluorescent Alexa Fluor® 350 phalloidin (A22281), and phosphorylated histone H3 was detected using a rabbit anti-phosphohistone H3 antibody pre-labeled with the Zenon® Alexa Fluor® 555 Rabbit IgG Labeling Kit (red fluorescence, Z25305). Endogenous biotin associated with the mitochondria was labeled using streptavidin (S888) followed by a rabbit anti-streptavidin antibody pre-labeled with the Zenon® Alexa Fluor® 488 Rabbit IgG Labeling Kit (green fluorescence, Z25302).

Figure 7.3.6 Four-color staining of muntjac skin fibroblast with probes for cytoskeletal, nuclear and mitochondrial proteins. Fixed and permeabilized cells were stained with Alexa Fluor® 350 phalloidin (A22281), an anti- α -tubulin antibody (A11126), an anti-cdc6 peptide antibody and an anti-OxPhos Complex V inhibitor protein antibody (A21355). The anti-OxPhos Complex V inhibitor protein antibody was pre-labeled with the Zenon® Alexa Fluor® 488 Mouse IgG₁ Labeling Kit (Z25002), the anti- α -tubulin antibody was pre-labeled with the Zenon® Alexa Fluor® 568 Mouse IgG₁ Labeling Kit (Z25002), and the anti-cdc6 peptide antibody was pre-labeled with the Zenon® Alexa Fluor® 647 Mouse IgG₁ Labeling Kit (Z25008). The image was deconvolved using Huygens software (Scientific Volume Imaging, <http://www.svi.nl/>).

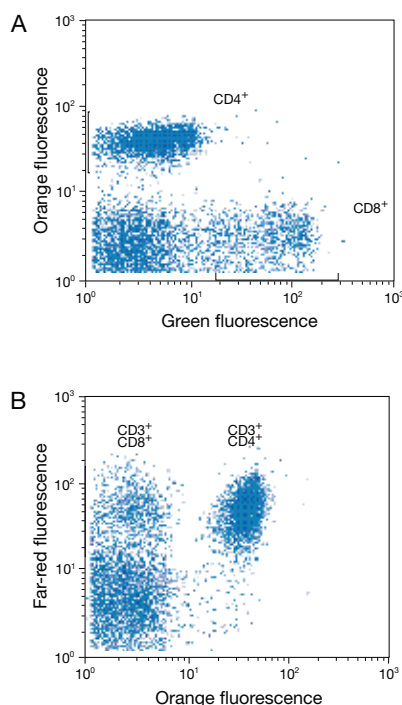

Figure 7.3.7 Human peripheral blood lymphocytes were stained with the following three antibodies: an anti-CD3 mouse IgG₁ antibody pre-labeled with the Zenon® Alexa Fluor® 647 Mouse IgG₁ Labeling Kit (Z25008), an anti-CD4 mouse IgG₁ antibody pre-labeled with the Zenon® R-Phycoerythrin Mouse IgG₁ Labeling Kit (Z25055) and an anti-CD8 mouse IgG_{2a} antibody pre-labeled with the Zenon® Alexa Fluor® 488 Mouse IgG_{2a} Labeling Kit (Z25102). Panels A and B show that cells can be separated by plotting the orange-fluorescent versus green-fluorescent signal or red-fluorescent versus orange-fluorescent signal, respectively, demonstrating that the Zenon® label does not transfer to other antibodies in the same sample. The samples were analyzed on a Coulter® Elite flow cytometer using 488 nm excitation for R-phycoerythrin and the Alexa Fluor® 488 dye, and 633 nm excitation for the Alexa Fluor® 647 dye.

cluster of differentiation (CD) antibodies) in order to perform multicolor flow cytometry (Figure 7.3.7) and imaging protocols.

The fluorescence intensity or enzymatic activity of a Zenon® complex prepared using our protocol is usually similar to that of the corresponding directly labeled conjugate of the primary antibody, although it is typically somewhat lower than the intensity that can be obtained using a labeled secondary antibody. If necessary, the sensitivity of the assay can be increased through use of a Zenon® complex in combination with a signal amplification method such as TSA™ (Section 6.2); see below for a description of our Zenon® Alexa Fluor® 488 Mouse IgG₁ Labeling Kit enhanced with TSA™ technology (Z25090).

Zenon® Labeling Kits and Their Applications

Our wide selection of Zenon® Kits can be mixed and matched in the same experimental protocol and even in the same cell-labeling solution, providing the freedom to experiment with multiple dye-antibody combinations in flow cytometry and imaging applications. In addition, we offer Zenon® Mouse IgG₁ Labeling Kits enhanced with TSA™ technology (Z25090), which combine the advantages of Zenon® labeling technology with the sensitivity of tyramide signal amplification (TSA™).

We offer an extensive assortment of Zenon® Antibody Labeling Kits for use with mouse IgG₁, mouse IgG_{2a}, mouse IgG_{2b}, rabbit IgG, goat IgG and human IgG antibodies (Antibody Structure and Classification—Note 7.1). Each of these kits contain a Zenon® labeling reagent, comprising Fab fragments generated from goat secondary antibodies—or in the case of the Zenon® labeling reagents for goat IgG antibodies, from rabbit secondary antibodies—directed against the Fc portion of the corresponding primary antibody and covalently conjugated with a detectable label. These detectable labels include our outstanding Alexa Fluor® dyes (Section 1.3), as well as phycobiliproteins, tandem conjugates of phycobiliproteins with Alexa Fluor® dyes (Section 6.4), enzymes (horseradish peroxidase and alkaline phosphatase), biotin and some conventional dyes such as fluorescein. Three types of kits are available:

- Zenon® Antibody Labeling Kits that contain an affinity-purified Fab fragment of a goat anti-Fc antibody (or, in the case of the Zenon® Goat IgG Labeling Kits, a rabbit anti-Fc antibody) that has been conjugated to one of our premier Alexa Fluor® dyes or to Pacific Blue™, Pacific Orange™, fluorescein, Texas Red®-X dyes or biotin.
- Zenon® Antibody Labeling Kits that contain a Fab fragment of an anti-Fc antibody labeled with a R-phycoerythrin (R-PE), allophycocyanin (APC) or a tandem conjugate of R-PE or APC with one of our long-wavelength Alexa Fluor® dyes.
- Zenon® Antibody Labeling Kits that contain HRP or alkaline phosphatase conjugates for use in enzyme-amplified protocols (Section 6.2, Section 6.3); see below for a description of the Zenon® Alexa Fluor® 488 Mouse IgG₁ Labeling Kit enhanced with TSA™ technology (Z25090).

In addition to these Zenon® Antibody Labeling Kits, we offer three different types of Zenon® Tricolor Labeling Kits for mouse IgG antibodies,⁵ rabbit IgG and human IgG antibodies (Table 7.7). The Zenon® Tricolor Labeling Kit #1 contains 10 µg each of the Alexa Fluor® 488, Alexa Fluor® 555 and Alexa Fluor® 647 Zenon® labeling reagents. This kit is designed for optimal triple-antibody staining with confocal laser-scanning microscopes but it can also be used with any suitably equipped fluorescence microscope. The Zenon® Tricolor Labeling Kit #2 contains 10 µg each of the Alexa Fluor® 350, Alexa Fluor® 488 and Alexa Fluor® 594 Zenon® labeling reagents, yielding simultaneous blue-, green- and red-fluorescent immunostaining that is useful with almost any fluorescence microscope. The Zenon® Tricolor Labeling Kit #3 is especially suitable for flow cytometry applications and contains 10 µg each of the Alexa Fluor® 488, R-phycoerythrin (R-PE) and Alexa Fluor® 647-R-PE Zenon® labeling reagents, which are each excited efficiently with an argon-ion laser and exhibit minimal spectral overlap.

Zenon® Antibody Labeling Kit Enhanced with TSA™ Technology

The Zenon® Alexa Fluor® 488 Mouse IgG₁ Labeling Kit enhanced with TSA™ technology (Z25090) provides exceptional target-identification capabilities. This kit provides the necessary reagents from both the Zenon® Horseradish Peroxidase Mouse IgG₁ Labeling Kit and the Alexa

Fluor® 488 TSA™ Kit for researchers who want both the ease of labeling mouse IgG₁ antibodies with Zenon® labeling reagents and the signal amplification afforded by use of TSA™ technology. TSA™ technology is an enzyme-mediated detection method that utilizes the catalytic activity of horseradish peroxidase (HRP) to generate high-density labeling of a target protein (Section 6.2). Each HRP label on the target-bound Fab–mouse IgG₁ complexes can activate multiple copies of Alexa Fluor® 488 tyramide to produce short-lived tyramide radicals that are highly reactive with nucleophilic residues near the interaction site, yielding an amplified fluorescent signal with minimal diffusion. The Zenon® Alexa Fluor® 488 Mouse IgG₁ Labeling Kit enhanced with TSA™ technology provides sufficient reagents for 25 labelings, including:

- Zenon® HRP mouse IgG₁ labeling reagent
- Zenon® mouse IgG blocking reagent
- Alexa Fluor® 488 tyramide
- DMSO
- TSA™ blocking reagent
- TSA™ amplification buffer
- Hydrogen peroxide (H₂O₂)
- Detailed protocols for Zenon® complex formation and fluorescent tyramide labeling

Use and Applications of Zenon® Technology

With the exception of our Zenon® Tricolor Labeling Kits, our Zenon® Antibody Labeling Kits contain sufficient reagents for 50 labelings (with the low molecular weight dye–derived Zenon® labeling reagents), 25 labelings (with the R-PE–, APC–, HRP– and alkaline phosphatase–derived reagents) or 10 labelings (with the Zenon® labeling reagents containing one of five different Alexa Fluor® dye–phycobiliprotein tandem conjugates). The Zenon® Tricolor Labeling Kits #1, #2 and #3 contain sufficient reagents for 10 labelings of the same or different antibodies with each of three different Alexa Fluor® dyes. “One labeling” is defined as the amount of Zenon® labeling reagent required for labeling 1 µg of an intact mouse, rabbit, goat or human IgG antibody; however, smaller (or larger) quantities of a primary antibody can be reliably labeled with any of the Zenon® labeling reagents.

For single-color labeling, it is usually not necessary to block any residual Zenon® labeling reagent that has not complexed with the primary antibody; however, in applications that involve multiple antibodies of any type (including antibodies from other species or of other isotypes that may react to a small degree with the Zenon® labeling reagent), adsorption of residual Zenon® labeling reagent is essential to avoid cross-reactivity. Adsorption can be done with a solution of soluble nonspecific IgG, which is included in all of the Zenon® Antibody Labeling Kits. When the Zenon® complexes are in a solution containing the Zenon® labeling reagents adsorbed onto soluble nonspecific IgG, they should be used for staining within an hour to avoid possible transfer of the Zenon® labeling reagent to the excess nonspecific IgG. Zenon® complexes can be used with standard immunolabeling techniques; staining with Zenon® complexes can be performed sequentially or combined with each other or with additional dye- or enzyme-labeled primary antibody conjugates in a one-step, multiparameter labeling protocol. Fixation with aldehyde-based fixatives following staining is recommended to prevent transfer of the Zenon® label between antibodies.

We have demonstrated the utility of Zenon® staining for imaging in an assortment of cells (Figure 7.3.4, Figure 7.3.8, Figure 7.3.9) and tissues (Figure 7.3.10). As with the use of any antibody conjugate in tissues, staining with Zenon® complexes requires good accessibility of the antibody to the target, which can be affected by the specific conditions of fixation and permeabilization. Zenon® complexes of intact primary antibodies have somewhat higher molecular weights than direct conjugates of antibodies, potentially reducing the accessibility of the complexes to tissue antigens in some cases.

Figure 7.3.8 Fixed and permeabilized muntjac skin fibroblasts stained with Alexa Fluor® 488 phalloidin (A12379), an anti- α -tubulin antibody (A11126) and anti-cdc6 peptide antibody. The anti- α -tubulin antibody was pre-labeled with the Zenon® Alexa Fluor® 568 Mouse IgG₁ Labeling Kit (Z25006), and the anti-cdc6 peptide antibody was pre-labeled with the Zenon® Alexa Fluor® 350 Mouse IgG₁ Labeling Kit (Z25000).

Figure 7.3.9 Fixed and permeabilized HeLa cells stained with Alexa Fluor® 350 phalloidin (A22281) and an anti-OxPhos Complex V inhibitor protein antibody (A21355) to label actin filaments and the mitochondria, respectively. An anti-cdc6 peptide antibody was used to label the nucleus. The anti-OxPhos Complex V inhibitor protein antibody was labeled with the Zenon® Alexa Fluor® 488 Mouse IgG₁ Labeling Kit (Z25002), and the anti-cdc6 peptide antibody was labeled with the Zenon® Alexa Fluor® 568 Mouse IgG₁ Labeling Kit (Z25006).

Figure 7.3.10 A 14 µm coronal section of mouse hippocampus stained with an anti- α -tubulin antibody (A11126) labeled with the Zenon® Alexa Fluor® 488 Mouse IgG₁ Labeling Kit (Z25002). The section was counterstained with the NeuroTrace® 530/615 red fluorescent Nissl stain (N21482) to visualize neuronal cell bodies and Hoechst 33258 (H1398, H3569, H21491) to stain nuclei.

PRODUCT LIST 7.3 ZENON® TECHNOLOGY: VERSATILE REAGENTS FOR IMMUNOLABELING

Cat. No.	Product	Quantity

7.4 Anti-Dye and Anti-Hapten Antibodies

Figure 7.4.1 The cytoskeleton of a fixed and permeabilized bovine pulmonary artery endothelial cell detected using mouse monoclonal anti- α -tubulin antibody (A11126), visualized with Alexa Fluor® 647 goat anti-mouse IgG antibody (A21235) and pseudocolored magenta. Endogenous biotin in the mitochondria was labeled with green-fluorescent Alexa Fluor® 488 streptavidin (S11223) and DNA was stained with blue-fluorescent DAPI (D1306, D3571, D21490).

Anti-Dye and Anti-Hapten Antibodies

Fluorescent dyes and nonfluorescent ligands are excellent affinity tags that can be recognized by labeled primary antibodies, providing an alternative to the traditional avidin–biotin system in applications such as *in situ* hybridization,¹ enzyme-linked immunosorbent assays (ELISAs) and western blot analysis (Section 4.2, Table 4.2). Antibodies to dyes and other ligands provide unique opportunities both for signal enhancement and for correlated fluorescence and electron microscopy studies. Essentially all of the methods that use biotin and avidin reagents (Section 7.6) are also possible using dyes as haptens, as long as the corresponding anti-dye antibody is also available (Table 7.8).

One advantage of using fluorescent dyes as haptens instead of biotin is that the hapten signal is usually visible, or at least its concentration can be measured by its absorption in solution, preceding the secondary detection step. Unlike biotin, which is an endogenous ligand in mitochondria (Figure 7.4.1), dye-based haptens permit background-free staining of cells and tissues. We provide a large assortment of anti-dye antibodies (Table 7.8), including rabbit polyclonal IgG antibodies to the fluorescein, tetramethylrhodamine, Texas Red®, dansyl, Alexa Fluor® 488, BODIPY® FL, lucifer yellow and Alexa Fluor® 405/Cascade Blue® fluorophores, as well as a goat anti-fluorescein/Oregon Green® IgG antibody (A11095). We also provide antibodies against three nonfluorescent haptens: dinitrophenyl (DNP), biotin and nitrotyrosine (Table 7.8).

Table 7.8 Anti-fluorophore and anti-hapten antibodies.

Cat. No.	Anti-Fluorophore	Host	Label
Anti-Fluorophore Antibodies and Their Conjugates			
A5760	Alexa Fluor® 405/Cascade Blue® dye	Rabbit	None
A11094	Alexa Fluor® 488 dye	Rabbit	None

* Properties and applications of Qdot® nanocrystal conjugates are described in Section 6.6. More information is available at www.invitrogen.com/handbook/antibodies.

Antibodies to Fluorescein and Oregon Green® Dyes

We have observed complete cross-reactivity of our anti-fluorescein antibodies with the Oregon Green® 488 and Oregon Green® 514 dyes (Section 1.5). These antibodies also quench the fluorescence of the structurally similar dye resorufin (R363, Section 10.1). The high affinity and specificity of anti-fluorescein/Oregon Green® antibodies (A889, A6413, A6421, A11095) makes fluorescein and Oregon Green® dyes ideal haptens for various detection schemes.^{2,3} Researchers have found that fluorescein-anti-fluorescein ELISA techniques display low nonspecific binding and are similar in sensitivity to biotin-streptavidin methods.⁴

Our anti-fluorescein/Oregon Green® rabbit polyclonal antibody (A889) and anti-fluorescein/Oregon Green® goat polyclonal antibody (A11095) can be used in combination with any of our Zenon® Rabbit IgG and Zenon® Goat IgG Labeling Kits (Section 7.3, Table 7.7), respectively, to produce fluorophore-, biotin- or enzyme-labeled antibodies. In addition to these unlabeled anti-fluorescein/Oregon Green® antibodies, we offer an anti-fluorescein/Oregon Green® monoclonal antibody and an anti-fluorescein/Oregon Green® rabbit polyclonal Fab fragment (Antibody Structure and Classification—Note 7.1). The high-affinity anti-fluorescein/Oregon Green® mouse IgG_{2a} monoclonal 4-4-20 antibody (A6421) may reduce nonspecific binding in ELISAs and other second-step detection assays. The Fab fragment of our rabbit polyclonal anti-fluorescein/Oregon Green® antibody (A6413) provides researchers with a probe that more efficiently penetrates cell and tissue preparations. Furthermore, because the Fab fragment no longer contains the Fc portion, nonspecific interactions with Fc receptor-bearing cells are eliminated. As expected, none of our anti-fluorescein/Oregon Green® antibodies recognize the Alexa Fluor® or BODIPY® dyes.

We also offer the horseradish peroxidase (HRP) conjugate of the rabbit anti-fluorescein/Oregon Green® antibody (A21253). HRP conjugates are commonly used in histochemical amplification schemes such as tyramide signal amplification (TSA™) technology (Section 6.2). TSA™ technology provides a greater degree of resolution than many conventional enzyme-mediated fluorescent staining methods, and sequential TSA™ labeling followed by a second round of TSA™ labeling provides an extremely sensitive assay for detection of low-abundance targets in cells and tissues with high spatial resolution.⁵

Our Alexa Fluor® 488 dye-labeled rabbit or goat anti-fluorescein/Oregon Green® antibodies (A11090, A11096) can be used to enhance the intensity and photostability of the green-fluorescent signal of the fluorescein hapten without changing its fluorescence color.^{6–8} Thus, this conjugate allows researchers to take advantage of the superior photostability of the Alexa Fluor® 488 dye, while utilizing existing fluorescein-labeled probes and fluorescein-compatible optics. This strategy has been exploited in our Alexa Fluor® 488 Signal Amplification Kit for Fluorescein-Conjugated Probes (A11053), which is described in Section 7.2. The Alexa Fluor® 594 dye-labeled (A11091) anti-fluorescein/Oregon Green® antibody can be used to convert the green fluorescence of fluorescein conjugates to photostable red fluorescence, or potentially to amplify the signal from fluorescein conjugates (Figure 7.4.2).

The R-phycoerythrin conjugate of the rabbit anti-fluorescein/Oregon Green® IgG antibody (A21250), as well as the Qdot® 565 and Qdot® 655 conjugates of goat anti-fluorescein IgG antibody (Q15431MP, Q15421MP; Section 6.6) have the unique utility of both shifting the green-fluorescent emission of fluorescein-labeled probes to longer wavelengths and greatly intensifying the long-wavelength signal (Figure 7.4.3). Biotin-XX-labeled rabbit anti-fluorescein/Oregon Green® antibody (A982) is an excellent reagent for converting a fluorescence-based detection method into an enzyme-amplified light or electron microscopy technique. Biotin-XX anti-fluorescein/Oregon Green® can be combined with tyramide signal amplification (TSA™) technology (Section 6.2) in a variety of signal amplification schemes for cell and tissue labeling.

Some of the more important applications for anti-fluorescein/Oregon Green® antibodies—almost all of which could also be carried out with any of our other anti-dye antibodies and their complementary dyes—include:

- Amplification of the signal from a fluorescein tyramide in the TSA™ technology⁹ (Section 6.2)
- Detection of fluorescein-labeled primary antibodies^{10,11}
- Development of fluorescein-labeled cell preparations for electron microscopy¹²
- Investigation of the uptake of a fluorescein dextran in kidney proximal tubules¹³
- Localization of mRNA sequences in a double *in situ* hybridization experiment in which both fluorescein- and biotin-labeled oligonucleotides were used²

Figure 7.4.2 Fixed and permeabilized bovine pulmonary artery endothelial cells were labeled with the filamentous actin (F-actin) stain, fluorescein phalloidin (F432, top). An Alexa Fluor® 594 anti-fluorescein/Oregon Green® rabbit IgG antibody (A11091) converted the green fluorescence to red (bottom).

Figure 7.4.3 Color-shifting using a labeled anti-fluorescein/Oregon Green® antibody. Jurkat cells were first stained with a primary mouse anti-human CD3 antibody, followed by fluorescein goat anti-mouse IgG antibody (F2761), with the resultant fluorescence detected in the R-phycoerythrin (red-orange fluorescence) channel of a flow cytometer (blue curve). The weak signal was then shifted to better suit the R-phycoerythrin channel by the addition of an R-phycoerythrin conjugate of anti-fluorescein/Oregon Green® antibody (A21250). The resulting signal intensity is approximately two orders of magnitude greater (red curve) than the direct fluorescence from the first staining step (blue curve).

- Preparation of an anti-fluorescein affinity matrix, which was used to immobilize a fluoresceinated protein in order to study protein-protein interactions *in vitro*^{14,15}
- Separation of fluorescein antibody-labeled cell populations by immunoadsorption¹⁶ or magnetic separation techniques
- Assessment of the accessibility of active site-bound fluorescein probes¹⁷
- Investigation of the internalization pathway of fluorescein transferin^{18,19} (T2871, Section 16.1)

Antibody to the Alexa Fluor® 488 Dye

We have prepared a rabbit polyclonal antibody to our green-fluorescent Alexa Fluor® 488 dye (A11094). In a manner analogous to the anti-fluorescein/Oregon Green® antibodies, the anti-Alexa Fluor® 488 dye antibody specifically recognizes and efficiently quenches most of the fluorescence of the Alexa Fluor® 488 dye. In contrast, the anti-Alexa Fluor® 488 dye antibody does not appreciably quench the fluorescence of fluorescein, carboxytetramethylrhodamine or the Alexa Fluor® 594 dye. The high affinity of the anti-Alexa Fluor® 488 dye antibody makes it potentially useful for various immunochemical applications. This antibody can also be used to further amplify the signals from our Alexa Fluor® 488 tyramide-containing TSA™ Kits (Section 6.2).

Antibodies to Tetramethylrhodamine and the Rhodamine Red™ and Texas Red® Dyes

As with the anti-fluorescein/Oregon Green® antibodies, the rabbit polyclonal antibodies to the tetramethylrhodamine and Texas Red® fluorophores (A6397, A6399) are effective reagents for binding these dye-based haptens and quenching their fluorescence. However, these antibodies strongly cross-react with some other rhodamines, including the Rhodamine Red™ and Lissamine rhodamine B dyes, and therefore cannot be used for simultaneous detection of more than one rhodamine-based dye. These anti-tetramethylrhodamine and anti-Texas Red® dye antibodies do not appear to cross-react with fluorescein or the Oregon Green® or Alexa Fluor® dyes, and our anti-fluorescein/Oregon Green® antibodies do not cross-react with tetramethylrhodamine or the Rhodamine Red™ or Texas Red® dyes. Anti-tetramethylrhodamine has been used to localize retrogradely transported tetramethylrhodamine dextrans by an immunoperoxidase-based amplification technique.²⁰

Antibodies to the Lucifer Yellow Dye and the Cascade Blue® and Alexa Fluor® 405 Dyes

Lucifer yellow CH (L453) and Cascade Blue® hydrazide (C687) are frequently employed as polar tracers for neuronal cell labeling (Section

14.3). Our unconjugated (A5750, A5760) and biotinylated (A5751) rabbit polyclonal antibodies to these dyes are useful in standard enzyme-mediated immunohistochemical methods for permanently labeling neuronal tissue.^{21–25} Anti-lucifer yellow dye antibody (A5750) has also been used to follow dye coupling in smooth muscle cells by electron microscopy.^{26,27} The anti-Alexa Fluor® 405/Cascade Blue® dye antibody (A5760) has been employed in western blot analysis to identify cytoplasmic and luminal domains of the sarcoplasmic reticulum Ca²⁺-ATPase, which had been photolabeled with Cascade Blue® aminoethyl 4-azido-benzamide.²⁸ The anti-Alexa Fluor® 405/Cascade Blue® dye antibody also recognizes conjugates of our Alexa Fluor® 405 succinimidyl ester (A30000, A30100; Section 1.7), which is a derivative of our Cascade Blue® dye with a 4-piperidinecarboxylic acid spacer that separates the fluorophore from its reactive moiety.

Antibody to the BODIPY® FL Dye

Our unlabeled rabbit polyclonal antibody to the BODIPY® FL fluorophore (A5770) cross-reacts with some other BODIPY® dyes but does not cross-react appreciably with any other fluorophores. This anti-BODIPY® FL dye antibody should therefore not be used for simultaneous detection of more than one dye based on the BODIPY® fluorophore. In solution assays, we have found that the anti-BODIPY® FL dye antibody effectively quenches most of the fluorescence of the BODIPY® FL dye, but quenches the BODIPY® TR dye to a lesser degree and does not significantly quench the BODIPY® TMR dye. The anti-BODIPY® FL dye antibody has been used in a fluorescence quenching assay to determine the accessibility of BODIPY® FL dye-labeled cysteine residues in the transmembrane domain of diphtheria toxin.^{29–32}

Anti-Dansyl Antibody

In contrast to the other anti-fluorophore antibodies, which usually quench the fluorescence of the dye to which they bind, our rabbit polyclonal anti-dansyl antibody (A6398) typically *enhances* the fluorescence of dansyl amides by greater than 10-fold. Binding of the anti-dansyl antibody also blue shifts the emission spectrum of the fluorophore in water from ~520 nm to ~450 nm. These properties, combined with the unusually high Stokes shift of the dansyl dye (Figure 7.4.4), make this antibody particularly useful for determining the topography of dansyl-labeled probes, including that of dansyl-labeled phospholipids (Section 13.2) in cell and artificial membranes.³³ The dansyl hapten is preferably incorporated into biomolecules using the succinimidyl ester of dansyl-X (D6104, Section 4.2) because its aminohexanoyl spacer (“X”) reduces the interaction of the fluorophore with the biomolecule to which it is conjugated and makes it more accessible to anti-dansyl antibodies.^{33–35}

Figure 7.4.4 Absorption and fluorescence emission spectra of dansyl cadaverine in methanol.

Efficient Quenching by Anti-Fluorophore Antibodies

Quenching Efficiencies

Except for the anti-dansyl antibody, which enhances the fluorescence of the dansyl fluorophore, all of our anti-fluorophore antibodies strongly quench the fluorescence of their complementary dyes in free solution. For example, our anti-fluorescein/Oregon Green® antibodies typically effect up to 95% quenching of the fluorescence of both fluorescein and the Oregon Green® 488 dye. The anti-fluorescein/Oregon Green® antibody also quenches some other fluorescein derivatives, such as carboxyfluorescein, Calcium Green™-1 Ca²⁺ indicator and

BCECF pH indicator, making this antibody useful for reducing background fluorescence caused by leakage of these dyes from the cell.³⁶ However, quenching of our fluorescein-based Ca^{2+} indicators by our anti-fluorescein/Oregon Green® IgG antibody is apparently dependent on whether or not Ca^{2+} is bound; Calcium Green™-1 indicator is quenched by 89% in the presence of 5 μM Ca^{2+} , whereas it is quenched by only 46% in the presence of 10 mM EGTA. Maximal quenching efficiencies for fluorescein analogs (all at 5 nM dye using the rabbit anti-fluorescein/Oregon Green® IgG antibody, A889) are as follows (values may vary somewhat from batch to batch) and may be different using the goat anti-fluorescein/Oregon Green® IgG antibody, A11095, the mouse monoclonal anti-fluorescein/Oregon Green®, A6421 or the rabbit IgG Fab fragment of anti-fluorescein/Oregon Green®, A6413):

- Oregon Green® 488 dye, 95%
- Oregon Green® 514 dye, 92%
- Carboxyfluorescein, 93%
- Calcium Green™-1 indicator (in the presence of 5 μM Ca^{2+}), 89%
- Calcium Green™-1 indicator (in the presence of 10 mM EGTA), 46%
- BCECF indicator, 43%
- Fluo-3 indicator (in the presence of 5 μM Ca^{2+}), 32%
- Rhodamine Green™ dye, 9%
- Calcein, <5%
- Tetramethylrhodamine, <5%

Our preparations of the anti-tetramethylrhodamine and anti-Texas Red® dye antibodies are somewhat less effective as fluorescence quenchers of their complementary fluorophores, with maximal quenching efficiencies of ~75% and ~60%, respectively. Our rabbit anti-Alexa Fluor® 488 dye IgG antibody quenches the fluorescence of the free Alexa Fluor® 488 dye by >90%. Our antibody to the BODIPY® FL fluorophore typically quenches the dye's fluorescence by ~90%. It also quenches BODIPY® TR dye fluorescence by ~45%, but does not significantly quench BODIPY® TMR dye fluorescence. Antibodies to the lucifer yellow and Alexa Fluor® 405/Cascade Blue® fluorophores quench the fluorescence of their complementary dyes by ~85% and ~80%, respectively. In addition, anti-DNP antibodies have been reported to significantly quench the fluorescence of aminonitrobenzoxadiazoles³⁷ (NBD amines).

Quenching Assay

We use a sensitive fluorescence quenching-based assay to help ensure that the concentration of specific anti-dye antibody in its purified IgG fractions is provided at a consistently high titer. As supplied, 20 μL of the antibody solution is certified to produce $\geq 50\%$ of the maximal fluorescence quenching (or enhancement, in the case of anti-dansyl antibody) of 1 mL of a 50 nM solution of the corresponding dye, assayed in 100 mM sodium phosphate, pH 8.0. All maximal quenching values are determined using the free fluorophore; the maximal quenching of a fluorophore covalently bound to a protein is often significantly less due to steric hindrance.

Applications for Fluorescence Quenching by Anti-Fluorophore Antibodies

Fluorescence quenching of dye haptens by anti-dye antibodies provides a useful measure of topography in cells, proteins and membranes. For example, researchers have used anti-fluorescein quenching assays to determine the accessibility of a fluorescein-labeled ATP-binding site in both Na^+/K^+ -ATPase and $\text{Ca}^{2+}/\text{Mg}^{2+}$ -ATPase.^{17,38}

Similarly, the anti-BODIPY® FL dye antibody has been employed to identify shallow- and deep-membrane-penetrating forms of diphtheria toxin T domain.²⁹⁻³² In addition, anti-fluorophore antibodies have been used as cell-impermeant probes for determining whether fluorescent dye-conjugated ligands, proteins, bacteria or other biomolecules have been internalized by endocytic or pinocytotic processes³⁹⁻⁴² (Section 16.1). Anti-fluorophore antibodies also permit background-free observation of fusion events in an assay designed to monitor the fusion of membrane vesicles *in vitro*.⁴³ As noted above, however, these antibodies may quench dye-labeled proteins less effectively than they quench free dyes.

Anti-Dinitrophenyl Antibody

Because of its high affinity for the dinitrophenyl (DNP) hapten,^{44,45} our anti-DNP polyclonal rabbit antibodies (Table 7.8) are excellent reagents for probing DNP-labeled molecules, including nucleic acid probes prepared using DNP-labeled nucleotides. Unlike assays that use biotin as the hapten, it is usually easy to determine the degree of substitution of the DNP hapten in bioconjugates from the dye's visible absorption near 350 nm⁴⁶ ($\text{EC} \sim 18,000 \text{ cm}^{-1}\text{M}^{-1}$). It has been reported that human chromosomes can be probed with equal sensitivities using either biotinylated, DNP-modified or digoxigenin-modified cosmid probes.⁴⁷ Anti-DNP antibodies have been used to localize a DNP-labeled DNA probe in HIV-infected cells⁴⁸ and 2,4-dinitrophenylhydrazine-labeled proteins on blots.^{49,50} Researchers have also reported using anti-DNP antibodies to probe for DNP-labeled IgG as a method for detecting sparse antigens⁵¹ and, in conjunction with DNP-labeled bovine serum albumin (BSA), to study the Fc receptor-mediated endocytosis of IgG complexes.^{52,53}

In addition to the unlabeled anti-DNP antibody (A6430), we offer anti-DNP antibody conjugates of biotin-XX (A6435), fluorescein (A6423), Alexa Fluor® 488 dye (A11097) and Qdot® 655 nanocrystal (Q17421MP, Section 6.6). Our anti-DNP antibody is prepared against DNP-keyhole limpet hemocyanin (DNP-KLH) and thus the antibody and its conjugates do not cross-react with BSA, a common blocking reagent in hybridization applications.

For use in conjunction with our anti-DNP antibody, we offer the DNP-X succinimidyl ester (D2248, Section 4.2) for labeling proteins and amine-modified DNA. The literature also describes methods for incorporating DNP into DNA using DNP-labeled primers.⁵⁴ In addition to recognizing DNP, our anti-DNP antibody cross-reacts with trinitrobenzenesulfonic acid-modified proteins, making this antibody useful both for localizing and for isolating cell-surface molecules labeled with either DNP or TNP.⁵⁴ Furthermore, anti-DNP antibodies have been reported to quench aminonitrobenzoxadiazoles (NBD amines),³⁷ indicating that NBD-X succinimidyl ester (S1167, Section 1.7) will also be a useful haptenylating reagent for use with this antibody.

Anti-Nitrotyrosine Antibody

Our antibody to nitrotyrosine (A21285) is raised in rabbits that have been immunized with nitrated KLH. Nitrotyrosine-modified proteins are the principal reaction products of nitric oxide (through the formation of peroxynitrite) in cells (Section 18.3). Because tyrosine residues are also conveniently converted to nitrotyrosine by reaction at near-neutral pH with tetranitromethane,^{55,56} the nitrotyrosine hapten can be

Figure 7.4.6 Specificity of our rabbit anti-nitrotyrosine antibody (A21285) to nitrated proteins. Equal amounts of avidin (A887, lane 1) and CaptAvidin™ biotin-binding protein (C21385, lane 2) were run on an SDS-polyacrylamide gel (4–20%) and blotted onto a PVDF membrane. CaptAvidin™ biotin-binding protein, a derivative of avidin, has nitrated tyrosine residues in the biotin-binding site. Nitrated proteins were identified with the anti-nitrotyrosine antibody, in combination with an alkaline phosphatase conjugate of goat anti-rabbit IgG antibody (G21079) and the red-fluorescent substrate, DDAO phosphate (D6487).

readily created in almost any peptide or protein that contains a tyrosine residue. A further advantage is that nitrotyrosine has pH-dependent visible absorbance (absorption maxima ~360 nm⁵⁵ and 428 nm⁵⁷) that can be utilized to detect formation of the hapten in soluble biopolymers.

Our anti-nitrotyrosine antibody is useful for detecting nitrotyrosine-containing peptides and proteins both in immunohistochemical (Figure 7.4.5) and western blot applications (Figure 7.4.6). It can be used to identify nitrated proteins and to determine the level of protein nitrosylation in tissues.^{58,59} This rabbit IgG antibody can be labeled with fluorophores, biotin or enzymes using any of our Zenon® Rabbit IgG Antibody Labeling Kits (Section 7.3, Table 7.7).

Anti-Biotin Antibody

The high affinity of avidin for biotin was first exploited in histochemical applications in the early 1970s.^{60,61} The use of avidin–biotin techniques has since become standard for diverse detection schemes, although limitations of this method have also been recognized.^{62,63} As an alternative to avidin-based reagents, we offer a high-affinity mouse monoclonal antibody to biotin (03-3700). This anti-biotin antibody can be used to detect biotinylated molecules in immunohistochemistry, *in situ* hybridization, ELISAs and flow cytometry applications.

It has been shown that certain monoclonal antibodies to biotin have biotin-binding motifs that are similar to those seen for avidin and streptavidin.⁶⁴ Anti-biotin antibody has been shown to selectively stain endogenous biotin-dependent carboxylase proteins used in fatty acid synthesis of the mitochondria.^{65,66} Nonspecific staining of mitochondrial proteins by labeled avidins and by anti-biotin antibodies can be a complicating factor in using avidin–biotin techniques (Figure 7.4.1). This nonspecific binding can usually be blocked by pretreatment of the sample with the reagents in our Endogenous Biotin-Blocking Kit (E21390, Section 7.6).

Figure 7.4.5 Fixed and permeabilized bovine pulmonary artery endothelial cells were treated with either degraded peroxyxynitrite (left) or 100 μM peroxyxynitrite (right) for 5 minutes at room temperature to induce protein nitration. Nitrated tyrosine residues were detected with our rabbit anti-nitrotyrosine antibody (A21285) and visualized with the green-fluorescent Alexa Fluor® 488 goat anti-rabbit IgG antibody (A11008). Nuclei were counterstained with blue-fluorescent DAPI (D1306, D3571, D21490).

PRODUCT LIST 7.4 ANTI-DYE AND ANTI-HAPTEN ANTIBODIES

Cat. No.	Product	Quantity
A11053	Alexa Fluor® 488 Signal-Amplification Kit for Fluorescein- and Oregon Green® Dye-Conjugated Probes *60–120 assays*	1 kit
A5760	anti-Alexa Fluor® 405/Cascade Blue®, rabbit IgG fraction *3 mg/mL*	0.5 mL
A11094	anti-Alexa Fluor® 488, rabbit IgG fraction *1 mg/mL*	0.5 mL
03-3700	anti-Biotin, Mouse IgG monoclonal	0.5 mg
A5770	anti-BODIPY® FL, rabbit IgG fraction *3 mg/mL*	0.5 mL
A6398	anti-dansyl, rabbit IgG fraction *1 mg/mL*	0.5 mL
A6430	anti-dinitrophenyl-KLH, rabbit IgG fraction *2 mg/mL*	0.5 mL
A11097	anti-dinitrophenyl-KLH, rabbit IgG fraction, Alexa Fluor® 488 conjugate *2 mg/mL*	0.5 mL
A6435	anti-dinitrophenyl-KLH, rabbit IgG fraction, biotin-XX conjugate *2 mg/mL*	0.5 mL
A6423	anti-dinitrophenyl-KLH, rabbit IgG fraction, fluorescein conjugate *2 mg/mL*	0.5 mL
A11095	anti-fluorescein/Oregon Green®, goat IgG fraction *1 mg/mL*	0.5 mL
A11096	anti-fluorescein/Oregon Green®, goat IgG fraction, Alexa Fluor® 488 conjugate *1 mg/mL*	0.5 mL
A6421	anti-fluorescein/Oregon Green®, mouse IgG _{2a} , monoclonal 4-4-20	0.5 mg
A6413	anti-fluorescein/Oregon Green®, rabbit IgG Fab fragment *0.5 mg/mL*	0.5 mL
A889	anti-fluorescein/Oregon Green®, rabbit IgG fraction *1 mg/mL*	0.5 mL
A11090	anti-fluorescein/Oregon Green®, rabbit IgG fraction, Alexa Fluor® 488 conjugate *1 mg/mL*	0.5 mL
A11091	anti-fluorescein/Oregon Green®, rabbit IgG fraction, Alexa Fluor® 594 conjugate *1 mg/mL*	0.5 mL
A982	anti-fluorescein/Oregon Green®, rabbit IgG fraction, biotin-XX conjugate *1 mg/mL*	0.5 mL
A21253	anti-fluorescein/Oregon Green®, rabbit IgG fraction, horseradish peroxidase conjugate	0.5 mg
A21250	anti-fluorescein/Oregon Green®, rabbit IgG fraction, R-phycoerythrin conjugate *2 mg/mL*	250 µL
A5750	anti-lucifer yellow, rabbit IgG fraction *3 mg/mL*	0.5 mL
A5751	anti-lucifer yellow, rabbit IgG fraction, biotin-XX conjugate *3 mg/mL*	0.5 mL
A21285	anti-nitrotyrosine, rabbit IgG fraction *1 mg/mL*	0.5 mL
A6397	anti-tetramethylrhodamine, rabbit IgG fraction *1 mg/mL*	0.5 mL
A6399	anti-Texas Red®, rabbit IgG fraction *1 mg/mL*	0.5 mL
Q15431MP	Qdot® 565 goat anti-fluorescein conjugate *1 µM solution* *whole IgG*	200 µL
Q15421MP	Qdot® 655 goat anti-fluorescein conjugate *1 µM solution* *whole IgG*	200 µL
Q17421MP	Qdot® 655 rat anti-dinitrophenol conjugate *1 µM solution* *whole monoclonal IgG*	200 µL

7.5 Antibodies against Expression Tags

This section presents a selected set of primary antibodies for detecting expression tags, including Green Fluorescent Protein (GFP) and Red Fluorescent Protein (RFP) as well as oligohistidine, hemagglutinin and c-myc. The full range of Invitrogen™ primary antibodies can be surveyed using our online primary antibody search utility at www.invitrogen.com/handbook/antibodies.

Direct labeling of primary antibodies can be accomplished via amine-reactive chemistry implemented in our comprehensive selection of convenient and easy-to-use protein labeling kits (Section 1.2). Alternatively, Zenon® immunolabeling technology (Section 7.3) can be used to prepare fluorophore-, biotin- or enzyme-labeled primary antibodies but is less demanding than chemical labeling methods in terms of antibody quantity and purity requirements.

Antibodies Specific for Reporter Gene Products

Anti-Green Fluorescent Protein (GFP) Antibodies

Expression of the intrinsically fluorescent Green Fluorescent Protein (GFP) from the jellyfish *Aequorea victoria* has become a popular method for following gene expression and protein localization.^{1–5} We offer a rabbit polyclonal antibody that is raised against GFP purified directly from *A. victoria*. This anti-GFP antibody, which is available as a complete serum (A6455) or as an IgG fraction (A11122) purified by ion-exchange chromatography, facilitates the detection of native GFP, recombinant GFP and GFP fusion proteins by immunofluorescence⁶

(Figure 7.5.1), western blot analysis⁷ and immunoprecipitation. Several direct conjugates derived from the IgG fraction are also available:

- Green-fluorescent Alexa Fluor® 488 rabbit anti-GFP antibody (A21311)
- Orange-fluorescent Alexa Fluor® 555 rabbit anti-GFP antibody (A31851)
- Red-fluorescent Alexa Fluor® 594 rabbit anti-GFP antibody (A21312)
- Far-red-fluorescent Alexa Fluor® 647 rabbit anti-GFP antibody (A31852)
- Biotin-XX rabbit anti-GFP antibody (A10259)
- Horseradish peroxidase (HRP) rabbit anti-GFP antibody (A10260)

Figure 7.5.1 NIH 3T3 cells that were transiently transfected with a Green Fluorescent Protein (GFP) expression vector, then plated and allowed to attach and proliferate. The cells were fixed and labeled with our Alexa Fluor® 594 conjugate of the anti-GFP antibody (A21312). Cells expressing GFP show dual labeling of both GFP (green fluorescence) and the anti-GFP antibody (red fluorescence). In this overlay of fluorescence and differential interference contrast (DIC) micrographs, the GFP-transfected cells exhibit green and red signals that overlap to yield yellow, and DAPI (D1306, D3571, D21490) stains the nuclei with a light-blue fluorescence. In the cells that are not transfected, the DAPI-stained nuclei exhibit a bright blue fluorescence.

In addition, we offer an affinity-purified IgY fraction of chicken anti-GFP antibody, both unlabeled (A10262) and as the biotin-XX conjugate (A10263). Chicken IgY lacks a classic Fc domain and therefore does not bind to mammalian IgG Fc receptors, resulting in lower backgrounds during immunostaining protocols. The chicken IgY is also antigenically different from the mammalian IgG, allowing antibodies from both species to be used in a single immunostaining experiment.

Lastly, we offer a rabbit monoclonal anti-GFP antibody (G10362), as well as two mouse monoclonal anti-GFP antibodies. The rabbit monoclonal anti-GFP antibody is raised against full-length GFP and is suitable for applications such as ELISAs, immunohistochemistry, immunocytochemistry, immunoprecipitation and western blotting. Mouse monoclonal 11E5 (anti-GFP, clone 11E5; A11121) is optimized for western analysis, allowing colorimetric detection of as little as 10 ng of GFP or GFP-fusion proteins. Mouse monoclonal 3E6 (anti-GFP, clone 3E6; A11120) is useful for immunoprecipitation, immunocytochemical localization and immunosorbent assays (ELISAs).

Anti-Red Fluorescent Protein (RFP) Antibody

We offer an affinity-purified rabbit polyclonal anti-Red Fluorescent Protein antibody (anti-RFP, R10367) for western blot and immunocytochemistry applications. Full-length recombinant denatured and non-denatured TagRFP was used as the immunogen, making the antibody suitable for immunocytochemical detection of the expression products of our CellLight® RFP BacMam vectors (Table 11.1; Note 11.1—BacMam Gene Delivery and Expression Technology).

Anti-Glutathione S-Transferase Antibody

One common partner in protein fusions is glutathione S-transferase (GST), a protein with natural binding specificity for glutathione that can be exploited to facilitate its purification.⁸ We prepare a highly purified rabbit polyclonal anti-GST antibody (A5800) that can be used for western blot analysis, immunodetection and immunoprecipitation of GST fusion proteins.^{9,10} This highly specific and high-titer antibody, which was generated against a 260-amino acid N-terminal fragment of the *Schistosoma japonica* enzyme expressed in *Escherichia coli*, is particularly useful for detecting GST distribution in cells.¹⁰⁻¹² To facilitate the localization of GST and GST-fusion proteins using immunofluorescence techniques, we prepare the anti-GST antibody labeled with our green-fluorescent Alexa Fluor® 488 dye (A11131).

Figure 7.5.2 Coomassie brilliant blue-stained SDS-polyacrylamide gel, demonstrating the purification of a glutathione S-transferase (GST) fusion protein using glutathione agarose (G2879). Lane 1 contains crude supernatant from an *Escherichia coli* lysate and lane 2 contains the affinity-purified GST fusion protein.

Because the GST portion of the fusion protein retains its affinity and selectivity for glutathione, the fusion protein can be conveniently purified from the cell lysate in a single step by affinity chromatography on glutathione agarose¹³⁻¹⁸ (Figure 7.5.2). For the purification of GST fusion proteins, we offer glutathione linked via the sulfur atom to cross-linked beaded agarose, which is available as 10 mL of a sedimented bead suspension (G2879, Section 9.4).

Anti-β-Glucuronidase Antibody

The *E. coli* β-glucuronidase (GUS) gene (*uidA*) is a popular reporter gene in plants.¹⁹⁻²² For western blot and immunohistochemical analysis of transformed plant tissue^{23,24} and transfected animal cells,²⁵ we offer unlabeled rabbit anti-β-glucuronidase antibody (A5790) raised against *E. coli* type X-A β-glucuronidase. Our fluorogenic and chromogenic β-glucuronidase substrates are described in Section 10.2.

Anti-β-Galactosidase Antibody

We offer a polyclonal antibody to the widely used reporter gene product β-galactosidase. Our rabbit anti-β-galactosidase antibody (A11132) is raised against *E. coli*-derived β-galactosidase and demonstrates high specificity for the enzyme. Whether the enzyme is used as a reporter or as a fusion protein, this antibody provides an easy tool for detecting the β-galactosidase protein. The antibody is suited to a variety of techniques, including immunoblotting, ELISA and immunoprecipitation. Our fluorogenic and chromogenic β-galactosidase substrates are described in Section 10.2.

Antibodies Specific for Epitope Tags

Epitope tagging is a powerful and versatile strategy for detecting and purifying proteins expressed by cloned genes. Protein expression vectors are often engineered with a nucleotide sequence that encodes a peptide epitope tag. Typically, a gene is cloned in-frame relative to the epitope tag such that, upon expression, a fusion protein containing the epitope tag is synthesized. Detection and purification of the epitope-tagged fusion protein can be mediated by antibodies to the engineered peptide, thus eliminating the need for antibodies to proteins from each newly cloned gene. Here we highlight a series of antibodies to common epitopes, including oligohistidine, hemagglutinin (HA) and c-myc, but a more comprehensive list can be found using our online primary antibody search utility at www.invitrogen.com/handbook/antibodies.

Penta-His Antibody

The oligohistidine domain is a Ni²⁺-binding peptide sequence comprising a sequence of four to six histidine residues.^{26,27} When the DNA sequence corresponding to an oligohistidine domain is fused in-frame with a gene of interest, the resulting recombinant fusion protein can be easily purified using a nickel-chelating resin.^{27,28}

In collaboration with QIAGEN, we offer a highly selective antibody to oligohistidine fusion proteins (Penta-His mouse monoclonal antibody, P21315). The antibody is useful for detecting sequences of five or six histidine residues, whether present at the C-terminus, the N-terminus or an internal position in a protein, in both western blots and in immunohistochemistry.

The Penta-His antibody can detect as little as 1–2 ng in western blot applications using fluorescent or chemiluminescent development techniques (Figure 7.5.3); the supplied amount (100 μg) is sufficient for

50–100 minigel blots. This antibody does not recognize tetrahistidine domains or domains in which the histidine string is interrupted by another amino acid. The antibody binds to the oligohistidine domain regardless of the surrounding amino acid context and even when the group is partially hidden, although subtle differences in the amino acid context may change the sensitivity limit for a particular fusion protein. The Penta-His antibody is directly useful for immunoprecipitation, ELISAs and immunohistochemistry.

Anti-HA Antibody

Our mouse monoclonal anti-hemagglutinin (HA) antibody was raised against the 12–amino acid peptide CYPYDVPDYASL. It recognizes the influenza hemagglutinin epitope YPYDVPDYA, which has been used extensively as a general epitope tag in expression vectors.²⁹ The extreme specificity of this antibody permits unambiguous identification and quantitative analysis of the tagged protein. This antibody is effective in immunoblotting, immunofluorescence and immunoprecipitation of tagged proteins. We offer Alexa Fluor® 488 (A21287) and Alexa Fluor® 594 (A21288) conjugates of the anti-HA antibody for those applications that require a directly conjugated antibody.

Anti-c-myc Antibody

We offer two antibodies to c-myc, which is commonly used in epitope tagging.²⁹ Our mouse monoclonal anti-c-myc antibody (IgG_{1κ}, clone 238; A21280) was raised against the peptide AEEQKLISEEDLLRKRREQLKHKLEQLRNSCA, which corresponds to amino acids 408–439 of the human c-myc protein. The chicken anti-c-myc antibody (IgY, A21281) was raised against the peptide EQKLISEEDL. These antibodies specifically react with the C-terminal epitope (AEEQKLISEEDL)³⁰ of human c-myc protein encoded in many expression vectors.

Figure 7.5.3 Detection of an oligohistidine fusion protein with the Penta-His mouse monoclonal antibody. Two-fold serial dilutions of an *Escherichia coli* lysate containing overexpressed oligomycin sensitivity-conferring protein (OSCP) fused with a hexahistidine domain were run on an SDS-polyacrylamide gel and blotted onto a PVDF membrane. The blot was stained with the SYPRO® Ruby protein blot stain (S11791) to detect the entire protein profile (top). After imaging, the blot was incubated with Penta-His mouse IgG₁ monoclonal antibody (P21315), followed by immunodetection using an alkaline phosphatase conjugate of goat anti-mouse antibody in conjunction with DDAO phosphate (bottom).

PRODUCT LIST 7.5 ANTIBODIES AGAINST EXPRESSION TAGS

Cat. No.	Product	Quantity
A21281	anti-c-myc, chicken IgY fraction *1 mg/mL*	100 µL
A21280	anti-c-myc, mouse IgG ₁ , monoclonal 289-19510 *1 mg/mL*	100 µL
A11132	anti-β-galactosidase, rabbit IgG fraction *2 mg/mL*	0.5 mL
A5790	anti-β-glucuronidase, rabbit IgG fraction *2 mg/mL*	0.5 mL
A5800	anti-glutathione S-transferase, rabbit IgG fraction *3 mg/mL*	0.5 mL
A11131	anti-glutathione S-transferase, rabbit IgG fraction, Alexa Fluor® 488 conjugate *2 mg/mL*	0.5 mL
A10262	anti-green fluorescent protein, chicken IgY fraction (anti-GFP, IgY) *2 mg/mL*	100 µL
A10263	anti-green fluorescent protein, chicken IgY fraction, biotin-XX conjugate (anti-GFP, IgY, biotin-XX conjugate) *2 mg/mL*	100 µL
A11120	anti-green fluorescent protein, mouse IgG _{2a} , monoclonal 3E6 (anti-GFP, mAb 3E6)	100 µg
A11121	anti-green fluorescent protein, mouse IgG ₁ , monoclonal 11E5 (anti-GFP, mAb 11E5)	100 µg
A11122	anti-green fluorescent protein, rabbit IgG fraction (anti-GFP, IgG) *2 mg/mL*	100 µL
A21311	anti-green fluorescent protein, rabbit IgG fraction, Alexa Fluor® 488 conjugate (anti-GFP, IgG, Alexa Fluor® 488 conjugate) *2 mg/mL*	100 µL
A31851	anti-green fluorescent protein, rabbit IgG fraction, Alexa Fluor® 555 conjugate (anti-GFP, IgG, Alexa Fluor® 555 conjugate) *2 mg/mL*	100 µL
A21312	anti-green fluorescent protein, rabbit IgG fraction, Alexa Fluor® 594 conjugate (anti-GFP, IgG, Alexa Fluor® 594 conjugate) *2 mg/mL*	100 µL
A31852	anti-green fluorescent protein, rabbit IgG fraction, Alexa Fluor® 647 conjugate (anti-GFP, IgG, Alexa Fluor® 647 conjugate) *2 mg/mL*	100 µL
A10259	anti-green fluorescent protein, rabbit IgG fraction, biotin-XX conjugate (anti-GFP, IgG, biotin-XX conjugate) *2 mg/mL*	100 µL
A10260	anti-green fluorescent protein, rabbit IgG fraction, horseradish peroxidase conjugate (anti-GFP, IgG, HRP)	200 µg
A6455	anti-green fluorescent protein, rabbit serum (anti-GFP, serum)	100 µL
A21287	anti-hemagglutinin, mouse IgG ₁ , monoclonal 16B12, Alexa Fluor® 488 conjugate (anti-HA, Alexa Fluor® 488 conjugate) *1 mg/mL*	100 µL
A21288	anti-hemagglutinin, mouse IgG ₁ , monoclonal 16B12, Alexa Fluor® 594 conjugate (anti-HA, Alexa Fluor® 594 conjugate) *1 mg/mL*	100 µL
G10362	GFP, ABfinity™ recombinant rabbit monoclonal antibody, unconjugated (anti-GFP, rabbit mAb)	100 µg
P21315	Penta-His mouse IgG ₁ , monoclonal antibody (anti-pentahistidine) *BSA free*	100 µg
R10367	RFP, rabbit polyclonal antibody, unconjugated (anti-RFP)	100 µg

7.6 Avidin and Streptavidin Conjugates

The high affinity of avidin for biotin was first exploited in histochemical applications in the mid-1970s.^{1,2} This egg-white protein and its bacterial counterpart, streptavidin, have since become standard reagents for diverse detection schemes.^{3–6} In their simplest form, such avidin–biotin detection methods entail applying a biotinylated probe to a sample and then detecting the bound probe with a labeled avidin or streptavidin. These techniques are commonly used to localize antigens in cells and tissues^{7,8} and to detect biomolecules in immunoassays and DNA hybridization procedures.^{6,9–11} In some applications, immobilized avidins are used to capture and release biotinylated targets. In addition to our dye and enzyme conjugates of avidins and streptavidins, this section contains several products that can be used for the affinity isolation of biotin-conjugated molecules and their complexes in cell and tissues.

Our diverse set of biotinylation reagents and biotin conjugates are described in Section 4.3. Combining one of our biotinylated or DSB-X™ biotin-labeled secondary antibodies (Section 7.2, Table 7.1) with a fluorescent dye- or enzyme-labeled avidin provides an sensitive method for the indirect detection of antibodies from various animal sources.

Binding Characteristics of Biotin-Binding Proteins

Avidin, streptavidin and NeutrAvidin™ biotin-binding protein each bind four biotins per molecule with high affinity and selectivity. Dissociation of biotin from streptavidin (S888) is reported to be about 30 times faster than dissociation of biotin from avidin¹² (A887, A2667). Their multiple binding sites permit a number of techniques in which unlabeled avidin, streptavidin or NeutrAvidin™ biotin-binding protein can be used to bridge two biotinylated reagents. This bridging method, which is commonly used to link a biotinylated probe to a biotinylated enzyme in enzyme-linked immunohistochemical applications, often eliminates the background problems that can occur when using direct avidin- or streptavidin-enzyme conjugates. However, endogenously biotinylated proteins that have carboxylase activity are

Figure 7.6.1 The cytoskeleton of a fixed and permeabilized bovine pulmonary artery endothelial cell detected using mouse monoclonal anti- α -tubulin antibody (A11126), visualized with Alexa Fluor® 647 goat anti-mouse IgG antibody (A21235) and pseudocolored magenta. Endogenous biotin in the mitochondria was labeled with green-fluorescent Alexa Fluor® 488 streptavidin (S11223) and DNA was stained with blue-fluorescent DAPI (D1306, D3571, D21490).

found in the mitochondria (Figure 7.6.1); therefore, sensitive detection of biotinylated targets in cells requires the use of biotin-blocking agents to reduce this background.^{13,14} Our Endogenous Biotin-Blocking Kit (E21390) provides the reagents and a protocol for this application. Nonspecific binding of avidin conjugates of enzymes to nitrocellulose can be blocked more effectively by adding extra salts to buffers rather than by adding protein-based blocking reagents.¹⁵

High-purity unlabeled avidin (A887), streptavidin (S888), NeutrAvidin™ biotin-binding protein (A2666) and CaptAvidin™ biotin-binding protein (C21385) are available in bulk. We also offer avidin specially packaged in a smaller unit size for extra convenience (A2667). Our avidin, streptavidin and deglycosylated NeutrAvidin™ biotin-binding protein typically bind greater than 12 μ g of biotin per mg protein.

Avidin

Avidin (A887, A2667; Table 7.9) is a highly cationic 66,000-dalton glycoprotein^{16,17} with an isoelectric point of about 10.5. It is thought that avidin's positively charged residues and its oligosaccharide component (heterogeneous structures composed largely of mannose and *N*-acetylglucosamine) can interact nonspecifically with negatively charged cell surfaces and nucleic acids, sometimes causing background problems in some histochemical applications and flow cytometry. Methods have been developed to suppress this nonspecific avidin binding.¹⁴ In some cases, avidin's nonspecific binding can also be exploited. For example, avidin and its conjugates selectively bind to a component in rodent and human mast cell granules in fixed-cell preparations and can be used to identify mast cells in normal and diseased human tissue without requiring a biotinylated probe.^{18,19}

Streptavidin

Streptavidin (S888, Table 7.9), a nonglycosylated 52,800-dalton protein with a near-neutral isoelectric point, reportedly exhibits less nonspecific binding than avidin. However, streptavidin contains the tripeptide sequence Arg–Tyr–Asp (RYD) that apparently mimics the Arg–Gly–Asp (RGD) binding sequence of fibronectin, a component of the extracellular matrix that specifically promotes cellular adhesion.²⁰ This universal recognition sequence binds integrins and related cell-surface molecules.^{21,22} Background problems sometimes associated with streptavidin may be attributable to this tripeptide. We have particularly observed binding of streptavidin and anti-biotin²³ conjugates to mitochondria in some cells (Figure 7.6.1) that can be blocked with the reagents in our Endogenous Biotin-Blocking Kit (E21390).

NeutrAvidin™ Biotin-Binding Protein

We provide an alternative to the commonly used avidin and streptavidin. Our conjugates of NeutrAvidin™ biotin-binding protein (A2666, Table 7.9)—a protein that has been processed to remove the carbohydrate and lower its isoelectric point—can sometimes reduce background staining. The methods used to deglycosylate the avidin are reported to retain both its specific binding²⁴ and its complement of amine-conjugation sites. NeutrAvidin™ conjugates have been shown to provide improved detection of single-copy genes in metaphase chromosome spreads.²⁵

Table 7.9 Molecular Probes® avidin, streptavidin, NeutrAvidin™ and CaptAvidin™ conjugates.

Figure 7.6.2 Diagram of the use of CaptAvidin™ agarose (C21386) in affinity chromatography. A biotinylated IgG molecule and target antigen are used as an example.

CaptAvidin™ Biotin-Binding Protein: Reversible Binding of Biotinylated Molecules

In addition to avidin, streptavidin and NeutrAvidin™ biotin-binding protein, we offer CaptAvidin™ biotin-binding protein (C21385, Table 7.9). Selective nitration of tyrosine residues in the four biotin-binding sites of avidin considerably reduces the affinity of the protein for biotinylated molecules above pH 9.²⁶ Consequently, biotinylated probes can be adsorbed at neutral pH and released at pH ~10 (Figure 7.6.2). We use free biotin to block any remaining high-affinity biotin-binding sites that have not been nitrated. CaptAvidin™ agarose (C21386) is particularly useful for separating and purifying biotin conjugates from complex mixtures. The biotin-binding capacity of CaptAvidin™ derivatives is typically at least 10 μg of free biotin per mg protein.

Secondary Detection with Avidins

Avidin, streptavidin and NeutrAvidin™ conjugates are extensively used as secondary detection reagents in histochemical applications (Figure 7.6.3, Figure 7.6.4), FISH (Figure 7.6.5), flow cytometry,^{27,28} microarrays (Figure 7.6.6) and blot analysis. These reagents can also be employed to localize biocytin, biotin ethylenediamine or any of our fluorescent biocytins—all of which are biotin derivatives commonly used as neuroanatomical tracers^{29,30} (Section 14.3).

The following are commonly used methods for employing avidin, streptavidin, NeutrAvidin™ biotin-binding protein and CaptAvidin™ biotin-binding protein as secondary detection reagents:

Figure 7.6.3 The cortical region of the developing follicle of the giant silkworm *Antheraea polyphemus* stained with a monoclonal antibody against cytoskeletal actin. The primary antibody was visualized using biotin-XX goat anti-mouse IgG antibody (B2763), followed by incubation with Texas Red® streptavidin (S872). The orange to pink colors in this confocal laser-scanning micrograph show the distribution of cytoskeletal actin in the oocyte cortex and follicle cell cytoplasm. The blue color can be attributed to autofluorescence. The image was contributed by Ivo Sauman, Wesleyan University.

Figure 7.6.4 The "delta" region of a developing follicle of the giant silkworm *Hyalophora cecropia* stained with an antibody against the largest subunit of the *Drosophila* RNA polymerase II (RNAP II). The primary antibody was visualized using a biotinylated secondary antibody followed by Texas Red® dye-conjugated streptavidin (S872). The distribution of the RNAP II appears violet because the Texas Red® staining colocalizes with the blue autofluorescence of the yolk granules. Image contributed by Ivo Sauman, Wesleyan University.

Figure 7.6.5 Fluorescence *in situ* hybridization detected by tyramide signal amplification. Chromosome spreads were prepared from the cultured fibroblast cell line MRC-5 and hybridized with a biotinylated α -satellite probe specific for chromosome 17. The probe was generated by nick translation in the presence of biotinylated dUTP. For detection by TSA™, hybridized chromosome spreads were labeled using TSA™ Kit #22 (T20932) with HRP-conjugated streptavidin and Alexa Fluor® 488 tyramide (A) or using TSA™ Kit #23 (T20933) with HRP-conjugated streptavidin and Alexa Fluor® 546 tyramide (B). After counterstaining with DAPI (D1306, D3571, D21490), images were obtained using filters appropriate for DAPI, FITC or TRITC.

- **Direct procedure.** A biotinylated primary probe such as an antibody, single-stranded nucleic acid probe or lectin is bound to tissues, cells or other surfaces. Excess protein is removed by washing, and detection is mediated by reagents such as our fluorescent avidins, streptavidins or NeutrAvidin™ biotin-binding proteins (Figure 7.6.7) or our enzyme-conjugated streptavidins plus a fluorogenic, chromogenic or chemiluminescent substrate. Enzyme conjugates of streptavidin are key reagents in some of our Tyramide Signal Amplification (TSA™) Kits (Section 6.2, Figure 7.6.5).
- **Capture and release.** Our unique DSB-X™ biotin technology permits the fully reversible labeling of DSB-X™ biotin derivatives by avidin and streptavidin conjugates.³¹ Consequently, targets in cells and tissues or on blots labeled with DSB-X™ biotin conjugates of antibodies or other DSB-X™ biotin reagents can initially be stained with fluorescent avidin or streptavidin conjugates, then the fluorescent staining can be reversed with D-biotin (B1595, B20656; Figure 7.6.8) and the sample restained with an enzyme-conjugated avidin or streptavidin derivative in conjunction with a permanent stain such as diaminobenzidine (DAB, D22187) or the combination of NBT and BCIP (N6495, B6492, N6547; Section 10.3).
- **Bridging methods.** A biotinylated antibody or oligonucleotide is used to probe a tissue, cell or other surface, and then this preparation is treated with unlabeled avidin, streptavidin or NeutrAvidin™ biotin-binding protein. Excess reagents are removed by washing, and detection is mediated by a biotinylated detection reagent such as a fluorescent biotin or biocytin dye (Section 4.3), biotinylated R-phycoerythrin³² (P811, Section 6.4), biotinylated FluoSpheres® microspheres (Section 6.5) or biotinylated horseradish peroxidase (P917) plus a fluorogenic, chromogenic or chemiluminescent substrate.
- **Indirect procedure.** An unlabeled primary antibody is bound to a cell followed by a biotinylated species-specific secondary antibody. After washing, the complex is detected by one of the two procedures described above. Our Zenon® Biotin-XX Antibody Labeling Kits (Section 7.3, Table 7.7) permit the rapid and quantitative biotinylation of antibodies for combination with avidin–biotin detection methods.

Figure 7.6.7 Microtubules of fixed bovine pulmonary artery endothelial cells (BPAEC) were localized with mouse monoclonal anti- α -tubulin antibody (A11126), followed by the biotin-XX-conjugated F(ab)₂ fragment of goat anti-mouse IgG antibody (B11027) and visualized with green-fluorescent Alexa Fluor® 488 streptavidin (S11223). Cells were counterstained with blue-fluorescent Hoechst 33342 (H1399, H3570, H21492) to image the DNA and red-fluorescent propidium iodide (P1304MP, P3566, P21493) to image nucleolar RNA. The multiple-exposure image was acquired using bandpass filter sets appropriate for Texas Red® dye, fluorescein and DAPI.

Figure 7.6.6 R-phycoerythrin used to detect DNA on a microarray. A DNA microarray containing a decreasing dilution of calf thymus DNA was hybridized with a biotinylated DNA probe and then incubated with R-phycoerythrin–streptavidin (SAPE; S866, S21388). After washing, the fluorescence signal was detected on a Packard ScanArray® 5000 using three different detection configurations: 488 nm excitation (argon-ion laser)/570 nm emission filter (left); 543.5 nm excitation (He-Ne laser)/570 nm emission filter (middle); 543.5 nm excitation (He-Ne laser)/592 nm emission filter (right).

Figure 7.6.8 Reversible binding by DSB-X™ biotin. Microtubules of fixed bovine pulmonary artery endothelial cells were labeled with mouse monoclonal anti- α -tubulin antibody (A11126), detected with either biotin-XX goat anti-mouse IgG antibody (B2763, panel A) or DSB-X™ biotin goat anti-mouse IgG antibody (D20691, panel B) and visualized with green-fluorescent Alexa Fluor® 488 streptavidin (S11223). Nuclei were stained with blue-fluorescent DAPI (D1306, D3571, D21490). After incubating with 10 mM D-biotin (B1595, B20656), the binding between the biotinylated antibody is unaltered (panel C), whereas the streptavidin conjugate has been stripped from the DSB-X™ biotin-labeled antibody (panel D).

Figure 7.6.9 A multinucleate HeLa cell in metaphase that was fixed and then stained with a combination of fluorescent dyes. The chromosomes were stained with DAPI (D1306, D3571, D21490). The cytoskeleton was detected with the biotin-XX conjugate of mouse monoclonal anti- α -tubulin antibody (A21371), which was then visualized with red-fluorescent Alexa Fluor® 568 streptavidin (S11226). The multiple-exposure image was acquired using filter sets appropriate for rhodamine and DAPI.

Endogenous Biotin and Biotinidase

Mammalian cells and tissues contain biotin-dependent carboxylases, which are required for a variety of metabolic functions. These biotin-containing enzymes often produce substantial background signals when avidin–biotin or streptavidin–biotin detection systems are used to identify cellular targets^{33,34} (Figure 7.6.1). Endogenous biotin is particularly prevalent in mitochondria^{35,36} and in kidney, liver and brain tissues.^{33,37} In mammalian serum and plasma, biotinylated proteins are susceptible to cleavage by endogenous biotinidases, producing free biotin and unlabeled protein.³⁸

The reagents in the Endogenous Biotin-Blocking Kit (E21390) can be used to minimize interference from endogenous biotin in these techniques. This kit provides streptavidin and biotin solutions in convenient dropper bottles and an easy-to-follow protocol. Sufficient material is provided for approximately one hundred 18 mm × 18 mm glass coverslips.

Fluorescent Avidin and Streptavidin Conjugates

Fluorophore-Labeled Avidin, Streptavidin and NeutrAvidin™ Biotin-Binding Protein

Fluorescent avidin and streptavidin are extensively used in DNA hybridization techniques,^{39,40} immunohistochemistry (Figure 7.6.9), MHC tetramer technology⁴¹ (MHC Tetramer Technology—Note 7.2) and multicolor flow cytometry.^{42–44} Our selection of avidin, streptavidin and NeutrAvidin™ conjugates continues to expand as we introduce new and improved fluorophores and signal amplification technologies (Table 7.9). We continue to provide avidin, streptavidin and NeutrAvidin™ conjugates of fluorescein (A821, S869, A2662), tetramethylrhodamine

NOTE 7.2

MHC Tetramer Technology

Cytotoxic T lymphocytes (CTLs) or "killer" T cells perform a crucial function in the vertebrate immune system by destroying cells that display foreign antigens on their surfaces. CTLs are distinguished from other types of T lymphocytes (such as "helper" T cells) by their expression of CD8, a transmembrane protein with immunoglobulin-like domains that interact with class I Major Histocompatibility Complexes¹ (MHCs). MHC molecules have a dual role; their amino-terminal domains bind antigen for presentation to T cells and also serve as a marker identifying host cells to the immune system. Activation of CTLs to eliminate a target cell occurs only if the CD8 protein recognizes the proper MHC molecule and the α/β T cell receptor binds the MHC-presented antigen.²

Historically, assays for an antigen-specific T cell response made use of the limiting dilution analysis (LDA) method, which requires that single clones survive, divide and differentiate before they can be detected. However, this method likely underestimates the number of CTLs that respond to a particular antigen because it will not detect cells that are part of the expanded effector population that can no longer divide.³ Alternate approaches attempt to directly measure CTL response using an antigenic peptide and MHC. However, these experiments are hampered by the low affinity of the interaction between the MHC/antigen complex and the corresponding CTL receptors.⁴

Joining multiple copies of the MHC/antigen complex into a single probe—tetramer technology—resolves the difficulties presented by the low affinity of the class I MHC molecule for the CD8 receptor.⁵ CTL response assays using tetramer technology often detect a response rate that is 50–500 times higher than detected by the LDA method,³ and they have proven indispensable for the study of the CTL response to HIV, cancers and transplants.⁶ Similar methods using class II MHC tetramers are also being employed to explore the response of helper (CD4 expressing) T cells.⁷

MHC tetramers are formed by first refolding MHCs in the presence of high concentrations of the desired antigenic peptide, followed by biotinylation of the carboxy-terminus of one chain of the MHC molecule. This MHC/peptide complex can then be bound to streptavidin. Because the latter has four biotin-binding sites, four MHC molecules can be linked together in a single complex (Figure 1). The use of fluorophore-labeled streptavidin or streptavidin-coated magnetic beads for tetramer formation allows for efficient detection by flow cytometry or immunomagnetic methods.^{8–10} It is critical for MHC tetramer-based assays that the labeled streptavidin be free of unlabeled streptavidin because this lowers the apparent activity of the MHC complex by "blocking" the biotinylation site from binding to the labeled streptavidin.

Figure 1 An MHC tetramer.

(S870, A6373), rhodamine B (S871) and Texas Red® (A820, S872, A2665, S6370) dyes. However, we strongly recommend that researchers evaluate our many newer fluorescent conjugates:

- The green-fluorescent Alexa Fluor® 488 and Oregon Green® conjugates are not only brighter than fluorescein conjugates, but also much more photostable (Figure 7.6.10) and less pH sensitive (Section 1.3).
- The orange- and red-orange-fluorescent Alexa Fluor® 546, Alexa Fluor® 555, Alexa Fluor® 568 and Rhodamine Red™-X dyes, and the red-fluorescent Alexa Fluor® 594 and Texas Red®-X dyes are more fluorescent than traditional Lissamine rhodamine B and Texas Red® conjugates, yet have similar excitation and emission maxima.
- The far-red- and infrared-fluorescent Alexa Fluor® 633, Alexa Fluor® 635, Alexa Fluor® 647, Alexa Fluor® 660, Alexa Fluor® 680, Alexa Fluor® 700 and Alexa Fluor® 750 conjugates of streptavidin have fluorescence that is not visible to the eye, but they are efficiently excited by laser light sources and their fluorescence is easily detected with infrared light-sensitive detectors. Conjugates of the Alexa Fluor® 555 and Alexa Fluor® 647 dyes, in particular, have fluorescence that is superior to that of the spectrally similar Cy*3 and Cy*5 dyes,⁴⁵ respectively, and their conjugates are more photostable than Cy*3 and Cy*5 conjugates (Figure 7.6.11).
- The blue-fluorescent Alexa Fluor® 350 streptavidin (S11249) displays significantly more fluorescence than AMCA streptavidin (Figure 7.6.12) in side-by-side testing. The blue-fluorescent Alexa Fluor® 405 streptavidin (S32351), Pacific Blue™ streptavidin (S11222), yellow-fluorescent Cascade Yellow™ streptavidin (S11228) and orange-fluorescent Pacific Orange™ streptavidin (S32365) absorb maximally between 400 and 410 nm, making them near-perfect matches to the 405 nm violet laser used for both fluorescence microscopy and flow cytometry.
- R-phycoerythrin (R-PE) conjugates of streptavidin (SAPE; S866, S21388) and NeutrAvidin™ biotin-binding protein (A2660) and the B-phycoerythrin (B-PE) conjugate of streptavidin (S32350) are significantly brighter than our organic dye-conjugated avidins. Our streptavidin conjugates of R-PE and B-PE have been purified to help ensure that all unconjugated streptavidin has been removed (Figure 7.6.13), making them particularly important labels for multicolor flow cytometry (Section 6.4).

Furthermore, we have conjugated R-PE with four of our Alexa Fluor® dyes—the Alexa Fluor® 610, Alexa Fluor® 647, Alexa Fluor® 680 and Alexa Fluor® 750 dyes—and then conjugated these tandem labels to streptavidin to yield labeled conjugates that can be excited with the 488 nm spectral line of the argon-ion laser. The long-wavelength emission maxima are 628 nm for the Alexa Fluor® 610–R-PE conjugate (S20982), 668 nm for the Alexa Fluor® 647–R-PE conjugate (S20992), 702 nm for the Alexa Fluor® 680–R-PE conjugate (S20985) and 775 nm for the Alexa Fluor® 750–R-PE conjugate (S32363). Emission of the Alexa Fluor® 610–R-PE conjugates is shifted to longer wavelengths by about 13 nm relative to that of Texas Red® conjugates of R-PE

Figure 7.6.12 Comparison of the relative fluorescence of 7-amino-4-methylcoumarin-3-acetic acid (AMCA) streptavidin (O) and Alexa Fluor® 350 streptavidin, a sulfonated AMCA derivative (S11249, ●). Conjugate fluorescence is determined by measuring the fluorescence quantum yield of the conjugated dye relative to that of the free dye and multiplying by the number of fluorophores per protein.

Figure 7.6.13 Analytical size-exclusion chromatograms of free streptavidin (S888; red curve, detected by absorption at 280 nm) and R-phycoerythrin streptavidin (SAPE; S866, S21388; blue curve, detected by absorption at 565 nm), demonstrating that the R-phycoerythrin conjugate is substantially free of unconjugated streptavidin.

Figure 7.6.10 Photobleaching resistance of the green-fluorescent Alexa Fluor® 488, Oregon Green® 488 and fluorescein dyes, as determined by laser-scanning cytometry. EL4 cells were labeled with biotin-conjugated anti-CD44 antibody and detected by Alexa Fluor® 488 (S11223), Oregon Green® 488 (S6368) or fluorescein (S869) streptavidin. The cells were then fixed in 1% formaldehyde, washed and wet-mounted. After mounting, cells were scanned 10 times on a laser-scanning cytometer; laser power levels were 25 mW for the 488 nm spectral line of the argon-ion laser. Scan durations were approximately 5 minutes apiece, and each repetition was started immediately after completion of the previous scan. Data are expressed as percentages derived from the mean fluorescence intensity (MFI) of each scan divided by the MFI of the first scan. Data contributed by Bill Telford, Experimental Transplantation and Immunology Branch, National Cancer Institute.

Figure 7.6.11 Photobleaching resistance of the red-fluorescent Alexa Fluor® 647, Alexa Fluor® 633, PBXL-3 and Cy*5 dyes and the allophycocyanin fluorescent protein, as determined by laser-scanning cytometry. EL4 cells were labeled with biotin-conjugated anti-CD44 antibody and detected by Alexa Fluor® 647 (S21374), Alexa Fluor® 633 (S21375), PBXL-3, Cy*5 or allophycocyanin (APC, S868) streptavidin. The cells were then fixed in 1% formaldehyde, washed and wet-mounted. After mounting, cells were scanned eight times on a laser-scanning cytometer; laser power levels were 18 mW for the 633 nm spectral line of the He-Ne laser. Scan durations were approximately 5 minutes apiece, and each repetition was started immediately after completion of the previous scan. Data are expressed as percentages derived from the mean fluorescence intensity (MFI) of each scan divided by the MFI of the first scan. Data contributed by Bill Telford, Experimental Transplantation and Immunology Branch, National Cancer Institute.

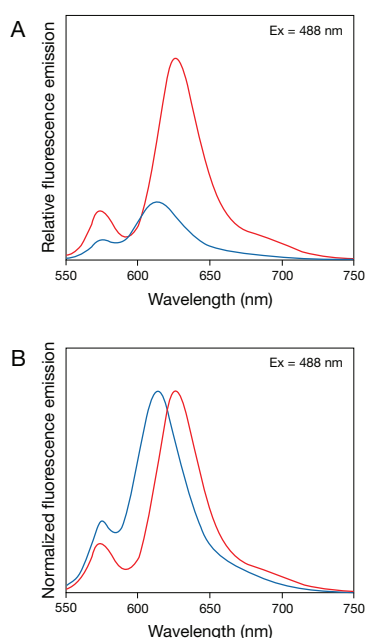

Figure 7.6.14 Fluorescence emission spectra of Alexa Fluor® 610-R-phycoerythrin streptavidin (S20982, red) and Texas Red® dye-R-phycoerythrin streptavidin (blue) tandem conjugates. **A)** A comparison of the spectra on a relative fluorescence intensity scale for samples prepared with equal absorbance at the excitation wavelength (488 nm). **B)** The same data normalized to the same peak intensity value to facilitate comparison of the spectral profiles.

(Figure 7.6.14), significantly improving the resolution that can be obtained in multicolor flow cytometry. The Alexa Fluor® 647-R-PE tandem conjugates have spectra virtually identical to those of Cy5 conjugates of R-PE but are about three times more fluorescent (Figure 7.6.15). We have also conjugated allophycocyanin (APC) with three of our Alexa Fluor® dyes—Alexa Fluor® 680, Alexa Fluor® 700 and Alexa Fluor® 750 dyes—and then conjugated these tandem labels to streptavidin (S21002, S21005, S21008). The resulting probes can all be excited by the He-Ne laser at 633 nm and have distinguishable emission spectra. A complete list of our current offerings of fluorophore-, enzyme- and gold-labeled avidins, streptavidins and NeutrAvidin™ biotin-binding proteins can be found in Table 7.9.

Streptavidin-, NeutrAvidin™- and Biotin-Labeled Fluorescent Microspheres

We offer streptavidin, NeutrAvidin™ and biotin conjugates of the intensely fluorescent FluoSpheres® and TransFluoSpheres® polystyrene microspheres in a variety of colors and sizes, including our europium and platinum luminescent beads labeled with the NeutrAvidin™ biotin-binding protein for time-resolved fluorometry (Table 14.8). Because single fluorescent microspheres can be detected, FluoSpheres® and TransFluoSpheres® beads have significant potential for ultrasensitive flow cytometry applications and immunoassays.^{46,47} They may also be useful as tracers that can be detected with standard enzyme-mediated histochemical methods (Section 14.6).

BlockAid™ blocking solution (B10710) is a protein-based reagent designed principally for use with our streptavidin-, NeutrAvidin™- and biotin-labeled FluoSpheres® (Table 6.8) and our streptavidin- and NeutrAvidin™-labeled TransFluoSpheres® microspheres (Table 6.9). Protein- and other macromolecule-labeled microspheres have hydrophobic regions that may cause them to bind to nontarget surfaces in some experimental systems. Although this nonspecific binding can often be relieved by the use of a blocking solution, we have found that microspheres require a stronger blocking solution than those in common use. In our tests, the BlockAid™ blocking solution was mixed with streptavidin-labeled FluoSpheres® microspheres, which were then used to stain several different cell types for subsequent analysis by flow cytometry. We found the BlockAid™ blocking solution to be superior to other commercially available blocking solutions, as well as to several standard blocking solutions described in the scientific literature for reducing nonspecific binding of labeled microspheres. BlockAid™ blocking solution has been found to be effective in flow cytometry applications with the NIH 3T3, A431, RAW and Jurkat cell lines; however, with the HMC-1 cell line, it did not appear to offer any advantages over standard blocking solutions. We expect that the BlockAid™ blocking solution will be useful for reducing the nonspecific binding of protein-coated or other macromolecule-coated microspheres in a variety of flow cytometry and microscopy applications.⁴⁸⁻⁵⁰

Qdot® Streptavidin Conjugates

Qdot® streptavidin conjugates combine the highly specific binding properties of streptavidin with the exceptional photostability of Qdot® nanocrystals (Section 6.6). The large surface area afforded by the Qdot® nanocrystal allows simultaneous conjugation of multiple streptavidin molecules to a single fluorophore. Advantages conferred by this approach include increased avidity for targets, the potential for cooperative binding in some cases and the use of efficient signal amplification methodologies. For example, combining biotin-functionalized products with the streptavidin labels allows for successive enhancements in signal via “sandwiching” (streptavidin/biotin/streptavidin, etc.) following an initial labeling step.

These powerful fluorescence detection reagents offer unique performance advantages in a wide variety of tissue labeling and flow cytometry experiments; they are efficiently excited using the 405 nm violet laser, and the Qdot® nanocrystal fluorescence is extremely resistant to photobleaching. Not only can tissues stained with Qdot® nanocrystals be observed for hours, but these stained tissues can be archived permanently; re-analysis of properly stored archive samples remains as quantitative as it was during the initial assay.

Our selection of Qdot® streptavidin conjugates can all be excited by a single excitation source, enabling easy multicolor analysis of multiple targets or events in a single sample using color filtering to resolve the individual signals:

- Qdot® 525 streptavidin conjugate (Q10141MP)
- Qdot® 565 streptavidin conjugate (Q10131MP)
- Qdot® 585 streptavidin conjugate (Q10111MP)

- Qdot® 605 streptavidin conjugate (Q10101MP)
- Qdot® 655 streptavidin conjugate (A10196)
- Qdot® 655 streptavidin conjugate (Q10121MP)
- Qdot® 705 streptavidin conjugate (Q10161MP)
- Qdot® 800 streptavidin conjugate (Q10171MP)
- Qdot® Streptavidin Sampler Kit (Q10151MP)

Nucleic acid hybridization can be detected by complexation of terminally biotinylated oligonucleotides with Qdot® streptavidin conjugates.^{51–54} Qdot® streptavidin conjugates in combination with biotinylated antibodies provide increased multiplexing capacity for immunodetection of proteins on both imaging^{55–59} and flow cytometry^{60,61} platforms. Single-particle tracking of molecular motion is a particularly compelling application of Qdot® streptavidin conjugates that takes advantage of their extraordinary fluorescence capacity.⁶² The principal subjects for these measurements are cell-surface receptors^{62–68} and molecular motors such as myosin.^{69,70} Single-molecule detection uncovers details of molecular motion and assembly that are obscured by the averaging effects of bulk measurements. Qdot® nanocrystals are quite essential in such applications, as fluorescence photon output ultimately propagates into the spatial and temporal resolution of the measurements.

Typically, labeling is accomplished using biotinylated ligands such as biotin EGF (E3477, Section 4.3) and biotin-XX α -bungartoxin (B1196, Section 4.3) to couple Qdot® streptavidin conjugates to the receptor of interest. Because these conjugates incorporate multiple streptavidins (typically 5–10) per Qdot® nanocrystal, careful attention must be paid to the streptavidin:ligand stoichiometry to avoid receptor crosslinking mediated by the Qdot® streptavidin–biotinylated ligand complex.^{67,71} A molar excess of Qdot® streptavidin conjugate over the biotinylated ligand biases the complex stoichiometry towards the desired outcome of one ligand per nanocrystal. Qdot® streptavidin conjugates are supplied as 1 μ M solutions in 50 mM borate, pH 8.3 containing 0.05% sodium azide and 1 M betaine cryoprotectant in 200 μ L units. The Qdot® Streptavidin Sampler Kit (Q10151MP) provides 50 μ L units of six different Qdot® streptavidin conjugates in a single package.

We also offer Qdot® ITK™ streptavidin quantum dots, in which streptavidin is directly attached to the inner amphiphilic coating without a PEG linker. This formulation results in a smaller overall particle size and an increase in the number of streptavidins per nanocrystal relative to PEG-linked conjugates. These characteristics are advantageous in fluorescence resonance energy transfer (FRET) assays for detecting hybridization of target nucleic acid sequences to biotinylated oligonucleotides captured on the Qdot® nanocrystal surface.^{72–74} Qdot® ITK™ streptavidin conjugates are described in Section 6.6.

Enzyme Conjugates of Avidin and Streptavidin

Enzyme conjugates of avidin and streptavidin are extensively used in enzyme-linked immunosorbent assays (ELISAs),⁷⁵ blotting techniques,⁷⁶ *in situ* hybridization⁷⁷ and cytochemistry and histochemistry.⁷⁸ Enzyme-mediated *in situ* techniques using these conjugates provide better resolution and are safer, more sensitive and faster than radioactive methods. Most frequently, the enzymes of choice are horseradish peroxidase, alkaline phosphatase and *Escherichia coli* β -galactosidase because of their high turnover rate, stability, ease of conjugation and relatively low cost.

Our enzyme conjugates of streptavidin and NeutrAvidin™ biotin-binding protein are prepared by techniques that yield an approximate 1:1 ratio of enzyme to avidin analog, thus maximizing retention of both enzyme and carrier protein activity. We have prepared highly active streptavidin and NeutrAvidin™ biotin-binding protein conjugates of horseradish peroxidase⁷⁹ (S911, A2664), alkaline phosphatase (S921), β -galactosidase (S931) and β -lactamase TEM-1 (S31569). Fluorogenic, chromogenic and chemiluminescent substrates for these enzymes are described in Chapter 10. To decrease background problems, researchers often prefer to use the biotin-XX conjugate of horseradish peroxidase (P917) in conjunction with an avidin or streptavidin bridge for indirect detection of a wide array of biotinylated biomolecules.

A principal application of HRP and alkaline phosphatase conjugates of avidins and secondary antibodies is in enzyme-amplified histochemical staining of cells and tissues. Several of the Tyramide Signal Amplification (TSA™) Kits (Table 6.1) in Section 6.2 and Enzyme-Labeled Fluorescence (ELF®) Kits in Section 6.3 utilize enzyme conjugates of streptavidin to yield

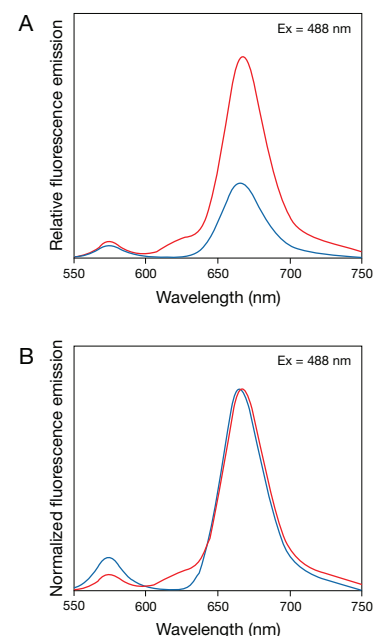

Figure 7.6.15 Fluorescence emission spectra of Alexa Fluor® 647-R-phycoerythrin streptavidin (S20992; red) and Cy5-R-phycoerythrin streptavidin (blue) tandem conjugates. **A)** A comparison of the spectra on a relative fluorescence intensity scale for samples prepared with equal absorbance at the excitation wavelength (488 nm). **B)** The same data normalized to the same peak intensity value to facilitate comparison of the spectral profiles.

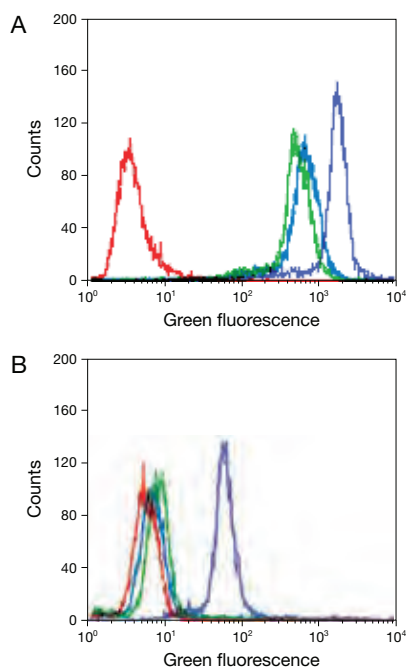

Figure 7.6.16 Detection of epidermal growth factor (EGF) receptors directly or with signal amplification. Cells expressing high (A431 cells, **A**) and low (NIH 3T3 cells, **B**) levels of EGF receptors were either directly labeled with the pre-formed Alexa Fluor® 488 complex of biotinylated epidermal growth factor (E13345, blue) or indirectly labeled with biotinylated EGF (E3477) followed by either Alexa Fluor® 488 streptavidin (S11223, green) or HRP-conjugated streptavidin and Alexa Fluor® 488 tyramide (purple), components of our TSA™ Kit #22 (T20932).

intensely fluorescent staining of cellular targets (Figure 7.6.5, Figure 7.6.16). These kits are very useful for immunofluorescence, *in situ* hybridization and flow cytometry. Use of a combination of the TSA™ and ELF® technologies or double application of TSA™ methods provides enhanced sensitivity for detection of low-abundance targets.⁸⁰

Gold-Labeled Streptavidin

NANOGOLD® and Alexa Fluor® FluoroNanogold™ Streptavidin

In collaboration with Nanoprobe, Inc. (www.nanoprobe.com), we offer NANOGOLD® and Alexa Fluor® FluoroNanogold™ conjugates of streptavidin to facilitate immunoblotting, light microscopy and electron microscopy applications. NANOGOLD® conjugates are covalently conjugated to the 1.4 nm NANOGOLD® gold cluster label, whereas Alexa Fluor® FluoroNanogold™ conjugates are coupled to both a NANOGOLD® label and either the Alexa Fluor® 488 or Alexa Fluor® 594 fluorophore, resulting in gold clusters with green or red fluorescence, respectively. Alexa Fluor® FluoroNanogold™ streptavidin conjugates have all the advantages of the NANOGOLD® conjugates, with the additional benefit that they may be used for correlative fluorescence, light and electron microscopy^{81,82} (Figure 7.6.17).

NANOGOLD® gold clusters have several advantages over colloidal gold. They develop better with silver than do most gold colloids and therefore provide higher sensitivity.⁸³ Silver enhancement, such as the system provided in the LI Silver Enhancement Kit (L24919), is described below. Additionally, NANOGOLD® particles do not have as high affinity for proteins as do gold colloids, thereby reducing background due to nonspecific binding. Several additional features of NANOGOLD® and Alexa Fluor® FluoroNanogold™ conjugates include:

- NANOGOLD® gold clusters are an extremely uniform (1.4 nm ± 10% diameter) and stable compound, not a gold colloid.
- NANOGOLD® gold clusters are smaller than a complete IgG (H+L) antibody—approximately 1/15 the size of an Fab fragment—and therefore will be able to better penetrate cells and tissues, reaching antigens that are inaccessible to conjugates of larger gold particles.
- NANOGOLD® conjugates contain absolutely no aggregates, as they are chromatographically purified through gel filtration columns. This feature is in sharp contrast to colloidal gold conjugates, which are usually prepared by centrifugation to remove the largest aggregates and frequently contain significantly smaller aggregates.
- The ratio of NANOGOLD® particle to Fab fragment is nearly 1:1, making this product distinct from the 0.2–10 variable stoichiometry of most colloidal gold–antibody preparations.

NANOGOLD® and Alexa Fluor® FluoroNanogold™ products can be used in immunoblotting, light microscopy and electron microscopy. Standard immunostaining methodologies can be used successfully with NANOGOLD® and Alexa Fluor® FluoroNanogold™ immunoreagents. Also, because the concentration of antibody and gold is similar to most commercial preparations of colloidal gold antibodies, similar dilutions and blocking agents are appropriate.

We offer several other NANOGOLD® and Alexa Fluor® FluoroNanogold™ reagents (Table 7.5), including the affinity-purified Fab fragments of the goat anti–mouse IgG and anti–rabbit IgG antibodies covalently conjugated to the 1.4 nm NANOGOLD® gold cluster label (Section 7.2). Also available is NANOGOLD® monomaleimide (N20345, Section 2.2), which can be conjugated to thiols in the same way that dyes are conjugated to proteins and nucleic acids.⁸⁴

Colloidal Gold Complexes

We offer Alexa Fluor® 488 dye–labeled colloidal gold conjugates, including those of goat anti–mouse IgG (A31560, A31561; Section 7.2) and goat anti–rabbit IgG antibodies (A31565, A31566; Section 7.2) and streptavidin (A32360, A32361; Table 7.9). These conjugates, which have been adsorbed to 5 nm or 10 nm gold colloids, may be used as probes in immunoblotting, light microscopy, fluorescence microscopy or electron microscopy. The fluorescence of these conjugates can be easily detected by standard techniques, but visualization of colloidal gold can be greatly improved using silver-enhancement methods, such as those we provide in the LI Silver Enhancement Kit (L24919) described in Section 7.2.

Combining fluorescent secondary detection reagents with colloidal gold to form functional complexes is difficult because the fluorescence of fluorophores such as fluorescein is significantly quenched by proximity to the colloidal gold.⁸⁵ We prepare fluorescent colloidal gold complexes with our Alexa Fluor® 488 dye, a dye that has superior brightness and photostability. Our Alexa Fluor® 488 dye-labeled colloidal gold complexes of anti-IgG antibody and of streptavidin can potentially be used to perform correlated immunofluorescence and electron microscopy in a two-step labeling procedure, rather than in the three-step indirect labeling procedure that is required with conventional nonfluorescent colloidal gold complexes of anti-IgG antibodies or streptavidin.⁸⁶

Affinity Chromatography

Streptavidin Agarose

We prepare streptavidin conjugated to 4% beaded crosslinked agarose (S951)—a matrix that can be used to isolate biotinylated peptides, proteins, hybridization probes, haptens and other molecules.⁸⁷ In addition, biotinylated antibodies can be bound to streptavidin agarose to generate an affinity matrix for the large-scale isolation of antigens.⁸⁷ For instance, staurosporine-treated myotubules have been incubated with biotinylated α -bungarotoxin (B1196, Section 16.2) in order to isolate the acetylcholine receptors (AChRs) on streptavidin agarose and assess staurosporine's effect on the degree of phosphorylation of this receptor.⁸⁸ Streptavidin agarose has also been used to investigate the turnover of cell-surface proteins that had previously been derivatized with an amine-reactive biotin⁸⁹ (B1582, Section 4.2).

CaptAvidin™ Agarose

CaptAvidin™ agarose (C21386) is another versatile form of a biotin-binding protein in that its affinity for biotinylated molecules can be completely reversed by raising the pH to 10, permitting the facile separation and isolation of biotin-labeled molecules from complex mixtures (Figure 7.6.2). This form of agarose-immobilized biotin-binding protein has been used to purify immunoglobulin from whole rabbit serum and to isolate anti-transferrin antibodies directly from rabbit antiserum.²⁶

Acrylamide Conjugates for Immobilization of Avidins in Polymers

Streptavidin acrylamide (S21379), which is prepared from the succinimidyl ester of 6-((N-acryloyl)amino)hexanoic acid (acryloyl-X, SE; A20770, Section 5.2), is a reagent that may be useful for preparing biosensors.⁹⁰ A similar streptavidin acrylamide has been shown to copolymerize with acrylamide on a polymeric surface to create a uniform monolayer of the immobilized protein. The streptavidin can then bind biotinylated ligands, including biotinylated hybridization probes, enzymes, antibodies and drugs.

Anti-Biotin Antibody: An Alternative to Avidins

The high affinity of avidin for biotin was first exploited in histochemical applications in the early 1970s.^{1,2} The use of avidin-biotin techniques has since become widely adopted for diverse detection schemes, although limitations of this method have also been recognized.^{4,5} As an alternative to avidin-based reagents, we offer a high-affinity mouse monoclonal antibody to biotin (03-3700). This anti-biotin antibody can be used to detect biotinylated molecules in immunohistochemistry, *in situ* hybridization, ELISAs and flow cytometry applications.

It has been shown that certain monoclonal antibodies to biotin have biotin-binding motifs that are similar to those seen for avidin and streptavidin.⁹¹ Anti-biotin antibody has been shown to selectively stain endogenous biotin-dependent carboxylase proteins used in fatty acid synthesis of the mitochondria.^{23,36} Nonspecific staining of mitochondrial proteins by labeled avidins and by anti-biotin antibodies can be a complicating factor in using avidin-biotin techniques (Figure 7.6.1). This nonspecific binding can usually be blocked by pretreatment of the sample with the reagents in our Endogenous Biotin-Blocking Kit (E21390, Section 7.6).

Figure 7.6.17 Human prostate tissue with adenocarcinoma imaged using an Alexa Fluor® 488 FluoroNanogold™ conjugate. Tissues were labeled with an anti-cytokeratin antibody, followed by staining with the Alexa Fluor® 488 FluoroNanogold™ Fab' fragment of goat anti-mouse IgG antibody (A24920). The fluorescence image in the top panel was taken with filters appropriate for fluorescein. The bottom panel shows a bright-field image of the same system, processed with the LI Silver (LIS) Enhancement Kit (L24919) to visualize the gold distribution. Image courtesy of Nanoprobes, Inc.

PRODUCT LIST 7.6 AVIDIN AND STREPTAVIDIN CONJUGATES

Cat. No.	Product	Quantity
A24926	Alexa Fluor® 488 FluoroNanogold™ streptavidin *80 µg protein/mL*	1 mL
A24927	Alexa Fluor® 594 FluoroNanogold™ streptavidin *80 µg protein/mL*	1 mL
A32360	Alexa Fluor® 488 streptavidin, 5 nm colloidal gold conjugate *30 µg protein/mL*	0.5 mL
A32361	Alexa Fluor® 488 streptavidin, 10 nm colloidal gold conjugate *30 µg protein/mL*	0.5 mL
A2667	avidin, egg white	5 mg
A887	avidin, egg white	100 mg
A21370	avidin, Alexa Fluor® 488 conjugate	1 mg
A821	avidin, fluorescein conjugate	5 mg
A820	avidin, Texas Red® conjugate	5 mg
A2666	avidin, NeutrAvidin™ biotin-binding protein	5 mg
A11236	avidin, NeutrAvidin™, Alexa Fluor® 350 conjugate	1 mg
A2663	avidin, NeutrAvidin™, Cascade Blue® conjugate	1 mg
A2662	avidin, NeutrAvidin™, fluorescein conjugate	1 mg
A2664	avidin, NeutrAvidin™, horseradish peroxidase conjugate	1 mg
A6374	avidin, NeutrAvidin™, Oregon Green® 488 conjugate	1 mg
A6378	avidin, NeutrAvidin™, Rhodamine Red™-X conjugate	1 mg
A2660	avidin, NeutrAvidin™, R-phycoerythrin conjugate *1 mg/mL*	1 mL
A6373	avidin, NeutrAvidin™, tetramethylrhodamine conjugate	1 mg
A2665	avidin, NeutrAvidin™, Texas Red® conjugate	1 mg
B1595	D-biotin	1 g
B20656	D-biotin *50 mM aqueous solution*	10 mL
B10710	BlockAid™ blocking solution *for use with microspheres*	50 mL
C21386	CaptAvidin™ agarose *sedimented bead suspension*	5 mL
C21385	CaptAvidin™ biotin-binding protein	1 mg
D20657	D-desthiobiotin *50 mM aqueous solution*	10 mL
D22187	Diaminobenzidine (DAB) Histochemistry Kit #3 *with streptavidin-HRP*	1 kit
E21390	Endogenous Biotin-Blocking Kit *100 assays*	1 kit
F8769	FluoSpheres® biotin-labeled microspheres, 1.0 µm, nonfluorescent *1% solids*	0.4 mL
F8766	FluoSpheres® biotin-labeled microspheres, 0.04 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
F8767	FluoSpheres® biotin-labeled microspheres, 0.2 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
F8768	FluoSpheres® biotin-labeled microspheres, 1.0 µm, yellow-green fluorescent (505/515) *1% solids*	0.4 mL
F20883	FluoSpheres® NeutrAvidin™ labeled microspheres, 0.04 µm, europium luminescent (365/610) *0.5% solids*	0.4 mL
F20884	FluoSpheres® NeutrAvidin™ labeled microspheres, 0.2 µm, europium luminescent (365/610) *0.5% solids*	0.4 mL

PRODUCT LIST 7.6 AVIDIN AND STREPTAVIDIN CONJUGATES—*continued*

Cat. No.	Product	Quantity
F8772	FluoSpheres® NeutrAvidin™ labeled microspheres, 0.04 µm, nonfluorescent *1% solids*	0.4 mL

7.7 Lectins and Other Carbohydrate-Binding Proteins

Cellular proteoglycans, glycoproteins and glycolipids may contain any of a wide variety of oligosaccharides. Although most abundant on the cell surface, oligosaccharide residues are sometimes also found covalently attached to constituents within the cell.¹ Often, specific oligosaccharides are associated with a certain cell type or organelle. Lectins and certain other carbohydrate-binding proteins that bind to specific configurations of sugar molecules can thus serve to identify cell types or cellular components, making them versatile primary detection reagents

in histochemical applications and flow cytometry² (Figure 7.7.1, Figure 7.7.2, Figure 7.7.3). Fluorescent derivatives of carbohydrate-binding proteins and other reagents have been used to detect cell-surface and intracellular glycoconjugates by microscopy^{3,4} and flow cytometry,⁵ to localize glycoproteins in gels and on protein blots,^{6–9} to precipitate glycoproteins from solution and to cause agglutination of specific cell types.^{10,11} In addition, lectins are also useful markers of certain cancers because these cells often display altered surface glycoproteins.^{12,13}

Figure 7.7.1 Microtubules of fixed bovine pulmonary artery endothelial cells localized with mouse monoclonal anti- α -tubulin antibody (A11126), which was subsequently visualized with Alexa Fluor[®] 350 goat anti-mouse IgG antibody (A11045). Next, the F-actin was labeled with Alexa Fluor[®] 594 phalloidin (A12381). Finally, the cells were incubated with Alexa Fluor[®] 488 wheat germ agglutinin (W11261) to stain components of endosomal pathways. The superimposed and pseudocolored images were acquired sequentially using bandpass filter sets appropriate for DAPI, the Texas Red[®] dye and fluorescein, respectively.

Figure 7.7.2 Apoptotic human keratinocytes that were fixed with formaldehyde and stained with fluorescein concanavalin A (C827). The cells were subsequently permeabilized with acetone, stained with propidium iodide (P1304MP, P3566, P21493) and visualized by confocal laser-scanning microscopy. This photomicrograph clearly shows that the green-fluorescent lectin staining outlines the apoptotic surface blebs, whereas the red-fluorescent propidium iodide stains the interior of the blebs. Image contributed by Livia Casciola-Rosen and Antony Rose, Johns Hopkins University. Reproduced from *J Exp Med* (1994) 179:1317 by copyright permission of the Rockefeller University Press.

Figure 7.7.3 Zebrafish tissue section labeled with Texas Red[®]-X wheat germ agglutinin (W21405) and SYTOX[®] Green nucleic acid stain (S7020).

Concanavalin A and Wheat Germ Agglutinin and Their Conjugates

Properties of Concanavalin A and Wheat Germ Agglutinin

Concanavalin A (Con A) selectively binds to α -mannopyranosyl and α -glucopyranosyl residues. In moderately acidic solutions (pH 4.5–5.6), Con A exists as a dimer with a molecular weight of approximately 52,000 daltons; above pH 7, it is primarily a tetramer with a molecular weight of 104,000 daltons. Con A is a metalloprotein that requires one Ca^{2+} and one Mn^{2+} per subunit for carbohydrate binding.^{14,15} The 36,000-dalton dimeric wheat germ agglutinin (WGA), which is normally cationic, binds to *N*-acetylneuraminic acid (sialic acid) and *N*-acetylglucosaminyl residues.

When Con A is succinylated with succinic anhydride, as in the Alexa Fluor® 488 conjugate of succinylated Con A (C21401), it is irreversibly converted to a dimer that retains the same sugar-binding specificity as the parent lectin. Succinylated Con A, however, has a profile of biological activities quite different from that of the tetrameric form. In contrast to the tetramer, succinylated Con A does not induce capping of cell-surface glycoprotein receptors, nor does it inhibit capping of cell-surface immunoglobulin receptors or strongly agglutinate erythrocytes or spleen cells. The mitogenic effect of succinylated Con A is similar to that of the native lectin, although it is mitogenic over a significantly wider range of concentrations than is the tetramer.^{16,17}

Con A and WGA Conjugates

We offer several fluorescent conjugates of Con A and WGA—two of the most commonly used lectins in cell biology (Table 7.10). Although we continue to provide fluorescein and tetramethylrhodamine conjugates of these lectins, we strongly recommend that researchers also evaluate our other fluorescent conjugates, which exhibit excitation and emission maxima nearly identical to these traditional reagents but

exhibit superior brightness and photostability. In particular, our green-fluorescent Alexa Fluor® 488 conjugates of Con A, succinylated Con A and WGA (C11252, C21401, W11261) are not only brighter than fluorescein conjugates, but also much more photostable and pH insensitive in the physiological range (Section 1.3). Moreover, the red-fluorescent Alexa Fluor® 594 conjugates of Con A and WGA (C11253, W11262) are even more fluorescent than their Texas Red® counterparts. The Alexa Fluor® 633 and Alexa Fluor® 647 conjugates of Con A (C21402, C21421) and WGA (W21404, W32466) and the Alexa Fluor® 680 conjugate of WGA (W32465) emit light at long wavelengths and are exceptionally useful for multicolor fluorescent labeling of cells and tissues, including those that have high intrinsic autofluorescence. For blue-fluorescent labeling, we recommend the Alexa Fluor® 350 conjugates of Con A and WGA (C11254, W11263; Figure 7.7.4). For researchers interested in testing our fluorescent WGA conjugates in their various applications, we offer a Wheat Germ Agglutinin Sampler Kit (W7024), which

Figure 7.7.4 A zebrafish tissue section labeled with FRET 43 mouse monoclonal IgG in conjunction with Texas Red®-X goat anti-mouse IgG (T6390), Alexa Fluor® 350 wheat germ agglutinin (W11263) and SYTOX® Green nucleic acid stain (S7020). The multiple-exposure image was acquired using bandpass filter sets appropriate for DAPI, fluorescein and Texas Red® dye.

* Approximate absorption (Abs) and fluorescence emission (Em) maxima, in nm, for conjugates. † Lectin sources: Concanavalin A (Con A) isolated from *Canavalia ensiformis* (jack bean); Wheat Germ Agglutinin (WGA) isolated from *Triticum vulgare*; IB₄ isolated from *Griffonia simplicifolia* (an African legume); GS-II isolated from *Griffonia simplicifolia*; PHA-L isolated from *Phaseolus vulgaris* (red kidney bean); HPA isolated from *Helix pomatia* (edible snail); SBA isolated from *Glycine max* (soybean); PNA isolated from *Arachis hypogaea* (peanut). ‡ Succinylated Alexa Fluor® 488 concanavalin A is also available, C21401. § The properties and applications of Qdot® nanocrystal conjugates are described in Section 6.6. NA = Not applicable.

For researchers interested in testing our fluorescent WGA conjugates in their application, we also offer a Wheat Germ Agglutinin Stain Sampler Kit (W7024), which contains 1 mg quantities each of WGA conjugates of the Alexa Fluor® 350, Oregon Green® 488, tetramethylrhodamine and Texas Red®-X dyes.

Figure 7.7.5 Fixed and permeabilized osteosarcoma cells simultaneously stained with the fluorescent lectins Alexa Fluor® 488 concanavalin A (Con A) (C11252) and Alexa Fluor® 594 wheat germ agglutinin (WGA) (W11262). Con A selectively binds α -glucopyranosyl residues, whereas WGA selectively binds sialic acid and *N*-acetylglucosaminyl residues. The nuclei were counterstained with blue-fluorescent Hoechst 33342 nucleic acid stain (H1399, H3570, H21492). The image was acquired using bandpass filter sets appropriate for the Texas Red® dye, fluorescein and DAPI.

Figure 7.7.6 Live, highly confluent HeLa cells were transfected using pShooter™ vector pCMV/myc/mito/GFP and Lipofectamine® 2000 transfection reagent and stained with the reagents in the Image-iT® LIVE Plasma Membrane and Nuclear Labeling Kit (I34406). Plasma membranes were labeled with Alexa Fluor® 594 wheat germ agglutinin and nuclei were stained with Hoechst 33342. Cells were visualized using epifluorescence microscopy.

contains 1 mg quantities each of WGA conjugates of the Alexa Fluor® 350, Oregon Green® 488, tetramethylrhodamine and Texas Red®-X dyes.

The Qdot® 655 WGA conjugate (Q12021MP) extends our selection of dye-labeled WGA conjugates for labeling of *N*-acetylglucosaminyl and sialic acid residues of glycoproteins on cell surfaces;¹⁸ the physical and spectroscopic properties of Qdot® nanocrystals are described in Section 6.6.

Applications for Fluorescent Con A and WGA

Although the distribution of oligosaccharides that may be bound by Con A and WGA varies widely among cell types, these two lectins have proven to be useful reagents for a number of applications, including immunolocalization of oncogene products,¹⁹ specific intracellular enzymes,^{20,21} viral proteins²² and components of the cytoskeleton²³ (Figure 7.7.5). Con A also reportedly binds specifically to isolated Golgi fractions from rat liver, which enabled researchers to use fluorescein-labeled Con A to examine the effect of chronic ethanol intake on carbohydrate content in these organelles using flow cytometry.²⁴ Fluorescent Con A has been used to:

- Determine if human sperm cells have undergone the progesterone-induced acrosome reaction²⁵
- Investigate receptor capping in leukocytes²⁶
- Measure lateral diffusion of glycoproteins, glycolipids and viruses in membranes^{27,28}
- Show the redistribution of cell-surface glycoproteins in murine fibroblasts that had been induced to migrate by exposure to an electric field²⁹

WGA conjugates are useful for labeling of bacterial cell wall peptidoglycans, chitin and cartilage glycosaminoglycans. In addition, nuclear core complexes have been found to contain several proteins with *O*-linked *N*-acetylglucosaminyl residues.^{30–34} In a study of nuclear protein transport, nuclei isolated from monkey kidney epithelial cells were demonstrated to be intact by their bright staining with fluorescein WGA (W834); fluorescein Con A (C827), which binds to residues accessible only in nuclei with compromised membranes, was used as a negative control for intact nuclei.³⁵ Fluorescent WGA has also been employed to monitor reconstitution of the nuclear core complex in *Xenopus* egg extracts.³⁶ WGA conjugates undergo axonal transport^{37,38} and have been shown to cross from axonal nerve endings into adjacent neurons.³⁹

Fluorescent lectins are also useful in microbiology applications. Fluorescent WGA conjugates stain chitin in fungal cell walls⁴⁰ and have been reported to stain gram-positive but not gram-negative bacteria for subsequent analysis by either imaging⁴¹ or flow cytometry.⁴² Fluorescent WGA conjugates are utilized in our ViaGram™ Red⁺ Bacterial Gram Stain and Viability Kit (V7023, Section 15.3) to differentiate gram-positive and gram-negative bacteria. Fluorescent WGA also binds to sheathed microfilariae and has been used to detect filarial infection in blood smears.⁴³

In addition to these nuclear core and microbiology studies, fluorescent WGA has been used to:

- Bind the sarcolemma of rat and dog cardiac myocytes, even within the intercalated discs and transverse tubules, allowing researchers to map the distribution of gap junctions in these cell types⁴⁴
- Determine the intracellular distribution of altered lysosomal proteins, enabling the definition of the sequence requirements for proper cell sorting⁴⁵
- Identify the differentiation state of Madin–Darby canine kidney (MDCK) cells⁴⁶
- Investigate plant hemicelluloses⁴⁷
- Measure cell membrane potential in combination with potential-sensitive membrane probes⁴⁸

Image-iT® LIVE Plasma Membrane and Nuclear Labeling Kit

The Image-iT® LIVE Plasma Membrane and Nuclear Labeling Kit (I34406) provides two stains—red-fluorescent Alexa Fluor® 594 wheat germ agglutinin (WGA) (excitation/emission maxima ~590/617 nm) and blue-fluorescent Hoechst 33342 dye (excitation/emission maxima when bound to DNA ~350/461 nm)—for highly selective staining of the plasma membrane and nucleus, respectively, of live cells expressing Green Fluorescent Protein (GFP, Figure 7.7.6). These dyes can be combined into one staining solution using the protocol provided, saving labeling time and wash steps while still providing optimal staining. Cell-impermeant Alexa Fluor® 594 WGA binds selectively to *N*-acetylglucosamine and *N*-acetylneuraminic acid residues.⁴⁹

When used according to the protocol, Alexa Fluor® 594 WGA provides highly selective labeling of the plasma membrane with minimal background, although labeling may not be as distinct for flat cell types when viewed using standard epifluorescence microscopy or low magnification. Alexa Fluor® 594 WGA is retained after formaldehyde fixation and permeabilization with Triton® X-100. This fluorescent lectin conjugate can also be used to label fixed cells; however, to avoid labeling intracellular components, formaldehyde-fixed cells should not be permeabilized before labeling. It is important to note that Alexa Fluor® 594 WGA can stimulate biological activity, including clustering of glycosylated cell-surface proteins.

The kit also includes Hoechst 33342 dye, a cell-permeant nucleic acid stain that is selective for DNA and is spectrally similar to DAPI. This dye should not interfere with GFP fluorescence and is retained after fixation and permeabilization. The Image-iT® LIVE Plasma Membrane and Nuclear Labeling Kit contains:

- Alexa Fluor® 594 wheat germ agglutinin (WGA)
- Hoechst 33342
- Detailed experimental protocols

Each kit provides enough staining solution for 360 assays using the protocol provided for labeling live, cultured cells that are adhering to coverslips.

Other Carbohydrate-Binding Proteins and Their Conjugates

Lectins from *Griffonia simplicifolia*

Isolectin GS-IB₄ is a 114,000-dalton glycoprotein that is part of a family of five tetrameric type I isolectins (IA₄, IA₃B, IA₂B₂, IAB₃ and IB₄) isolated from the seeds of the tropical African legume *Griffonia simplicifolia* (formerly *Bandeiraea simplicifolia*). The A and B subunits are very similar, differing in amino acid sequence only at the N-terminus. The subunits, however, display remarkably different binding specificities. The A subunit prefers *N*-acetyl-D-galactosamine end groups, whereas the B subunit is selective for terminal α -D-galactosyl residues.⁵⁰

We offer Alexa Fluor® 488, Alexa Fluor® 568, Alexa Fluor® 594 and Alexa Fluor® 647 dye conjugates of this versatile isolectin (I21411, I21412, I21413, I32450), as well as its biotinylated^{51–53} (I21414) derivative. Isolectin GS-IB₄ specifically agglutinates blood group B erythrocytes and was originally employed for this purpose.⁵⁴ Subsequent work has shown that isolectin GS-IB₄ is cytotoxic to several normal and tumor cell types⁵⁵ and has particularly strong affinity for brain microglial and perivascular cells⁵⁶ (Figure 7.7.7). Conjugates of isolectin GS-IB₄ have been particularly valuable as histochemical and flow cytometric probes for specifically labeling endothelial cells in a number of species.^{57,58} They have also been used effectively for tracing central and peripheral neuronal pathways following local injections.^{59–61}

Lectin GS-II from *G. simplicifolia* differs from isolectin S-IB₄ in that it is the only known lectin that binds with high selectivity to terminal, nonreducing α - and β -*N*-acetyl-D-glucosaminyl (GlcNAc) residues of glycoproteins. Lectin GS-II is a tetrameric protein with each site binding a single carbohydrate and an aggregate molecular weight of ~113,000 daltons. Because of its affinity for GlcNAc, lectin GS-II conjugates are useful for staining intermediate-to-trans Golgi—the site of *N*-acetylglucosaminyltransferase activity. The Golgi apparatus of oligodendrocytes and ganglion neurons are also stained by fluorescent GS-II conjugates. We have prepared the green-fluorescent Alexa Fluor® 488 (L21415, Figure 7.7.8), red-fluorescent Alexa Fluor® 594 (L21416) and far-red-fluorescent Alexa Fluor® 647 (L32451) conjugates of lectin GS-II for use in cell staining.

Phaseolus vulgaris (Red Kidney Bean) Lectin

Phaseolus vulgaris lectin (PHA-L) is a tetrameric protein with a molecular weight of 120,000 daltons. Its binding to glycoproteins is strongly inhibited by *N*-acetylglucosaminyl (1-2) mannosyl residues.¹¹ Like WGA, PHA-L is widely used as an injectable neuronal tracer.⁶² Iontophoretically injected PHA-L clearly demonstrates the morphological features of the filled neurons at the injection site and the labeled axons and axon terminals. Furthermore, PHA-L that has been transported is not degraded over long periods. PHA-L has been used in combination with our biotinylated lysine-fixable dextrans (BDA dextrans; Section 14.5, Table 14.4) and the fluorescent dextrans fluoro-ruby and mini-ruby (D1817, D3312; Section 14.5) to demonstrate

Figure 7.7.7 Capillary endothelial cells and microglia in a rat brain cryosection labeled with the green-fluorescent Alexa Fluor® 488 isolectin IB₄ (I21411). Neurons were identified using the NeuroTrace® 530/615 red-fluorescent Nissl stain (N21482) and nuclei were counterstained with blue-fluorescent DAPI (D1306, D3571, D21490). The digital image was obtained using filters appropriate for fluorescein, rhodamine and DAPI.

Figure 7.7.8 Fixed and permeabilized NIH 3T3 cells were labeled with the Alexa Fluor® 488 conjugate of lectin GS-II from *Griffonia simplicifolia* (L21415) and counterstained with DAPI (D1306, D3571, D21490). The fluorescent images are shown overlaid with the differential interference contrast (DIC) image.

Figure 7.7.9 Capillaries in the hippocampal region of a mouse brain cryosection were visualized with the green-fluorescent Alexa Fluor® 488 conjugate of lectin HPA from *Helix pomatia* (L11271), which specifically binds to type A erythrocytes and α -N-acetylgalactosaminyl residues. The nuclei were counterstained with nuclear yellow (N21485). The multiple-exposure image was acquired using a DAPI long-pass filter set and a filter set appropriate for fluorescein.

their similar transport properties and to show the distribution of anterograde-labeled fibers.⁶³ We have prepared Alexa Fluor® 488, Alexa Fluor® 594 and Alexa Fluor® 647 conjugates of PHA-L (L11270, L32456, L32457).

Arachis hypogaea (Peanut) Lectin

Arachis hypogaea lectin (PNA) is a tetrameric protein with a molecular weight of ~110,000 daltons that has specificity for terminal β -galactose residues of glycoproteins. Lactose strongly inhibits binding of PNA to these glycoproteins, with D-galactose somewhat less effective. PNA binds to a broad range of receptors in human tissues, with some preference for glycoproteins that have been treated with neuraminidase (sialidase) to remove terminal sialic acids.⁶⁴ We offer Alexa Fluor® 488, Alexa Fluor® 568, Alexa Fluor® 594 and Alexa Fluor® 647 conjugates of PNA (L21409, L32458, L32459, L32460).

PNA-binding sites are widespread in human tissues, with staining patterns varying by tissue type.⁶⁵ Research has shown PNA to be selective for acrosomes in rat and human sperm,^{66,67} and PNA serves as a marker for certain melanomas.^{13,68} PNA has also been used to label the synaptic extracellular matrix in the study of developing neuromuscular junctions.⁶⁹

Applications for fluorescent PNA conjugates include:

- Binding to desialylated CD44, the PNA receptor in keratinocytes, as a marker of terminal differentiation⁷⁰
- Detecting the acrosome reaction of sperm⁷¹
- Labeling of photoreceptors in chick embryos and in intact retina and dissociated retinal cells⁷²
- Staining colonic mucins in cultured human tumor cells, transitional cell carcinomas in the bladder and leukemic cells^{73,74}

Helix pomatia (Edible Snail) Agglutinin

Helix pomatia agglutinin (HPA), a hexameric protein with a molecular weight of 70,000 daltons, selectively binds to type A erythrocytes and α -N-acetylgalactosaminyl residues¹¹ (Figure 7.7.9). In some cell types, HPA conjugates may be used as markers for the Golgi complex.^{75,76} Furthermore, HPA conjugates have been shown to be as effective as monoclonal antibodies for the detection and differentiation of herpes simplex virus type 1 and type 2 (HSV-1 and HSV-2) in cultured cells.⁷⁵ Our Alexa Fluor® 488 and Alexa Fluor® 647 conjugates of HPA (L11271, L32454) should be particularly useful for cell staining.⁷⁷

Glycine max (Soybean) Agglutinin

Soybean agglutinin (SBA) from *Glycine max* is a tetrameric protein that consists of a mixture of isolectins that have an aggregate molecular weight of ~120,000 daltons.¹¹ SBA has a stronger reaction with type A1 blood cells than with type A2 blood cells and is known to selectively bind to terminal α - and β -N-acetylgalactosaminyl and galactopyranosyl residues of glycoproteins. Neuraminidase-treated cells react more strongly with SBA conjugates than do untreated cells.⁶⁷ SBA has selective affinity for human CD34⁺ hematopoietic stem cells and lymphocytes, and its immobilized conjugates are important reagents for the depletion of T cells in bone marrow transplantation.⁷⁸ In addition, a fluorescein conjugate of SBA was shown to be useful for assessing the stage of lymphoid cell differentiation in human leukemic-lymphoma cell lines.⁷⁹ Like many lectins, fluorescent SBA conjugates have been shown to bind with high affinity to several types of tumor cells.^{80,81} SBA conjugates are also reported to be selective stains for glial cells⁸² and the zona pellucida of the mammalian egg.⁶⁷ For detecting SBA-binding cells, we have prepared the Alexa Fluor® 488, Alexa Fluor® 594 and Alexa Fluor® 647 conjugates of SBA (L11272, L32462, L32463).

Cholera Toxin Subunit B

Cholera toxin comprises two subunits, A and B, arranged in an AB₅ conformation. Subunit A is an ADP-ribosyltransferase, which disrupts the proper signaling of G proteins and eventually leads to dehydration of the cell.⁸³ The 12,000-dalton nontoxic subunit B (“choleraenoid”), which is assembled into a 60,000-dalton pentamer above pH 2,⁸⁴ allows the protein complex to bind to cellular surfaces via the pentasaccharide chain of ganglioside G_{M1}.⁸⁵

Fluorescent cholera toxin subunit B, which binds to galactosyl moieties, is a marker of lipid rafts—regions of cell membranes high in ganglioside G_{M1} that are thought to be important in cell signaling.^{86,87} Lipid rafts are detergent-insoluble, sphingolipid- and cholesterol-rich membrane microdomains that form lateral assemblies in the plasma membrane.^{88–94} Lipid rafts also sequester glycosylphosphatidylinositol (GPI)-linked proteins and other signaling proteins and receptors, which may be regulated by their selective interactions with these membrane microdomains.^{95–100} Research has demonstrated that lipid rafts play a role in a variety of cellular processes—including the compartmentalization of cell-signaling events,^{101–108} the regulation of apoptosis^{109–111} and the intracellular trafficking of certain membrane proteins and lipids^{112–114}—as well as in the infectious cycles of several viruses and bacterial pathogens.^{115–120}

The Vybrant® Lipid Raft Labeling Kits (V34403, V34404, V34405; Section 14.4) provide the key reagents for fluorescently labeling lipid rafts *in vivo* with our bright and extremely photostable Alexa Fluor® dyes (Figure 7.7.10). Live cells are first labeled with the green-fluorescent Alexa Fluor® 488, orange-fluorescent Alexa Fluor® 555 or red-fluorescent Alexa Fluor® 594 conjugate of cholera toxin subunit B (CT-B). This CT-B conjugate binds to the pentasaccharide chain of plasma membrane ganglioside G_{M1} , which selectively partitions into lipid rafts.^{84,99} An antibody that specifically recognizes CT-B is then used to crosslink the CT-B-labeled lipid rafts into distinct patches on the plasma membrane, which are easily visualized by fluorescence microscopy.^{121,122} Each Vybrant® Lipid Raft Labeling Kit contains sufficient reagents to label 50 live-cell samples, including:

- Recombinant cholera toxin subunit B (CT-B) labeled with the Alexa Fluor® 488 (in Kit V34403), Alexa Fluor® 555 (in Kit V34404) or Alexa Fluor® 594 (in Kit V34405) dye
- Anti-cholera toxin subunit B antibody (anti-CT-B)
- Concentrated phosphate-buffered saline (PBS)
- Detailed labeling protocol

Cholera toxin subunit B and its conjugates are also established as superior tracers for retrograde labeling of neurons.^{123,124} Cholera toxin subunit B conjugates bind to the pentasaccharide chain of ganglioside G_{M1} on neuronal cell surfaces and are actively taken up and transported; alternatively, they can be injected by iontophoresis. Unlike the carbocyanine-based neuronal tracers such as DiI (D282, D3911, V22885; Section 14.4), cholera toxin subunit B conjugates can be used on tissue sections that will be fixed and frozen.¹²⁵

All of our cholera toxin subunit B conjugates are prepared from recombinant cholera toxin subunit B, which is completely free of the toxic subunit A, thus eliminating any concern for toxicity or ADP-ribosylating activity. The Alexa Fluor® 488 (C22841, C34775), Alexa Fluor® 555 (C22843, C34776), Alexa Fluor® 594 (C22842, C34777) and Alexa Fluor® 647 (C34778) conjugates of cholera toxin subunit B combine this versatile tracer with the superior brightness of our Alexa Fluor® dyes to provide sensitive and selective receptor labeling and neuronal tracing. We also offer biotin-XX (C34779) and horseradish peroxidase (C34780) conjugates of cholera toxin subunit B for use in combination with diaminobenzidine (DAB) oxidation,¹²⁶ tyramide signal amplification (TSA™) and Qdot® nanocrystal–streptavidin conjugates.¹²⁷

Figure 7.7.10 A J774 mouse macrophage cell sequentially stained with BODIPY® FL ganglioside G_{M1} (B13950) and then with Alexa Fluor® 555 dye-labeled cholera toxin subunit B (C22843, C34776; also available as a component of V34404). The cell was then treated with an anti-CT-B antibody (a component of V34404) to induce crosslinking. Alexa Fluor® 555 dye fluorescence (top, red) and BODIPY® FL dye fluorescence (middle, green) were imaged separately and overlaid to emphasize the coincident staining (bottom, yellow). Nuclei were stained with blue-fluorescent Hoechst 33342 (H1399, H3570, H21492).

8.1 Nucleic Acid Stains

We offer an extensive assortment of nucleic acid stains, many of which have been developed in our research laboratories. This section discusses the physical properties of the various classes of dyes listed below. The sections that follow describe applications of these nucleic acid stains for genomics research. The four classes of Molecular Probes® cyanine dyes include:

- Premier dyes for ultrasensitive nucleic acid quantitation and gel staining (Table 8.1)
- Cell-impermeant TOTO®, TO-PRO® and SYTOX® families of dyes (Table 8.2)
- Cell-permeant SYTO® family of dyes (Table 8.3)
- Amine-reactive SYBR® dye that can be used to form bioconjugates

The three classes of classic nucleic acid stains (Table 8.4) include:

- Intercalating dyes (Figure 8.1.1), such as ethidium bromide and propidium iodide
- Minor-groove binders (Figure 8.1.1), such as DAPI and the Hoechst dyes
- Other types of nucleic acid binders (Figure 8.1.1) such as acridine orange, 7-AAD, LDS 751 and hydroxystilbamidine

Properties of Cyanine Dyes

Molecular Probes® nucleic acid-binding cyanine dyes share several important spectroscopic and physical properties:

- High molar absorptivity, with extinction coefficients typically greater than $50,000 \text{ cm}^{-1}\text{M}^{-1}$ at visible wavelengths
- Very low intrinsic fluorescence, with quantum yields usually less than 0.01 when not bound to nucleic acids
- Large fluorescence enhancements (often over 1000-fold) upon binding to nucleic acids, with increases in quantum yields to as high as 0.9
- Moderate to very high affinity for nucleic acids, with little or no staining of other biopolymers

Their fluorescence absorption and emission spectra span the visible-light spectrum from blue to near-infrared (Figure 8.1.2) with additional absorption peaks in the UV, making them compatible with many different types of instrumentation. The cyanine dyes also show important differences in some physical characteristics—particularly in cell membrane permeability and nucleic acid specificity—that allow their distribution into distinct classes, and these classes are discussed in detail below and in the following sections of this chapter.

Premier Cyanine Dyes for Ultrasensitive Nucleic Acid Detection and Quantitation

Several of our cyanine dyes provide excellent sensitivity in specific nucleic acid assays (Table 8.1). For these dyes, we have developed detailed and extensively tested protocols to facilitate reproducible, high-sensitivity results in these assays.

- PicoGreen®, OliGreen® and RiboGreen® quantitation reagents and their Quant-iT™ reagent counterparts in Section 8.3 set a benchmark for the detection and quantitation of DNA, oligonucleotides and RNA in solution. These reagents offer extremely simple and rapid protocols as well as linear ranges that span up to four orders of magnitude in nucleic acid concentration.
- SYBR® Gold, SYBR® Green I and SYBR® Green II nucleic acid gel stains in Section 8.4 are ultrasensitive gel stains that surpass the sensitivity of ethidium bromide by more than an order of magnitude in nucleic acid detection.
- SYBR® Safe DNA gel stain (Section 8.4) is not only significantly less mutagenic than ethidium bromide, but SYBR® Safe stain's detection sensitivity is comparable to that of ethidium bromide. SYBR® Safe stain showed no or very low mutagenic activity when tested by an independent, licensed testing laboratory, and it is not classified as hazardous waste under U.S. Federal regulations.
- CyQUANT® GR dye (C7026), discussed in Section 15.4, is a cyanine dye designed to quantitate cell proliferation and can reliably detect the nucleic acids in as few as 50 cells.

Figure 8.1.1 Schematic diagram showing the different binding modes of dyes (and other ligands) to DNA.

Figure 8.1.2 Normalized fluorescence emission spectra of DNA-bound cyanine dimers, identified by the color key on the sidebar.

Cell-Impermeant Cyanine Dimers: The TOTO® Family of Dyes

The cyanine dimer dyes listed in Table 8.2—sometimes referred to as the TOTO® family of dyes—are symmetric dimers of cyanine dyes with exceptional sensitivity for nucleic acids. This sensitivity is due to a high affinity for nucleic acids, in combination with a very high fluorescence enhancement and quantum yield upon binding. The unique physical characteristics of these dyes and some illustrative applications are discussed below; specific applications are discussed in later sections of this chapter.

Each of the cyanine dimer dyes is available separately. For researchers designing new applications, the Nucleic Acid Stains Dimer Sampler Kit (N7565) provides samples of eight spectrally distinct analogs of the dimeric cyanine dyes for testing (Table 8.2).

High Affinity for Nucleic Acids

Appropriately designed dimers of nucleic acid-binding dyes have nucleic acid-binding affinities that are several orders of magnitude greater than those of their parent monomer dyes.¹⁻³ For example, the intrinsic DNA binding affinity constants of ethidium bromide and ethidium homodimer-1 (E1169) are reported to be 1.5×10^5 and 2×10^8 M⁻¹, respectively, in 0.2 M Na⁺.⁴ As a result, the dimeric cyanine dyes are among the highest-affinity fluorescent probes available for nucleic acid staining.

For example, in the TOTO®-1 dimeric cyanine dye (T3600), the positively charged side chains of the TO-PRO®-1 monomeric cyanine dye (T3602, Figure 8.1.3) are covalently linked to form the TOTO®-1 molecule, with four positive charges (Figure 8.1.4). This linkage gives TOTO®-1 dye a greatly enhanced affinity for nucleic acids—more than 100 times greater than that of the TO-PRO®-1 monomer. TOTO®-1 dye

exhibits a higher affinity for double-stranded DNA (dsDNA) than even the ethidium homodimers and also binds to both single-stranded DNA (ssDNA) and RNA. The extraordinary stability of TOTO[®]-1–nucleic acid complexes^{2,5,6} allows the dye–DNA association remains stable, even during electrophoresis (Figure 8.1.5); thus, samples can be stained with nanomolar dye concentrations *prior to* electrophoresis,^{7,8} thereby reducing the hazards inherent in handling large volumes of ethidium bromide staining solutions.^{2,6,9} In contrast, the binding of thiazole orange—the parent compound of TOTO[®]-1 and TO-PRO[®]-1—is rapidly reversible, limiting the dye's sensitivity and rendering its nucleic acid complex unstable to electrophoresis.⁹

High Fluorescence Enhancements and High Quantum Yields upon Binding to Nucleic Acids

In addition to their superior binding properties, TOTO[®]-1 dye and the other cyanine dimers are essentially nonfluorescent in the absence of nucleic acids and exhibit fluorescence enhancements upon DNA binding of 100- to 1000-fold,^{5,10} which compares favorably with the fluorescence enhancement of thiazole orange upon DNA binding¹¹ (~3000-fold). Furthermore, the fluorescence quantum yields of the cyanine dimers bound to DNA are high (generally between 0.2 and 0.6), and their extinction coefficients are an order of magnitude greater than those of the ethidium homodimers.⁵ This sensitivity is sufficient for detecting single molecules of labeled nucleic acids by optical imaging (Figure 8.1.6) and flow cytometry and for tracking dye-labeled virus particles in microbial communities and aquatic systems by fluorescence microscopy.^{12,13} These dyes are generally considered to be cell impermeant, although their use to stain reticulo-cytes permeabilized by 5% DMSO has been reported.¹⁴

Modifying the Dimers Creates Compounds with Different Spectral Characteristics

Simply by changing the aromatic rings and the number of carbon atoms linking the cyanine monomers, we were able to synthesize an extended series of these dyes with different spectral characteristics (Table 8.2). Chemical modifications produce dramatic shifts in the absorption and emission spectra and reduce the quantum yields of the bound dyes but cause little or no change in their high affinity for DNA. The names of the dyes reflect their basic structure and spectral characteristics. For example, YOYO[®]-1 iodide (491/509) has one carbon atom bridging the aromatic rings of the oxacyanine dye and exhibits absorption/emission maxima of 491/509 nm when bound to dsDNA. YOYO[®]-3 dye (612/631)—which differs from YOYO[®]-1 dye only in the number of bridging carbon atoms—has absorption/emission maxima of 612/631 nm when bound to dsDNA. Fluorescence spectra for the POPO[™], BOBO[™], YOYO[®], TOTO[®], JOJO[™] and LOLO[™] dyes bound to dsDNA are shown in Figure 8.1.2. The spectra of these dyes at dye:base ratios of less than 1:1 are essentially the same for the corresponding dye–ssDNA and dye–RNA complexes. At higher dye:base ratios, however, ssDNA and RNA complexes of all of the monomethine (“-1”) dyes of the TOTO[®] series and TO-PRO[®] series have red-shifted emissions, whereas corresponding complexes of the trimethine (“-3”) analogs do not. Thus, the cyanine dimer family provides dyes with a broad range of spectral characteristics to match the output of almost any available excitation source.

Binding Modes of the Cyanine Dimers

The studies on cyanine dimer binding modes have focused on the YOYO[®]-1 and TOTO[®]-1 dyes. YOYO[®]-1 dye was found to exhibit at least two distinct binding modes. At low dye:base pair ratios, the binding mode appears to consist primarily of bis-intercalation^{15–19} (Figure 8.1.1). Each monomer unit intercalates between bases, with the benzazolium ring system sandwiched between the pyrimidines and the quinolinium ring between the purine rings, causing the helix to unwind. The distortion in the local DNA structure caused by YOYO[®]-1 bis-intercalation has been observed by two-dimensional NMR spectroscopy. At high dye:base pair ratios, a second, less well characterized mode of external binding begins to contribute.^{15,16} Circular dichroism measurements also indicate a possible difference in the binding modes of YOYO[®]-1 dye to ssDNA and dsDNA. These data are consistent with our own results, including the observation that the fluorescence emission of the YOYO[®]-1 dye complex with nucleic acids shifts to longer wavelengths at high dye:base ratios upon binding to single-stranded nucleic acids and that the salt, ethanol and sodium dodecyl sulfate (SDS) sensitivity of YOYO[®]-1 dye binding to DNA is a function of the dye:base pair ratio.¹⁹

Figure 8.1.5 Lambda bacteriophage *Hind*III fragments were prestained with various nucleic acid dyes, run on a 0.7% agarose gel and visualized using a standard 300 nm UV transilluminator. From left to right, the dyes used were: POPO[™]-1 (P3580), BOBO[™]-1 (B3582), YOYO[®]-1 (Y3601), TOTO[®]-1 (T3600), JOJO[™]-1 (J11372), POPO[™]-3 (P3584), LOLO[™]-1 (L11376), BOBO[™]-3 (B3586), YOYO[®]-3 (Y3606) and TOTO[®]-3 (T3604) nucleic acid stains. The longest-wavelength stains are barely visible to the eye but can be detected with infrared-enhanced films and imaging equipment.

Figure 8.1.6 The relaxation of a single, 39 μm -long DNA molecule stained with YOYO[®]-1 iodide (Y3601) imaged at 4.5 second intervals. After the 1 μm polystyrene sphere was trapped with optical tweezers, the attached DNA was stretched to its full extension in a fluid flow and then allowed to relax upon stoppage of fluid flow due to its entropic elasticity (Science (1994) 264:822). The YOYO[®]-1 iodide–DNA complex is excited with the 488 nm spectral line of the argon-ion laser and visualized through a 515 nm longpass optical filter using a Hamamatsu SIT camera with image processing. Image contributed by Thomas Perkins, Stanford University.

Figure 8.1.7 NMR solution structure of the TOTO[®]-1 dye (T3600) bound to DNA; the image was derived from data submitted to the Protein Data Bank (number PDB 108D, www.rcsb.org/pdb/) (Nucleic Acids Res (2000) 28:235). The NMR structure shows that TOTO[®]-1 binds to DNA through bis-intercalation (Biochemistry (1995) 34:8542).

TOTO[®]-1 dye is also capable of bis-intercalation,²⁰ although it reportedly interacts with dsDNA and ssDNA with similarly high affinity.¹ NMR studies of TOTO[®]-1 dye interactions with a double-stranded 8-mer indicate that TOTO[®]-1 dye is a bis-intercalator, with the fluorophores intercalating between the bases and the linker region having interactions in the minor groove²¹ (Figure 8.1.7). Binding of the dye partially unwinds the DNA,²¹ distorting and elongating the helix.²² However, another study using fluorescence polarization measurements suggests that an external binding mode, where the dipole of the dye molecule is aligned with the DNA grooves, may be more important.²³ TOTO[®]-1 dye reportedly exhibits some sequence selectivity for the site 5'-CTAG-3', although it will bind to almost any sequence in dsDNA.^{24–27} TOTO[®]-1 dye does not exhibit cooperative binding to DNA, suggesting that it may be a suitable dye for detecting nucleic acids in gels.²⁵

The binding modes of the other members of the TOTO[®] dye series have also been partially characterized. Electrophoresis and fluorescence lifetime measurements have shown that YOYO[®]-3 dye also appears to intercalate into DNA.²⁸ During application development, we have determined that staining of nucleic acids by BOBO[™]-1 and POPO[™]-1 dyes is much faster (occurring within minutes) than staining by YOYO[®]-1 or TOTO[®]-1 dyes (which can take several hours to reach equilibrium under the same experimental conditions),²⁰ indicating possible differences in their binding mechanisms. Fluorescence yield and lifetime measurements have been used to assess the base selectivity of an extensive series of these dyes.¹⁰ Circular dichroism measurements have shown that bis-intercalation is the predominant binding mode for the POPO[™]-1 dye.²⁹

Working with Cyanine Dimers

All of the dyes in the TOTO[®] series (Table 8.2) are supplied as 1 mM solutions in dimethylsulfoxide (DMSO), except for POPO[™]-3 (P3584), which is supplied as a 1 mM solution in dimethylformamide (DMF). These cationic dyes appear to be readily adsorbed out of aqueous solutions onto surfaces (particularly glass) but are very stable once complexed to nucleic acids.

Cell-Impermeant Cyanine Monomers: The TO-PRO[®] Family of Dyes

Our TO-PRO[®] family of dyes, all of which are listed in Table 8.2, each comprise a single cyanine dye and a cationic side chain (Figure 8.1.3). The monomeric dyes in the TO-PRO[®] series are spectrally analogous to the corresponding dimeric cyanine dyes; however, with only two positive charges and one intercalating unit, the TO-PRO[®] dyes exhibit somewhat reduced affinity for nucleic acids relative to the dyes in the TOTO[®] series. Like their dimeric counterparts, these monomeric cyanine dyes are typically impermeant to cells,³⁰ although YO-PRO[®]-1 (Y3603) dye has been shown to be permeant to apoptotic cells, providing a convenient indicator of apoptosis^{31–34} (Section 15.5). YO-PRO[®]-1 has also been observed to pass through P2X₇ receptor channels of live cells.^{35–37}

Figure 8.1.8 Absorption and fluorescence emission spectra of the SYTOX[®] Green nucleic acid stain bound to DNA.

Spectral Characteristics of the Cyanine Dye Monomers

The TO-PRO[®] family of dyes retains all of the exceptional spectral properties of the dimeric cyanine dyes discussed above. The absorption and emission spectra of these monomeric cyanine dyes cover the visible and near-infrared spectrum (Table 8.2). They also have relatively narrow emission bandwidths, thus facilitating multicolor applications in imaging and flow cytometry. YO-PRO[®]-1 (491/509) and TO-PRO[®]-1 (515/531) dyes are optimally excited by the 488 nm and 514 nm spectral lines of the argon-ion laser, respectively. In flow cytometric analysis, the TO-PRO[®]-3 (642/661) complex with nucleic acids has been excited directly by the red He-Ne laser³⁸ and indirectly by the argon-ion laser by using fluorescence resonance energy transfer (FRET) from co-bound propidium iodide³⁹ (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). The TO-PRO[®]-3 complex with nucleic acids has also been detected in a flow cytometer equipped with an inexpensive 3 mW visible-wavelength diode laser that provides excitation at 635 nm.⁴⁰ Although the DNA-induced fluorescence enhancement of TO-PRO[®]-5 dye (T7596) is not as large as that observed with our other cyanine dyes, its spectral characteristics (excitation/emission maxima ~745/770 nm) provide a unique alternative for multicolor applications.

Working with Cyanine Monomers

The binding affinity of the TO-PRO® series of dyes to dsDNA is lower than that of the TOTO® series of dyes but is still very high, with dissociation constants in the micromolar range.⁴¹ TO-PRO® dyes also bind to RNA and ssDNA, although typically with somewhat lower fluorescence quantum yields. Fluorescence polarization studies indicate that TO-PRO®-1 and PO-PRO™-1 dyes bind by intercalation, with unwinding angles of 2° and 31°, respectively.²⁹ Binding of these dyes to dsDNA is not sequence selective.⁴² All dyes of the TO-PRO® series (Table 8.2) are supplied as 1 mM solutions in DMSO.

Cell-Impermeant SYTOX® Dyes for Dead-Cell Staining

SYTOX® Green Stain

Our SYTOX® nucleic acid stains (Table 8.2) are cell-impermeant cyanine dyes that are particularly useful as dead-cell stains. SYTOX® Green nucleic acid stain (S7020) is a high-affinity nucleic acid stain that easily penetrates cells with compromised plasma membranes and yet will not cross the membranes of live cells. It is especially useful for staining both gram-positive and gram-negative bacteria, in which an exceptionally bright signal is required. Following brief incubation with the SYTOX® Green stain, dead cells fluoresce bright green when excited with the 488 nm spectral line of the argon-ion laser or with any other 450–500 nm source (Figure 8.1.8). Because all of the SYTOX® dyes are essentially nonfluorescent in aqueous medium, no wash steps are required. Unlike the DAPI or Hoechst dyes, the SYTOX® Green nucleic acid stain shows little base selectivity. These properties, combined with its ~1000-fold fluorescence enhancement upon nucleic acid binding and high quantum yield, make our SYTOX® Green stain a simple and quantitative single-step dead-cell indicator for use with epifluorescence and confocal laser-scanning microscopes, fluorometers, fluorescence microplate readers and flow cytometers (Figure 8.1.9).

The SYTOX® Green nucleic acid stain can be used with blue- and red-fluorescent labels for multiparameter analyses (Figure 8.1.10). It is also possible to combine the SYTOX® Green nucleic acid stain with the SYTO® 17 red-fluorescent nucleic acid stain (S7579) for two-color visualization of dead and live cells. Because the SYTOX® Green nucleic acid stain is an excellent DNA counterstain for chromosome labeling and for fixed cells and tissues (Figure 8.1.11), we have incorporated it into our SelectFX® Nuclear Labeling Kit (S33025), which is discussed in Section 12.5.

SYTOX® Blue Stain

SYTOX® Blue stain (S11348, S34857) is a high-affinity nucleic acid stain that typically penetrates only cells with compromised plasma membranes (Figure 8.1.12). The SYTOX® Blue stain

Figure 8.1.11 Adult zebrafish gut cryosections that have been incubated with BODIPY® TR-X phalloidin (B7464), followed by the SYTOX® Green nucleic acid stain (S7020), and then dehydrated and mounted. The image was obtained by taking multiple exposures through bandpass optical filter sets appropriate for fluorescein and the Texas Red® dye.

Figure 8.1.12 A mixed population of live and isopropyl alcohol-killed *Micrococcus luteus* stained with SYTOX® Blue nucleic acid stain (S11348), which does not penetrate intact plasma membranes. Dead cells exhibit bright blue-fluorescent staining. The image was acquired using a longpass optical filter set appropriate for the Cascade Blue® dye.

Figure 8.1.9 Quantitative flow cytometric analysis of *Escherichia coli* viability using the SYTOX® Green nucleic acid stain (S7020). A bacterial suspension containing an equal number of live and isopropyl alcohol-killed *E. coli* was stained with SYTOX® Green and analyzed using excitation at 488 nm. A bivariate frequency distribution for forward light scatter versus log fluorescence intensity (collected with a 510 nm longpass optical filter) shows two clearly distinct populations. When live and dead bacteria were mixed in varying proportions, a linear relationship between the population numbers and the actual percentage of live cells in the sample was obtained (see inset).

Figure 8.1.10 Bovine pulmonary artery endothelial cells (BPAEC) incubated with the fixable, mitochondrion-selective MitoTracker® Red CMXRos (M7512). After staining, the cells were formaldehyde-fixed, acetone-permeabilized, treated with DNase-free RNase and counterstained using SYTOX® Green nucleic acid stain (S7020). Microtubules were labeled with a mouse monoclonal anti- β -tubulin antibody, biotin-XX goat anti-mouse IgG antibody (B2763) and Cascade Blue® NeutrAvidin™ biotin-binding protein (A2663). This photograph was taken using multiple exposures through bandpass optical filters appropriate for Texas Red® dye, fluorescein and DAPI using a Nikon® Labophot 2 microscope equipped with a Quadflour epi-illumination system.

Figure 8.1.13 Absorption and fluorescence emission spectra of SYTOX® Blue nucleic acid stain bound to DNA.

Figure 8.1.14 Absorption and fluorescence emission spectra of SYTOX® Orange nucleic acid stain bound to DNA.

labels both DNA and RNA with extremely bright fluorescence centered near 470 nm (Figure 8.1.13). The absorption maximum of the nucleic acid-bound SYTOX® Blue stain (~445 nm) permits very efficient fluorescence excitation by the 436 nm spectral line of the mercury-arc lamp. Unlike many blue-fluorescent dyes, the SYTOX® Blue stain is also efficiently excited by tungsten-halogen lamps and other sources that have relatively poor emission in the UV portion of the spectrum. The brightness of the SYTOX® Blue stain allows sensitive detection with fluorimeters, microplate readers, arc-lamp-equipped flow cytometers and epifluorescence microscopes, including those not equipped with UV-pass optics.

* All products supplied as 250 µL of a 5 mM solution, with exceptions noted. † Wavelengths of excitation (Ex) and emission (Em) maxima, in nm. All excitation and emission maxima were determined for dyes bound to double-stranded calf thymus DNA in aqueous solution, except for the SYTO® RNASelect™ green-fluorescent cell stain, which was determined for the dye bound to *Escherichia coli* RNA. ‡ Supplied as individual 50 µL vials. § Unit size = 100 µL. ** Supplied as 250 µL of a 1 mM solution.

In a side-by-side comparison with the SYTOX® Green stain, the SYTOX® Blue stain yielded identical results when quantitating membrane-compromised bacterial cells. Furthermore, like the SYTOX® Green stain, the SYTOX® Blue stain does not interfere with bacterial cell growth. Because their emission spectra overlap somewhat, we have found that it is not ideal to use the SYTOX® Blue stain and green-fluorescent dyes together; however, fluorescence emission of the SYTOX® Blue stain permits clear discrimination from orange- or red-fluorescent probes, facilitating the development of multicolor assays with minimal spectral overlap between signals.

SYTOX® Orange Stain

SYTOX® Orange nucleic acid stain (S11368) is designed to clearly distinguish dead bacteria, yeast or mammalian cells from live cells. As compared with propidium iodide, SYTOX® Orange stain has shorter-wavelength emission and its spectra more closely matches the rhodamine filter set (Figure 8.1.14). In addition, the SYTOX® Orange stain has a much higher molar absorptivity (extinction coefficient) than propidium iodide and a far greater fluorescence enhancement upon binding DNA, suggesting that it may have a higher sensitivity as a dead-cell stain or as a nuclear counterstain. The SYTOX® Orange stain was shown to be extremely useful for DNA fragment sizing by single-molecule flow cytometry when using a Nd:YAG excitation source, with a 450-fold enhancement upon binding to dsDNA.⁴³

Cell-Permeant Cyanine Dyes: The SYTO® Nucleic Acid Stains

SYTO® Nucleic Acid Stains for DNA and RNA

The SYTO® dyes are somewhat lower-affinity nucleic acid stains that passively diffuse through the membranes of most cells. These UV- or visible light-excitabile dyes can be used to stain RNA and DNA in both live and dead eukaryotic cells, as well as in gram-positive and gram-negative bacteria. We have synthesized a large number of SYTO® dyes (Table 8.3) that share several important characteristics:

- Permeability to virtually all cell membranes, including mammalian cells and bacteria (Chapter 15)
- High molar absorptivity, with extinction coefficients greater than $50,000 \text{ cm}^{-1}\text{M}^{-1}$ at visible absorption maxima
- Extremely low intrinsic fluorescence, with quantum yields typically less than 0.01 when not bound to nucleic acids
- Quantum yields typically greater than 0.4 when bound to nucleic acids

Available as blue-, green-, orange- or red-fluorescent dyes, these novel SYTO® stains provide researchers with visible light-excitabile dyes for labeling DNA and RNA in live cells (Figure 8.1.15). SYTO® dyes differ from each other in one or more characteristics, including cell permeability, fluorescence enhancement upon binding nucleic acids, excitation and emission spectra (Table 8.3), DNA/RNA selectivity and binding affinity. The SYTO® dyes are compatible with a variety of fluorescence-based instruments that use either laser excitation or a conventional broadband illumination source (e.g., mercury- and xenon-arc lamps).

The SYTO® dyes can stain both DNA and RNA. In most cases, the fluorescence wavelengths and emission intensities are similar for solution measurements of DNA or RNA binding. Exceptions include the SYTO® 12 and SYTO® 14 dyes, which are about twice as fluorescent when complexed with RNA as with DNA, and SYTO® 16, which is about twice as fluorescent on DNA than RNA. Consequently, the SYTO® dyes do not act exclusively as nuclear stains in live cells and should not be equated in this regard with DNA-selective compounds such as DAPI or the Hoechst 33258 and Hoechst 33342 dyes, which readily stain cell nuclei at low concentrations in most cells. SYTO® dye-stained eukaryotic cells will generally show diffuse cytoplasmic staining, as well as nuclear staining. The SYTO® 14 dye (S7576) has been used to visualize the translocation of endogenous RNA found in polyribosome complexes in living cells.^{44,45} Particularly intense staining of intranuclear bodies is frequently observed. Because these dyes are generally cell permeant and most of the SYTO® dyes contain a net positive charge at neutral pH, they may also stain mitochondria. In addition, the SYTO® dyes will stain most gram-positive and

Figure 8.1.15 Human neutrophil nuclei stained with SYTO® 13 live-cell nucleic acid stain (S7575). The photo was acquired using an optical filter appropriate for fluorescein, and differential interference contrast (DIC) sequentially in a Nikon® Eclipse E800 microscope.

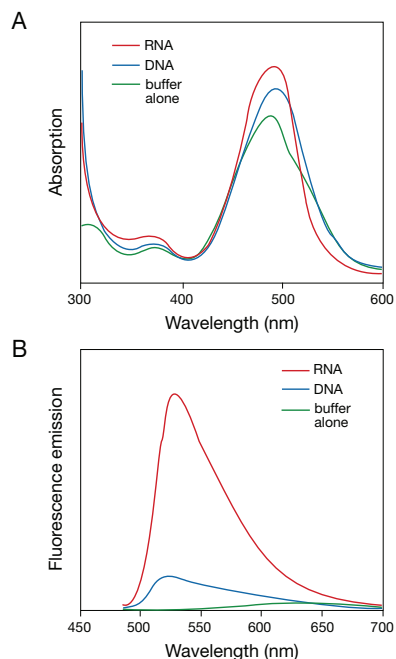

Figure 8.1.16 Relative absorption (A) and fluorescence emission (B) spectra of SYTO® RNaselect™ green-fluorescent cell stain (S32703) in the presence of *Escherichia coli* RNA or DNA or in buffer alone.

Figure 8.1.17 Methanol-fixed bovine pulmonary artery endothelial cells treated with RNase, DNase or both, and then labeled with SYTO® RNaselect™ Green cell stain (S32703). Removal of RNA with RNase prevented nucleolar labeling and greatly decreased nuclear and cytoplasmic labeling. Use of DNase resulted in less of a loss of label intensity in these cell compartments, reflecting the RNA-selective nature of this dye.

Figure 8.1.18 Methanol-fixed MRC-5 cells stained with SYTO® RNaselect™ green-fluorescent cell stain (S32703). Nuclei were stained with DAPI (D1306, D3571, D21490); the densely stained areas are nuclei.

gram-negative bacterial cells. Dead yeast cells are brightly stained with the SYTO® dyes, and live yeast cells typically exhibit staining of both the mitochondria and the nucleus. Some of the SYTO® dyes have been reported to be useful for detecting apoptosis^{46,47} (Section 15.5), and dyes structurally similar to the SYTO® dyes have been used to detect multidrug-resistant cells⁴⁸ (Section 15.6). The red-fluorescent SYTO® dyes are proving useful as counterstains (Section 12.5) when combined with green-fluorescent antibodies, lectins or the cell-impermeant SYTOX® Green nucleic acid stain.

All of the SYTO® dyes are available separately (Table 8.3), and several SYTO® dyes are included in our LIVE/DEAD® Viability Kits (Section 15.3, Table 15.2). The green-fluorescent SYBR® 14 dye, a component of our LIVE/DEAD® Sperm Viability Kit (L7011, Section 15.3) is also in the SYTO® family of dyes. To facilitate testing the SYTO® dyes in new applications, we offer several sampler kits containing sample sizes of SYTO® dyes in each color set (Table 8.3). The recommended dye concentration for cell staining depends on the assay and may vary widely but is typically 1–20 μM for bacteria, 1–100 μM for yeast and 10 nM–5 μM for other eukaryotes.

SYTO® RNaselect™ Green-Fluorescent Cell Stain

SYTO® RNaselect™ green-fluorescent cell stain (S32703, Section 15.2) is a cell-permeant nucleic acid stain that selectively stains RNA (Figure 8.1.16, Figure 8.1.17). Although virtually nonfluorescent in the absence of nucleic acids, the SYTO® RNaselect™ stain exhibits bright green fluorescence when bound to RNA (absorption/emission maxima ~490/530 nm), but only a weak fluorescent signal when bound to DNA (Figure 8.1.16). Filter sets that are suitable for imaging cells labeled with fluorescein (FITC) will work well for imaging cells stained with SYTO® RNaselect™ stain (Figure 8.1.18).

Amine-Reactive Cyanine Dye

The amine-reactive succinimidyl ester of SYBR® 101 dye (S21500) can be conjugated to peptides, proteins, drugs, polymeric matrices and biomolecules with primary amine groups. The conjugates are expected to be essentially nonfluorescent until they complex with nucleic acids, resulting in strong green fluorescence. Thus, they may be useful for studies of nucleic acid binding to various biomolecules, such as DNA-binding proteins. It is also possible that the fluorescence enhancement upon nucleic acid binding of SYBR® 101 dye conjugates will be useful for monitoring their transport into the nucleus. SYBR® 101 dye conjugates of solid or semisolid matrices (such as microspheres, magnetic particles or various resins) may be useful for detection or affinity isolation of nucleic acids.

The reactive SYBR® 101 dye may also be conjugated to amine-modified nucleic acids. Although it is possible that the SYBR® 101 dye may show some fluorescence when conjugated to amine groups on nucleic acids, they may be useful for developing homogeneous hybridization assays in which a specific sequence can be quantitated in solution without the need to separate bound and free probes. For example, a similar reactive nucleic acid stain has been used to label peptide–nucleic acid conjugates (PNA) for use as probes in real-time PCR. The labeled PNA probes exhibited a fluorescence increase upon hybridization to their complementary sequence and have been used to identify a single-base mismatch in a 10-base target sequence.^{49,50}

Figure 8.1.20 Propidium iodide (P1304MP).

Phenanthridines and Acridines: Classic Intercalating Dyes

Cell-Impermeant Ethidium Bromide and Propidium Iodide

Ethidium bromide (EtBr, 15585-011; Figure 8.1.19) and propidium iodide (PI, P1304MP; P3566, P21493; Figure 8.1.20) are structurally similar phenanthridinium intercalators. PI is more soluble in water and less membrane-permeant than EtBr, although both dyes are generally excluded from viable cells. EtBr and PI can be excited with mercury- or xenon-arc lamps or with the argon-ion laser, making them suitable for fluorescence microscopy, confocal laser-scanning microscopy (Figure 8.1.21), flow cytometry and fluorometry. These dyes bind with little or no sequence preference at a stoichiometry of one dye per 4–5 base pairs of DNA.⁵¹ Excitation of the EtBr–DNA complex may result in photobleaching of the dye and single-strand breaks.⁵² Both EtBr and PI also bind to RNA, necessitating treatment with nucleases to distinguish between RNA and DNA. Once these dyes are bound to nucleic acids, their fluorescence is enhanced ~10-fold, their excitation maxima are shifted ~30–40 nm to the red and their emission maxima are shifted ~15 nm to the blue⁵³ (Figure 8.1.22, Table 8.4). Although their molar absorptivities (extinction coefficients) are relatively low, EtBr and PI exhibit sufficiently large Stokes shifts to allow simultaneous detection of nuclear DNA and fluorescein-labeled antibodies, provided that the proper optical filters are used.

PI is commonly used as a nuclear or chromosome counterstain (Section 12.5, Figure 8.1.21) and as a stain for dead cells (Section 15.2, Figure 8.1.23). EtBr is the conventional dye used for nucleic acid gel staining (Section 8.4). However, our SYBR® Gold and SYBR® Green nucleic acid gel stains are far more sensitive than EtBr, and the SYBR® Green I stain has been shown to be significantly less mutagenic than EtBr by Ames testing⁵⁴ (Section 8.4). Furthermore, our SYBR® Safe DNA gel stain, which is as sensitive as EtBr and less mutagenic in the standard Ames test, has tested negative in three mammalian cell-based assays for genotoxicity and is not classified as hazardous waste under U.S. Federal regulations (Section 8.4).

EtBr and PI are potent mutagens and must be handled with extreme care. Solutions containing EtBr or PI can be decontaminated by filtration through activated charcoal, which is then incinerated, thus providing an economical decontamination procedure.⁵⁵ Alternatively, the dyes can be completely degraded in buffer by reaction with sodium nitrite and hypophosphorous acid.⁵⁶ PI is offered as a solid (P1304MP, P21493), and both EtBr and PI are available as aqueous solutions (15585-011, P3566).

Cell-Permeant Hexidium Iodide

Hexidium iodide (H7593) is a moderately lipophilic phenanthridinium dye (Figure 8.1.24) that is permeant to mammalian cells and selectively stains almost all gram-positive bacteria in the presence of gram-negative bacteria. Our LIVE *BacLight*™ Bacterial Gram Stain Kit and ViaGram™ Red+ Bacterial Gram Stain and Viability Kit (L7005, V7023; Section 15.3) use

hexidium iodide for the discrimination of bacterial gram sign (Figure 8.1.25). Hexidium iodide yields slightly shorter-wavelength spectra upon DNA binding than our ethidium or propidium dyes. Generally, both the cytoplasm and nuclei of eukaryotic cells show staining with hexidium iodide; however, mitochondria and nucleoli may also be stained.

Cell-Permeant Dihydroethidium (Hydroethidine)

Dihydroethidium (also known as hydroethidine) is a chemically reduced ethidium derivative (Figure 8.1.26) that is permeant to live cells and exhibits blue fluorescence in the cytoplasm. Many viable cells oxidize the probe to ethidium, which then fluoresces red upon DNA intercalation⁵⁷⁻⁵⁹ (Figure 8.1.27). Dihydroethidium, which is somewhat air sensitive, is available in a 25 mg vial (D1168) or specially packaged in 10 vials of 1 mg each (D11347); the special packaging is strongly recommended when small quantities of the dye will be used at a time. Dihydroethidium is also available as a 5 mM stabilized solution in dimethylsulfoxide (D23107).

* Excitation (Ex) and emission (Em) maxima in nm. All excitation and emission maxima were determined for dyes bound to double-stranded calf thymus DNA in aqueous solution, unless otherwise indicated. † Indication of dyes as "permeant" or "impermeant" are for the most common applications; permeability to cell membranes may vary considerably with the cell type, dye concentrations and other staining conditions. ‡ Available in aqueous solution for those wishing to avoid potentially hazardous and mutagenic powders. § After oxidation to ethidium. ** Prior to photolysis; after photolysis the spectra of the dye/DNA complexes are similar to those of ethidium bromide-DNA complexes.

High-Affinity Ethidium Homodimers

Ethidium homodimer-1 (EthD-1, E1169; Figure 8.1.28) and ethidium homodimer-2 (EthD-2, E3599; Figure 8.1.29) strongly bind to dsDNA, ssDNA, RNA and oligonucleotides with a significant fluorescence enhancement (>40-fold). EthD-1 also binds with high affinity to triplex nucleic acid structures.⁶⁰ One molecule of EthD-1 binds per four base pairs in dsDNA,⁴ and the dye's intercalation is not sequence selective.⁶¹ It was originally reported that only one of the two phenanthridinium rings of EthD-1 is bound at a time;⁴ subsequent reports indicate that bis-intercalation appears to be involved in staining both double-stranded and triplex nucleic acids.^{20,60}

The spectra and other properties of the EthD-1 and EthD-2 dimers are almost identical (Figure 8.1.30). However, the DNA affinity of EthD-2 is about twice that of EthD-1. EthD-2 is also about twice as fluorescent bound to dsDNA than to RNA. Because both EthD-1 and EthD-2 can be excited with UV light or by the 488 nm spectral line of the argon-ion laser, either dye can be used in combination with the TOTO[®]-1, YOYO[®]-1 or SYTOX[®] Green nucleic acid stains for multicolor experiments (Figure 8.1.31). The ethidium homodimer dyes are impermeant to cells with intact membranes, a property that makes EthD-1 useful as a dead-cell indicator in our

Figure 8.1.31 Normalized fluorescence emission spectra of DNA-bound SYTOX[®] Green nucleic acid stain (S7020) and ethidium homodimer-1 (EthD-1, E1169). Both spectra were obtained using excitation at 488 nm.

* Excitation (Ex) and emission (Em) maxima in nm. All excitation and emission maxima were determined for dyes bound to double-stranded calf thymus DNA in aqueous solution, unless otherwise indicated. † Indication of dyes as "permeant" or "impermeant" are for the most common applications; permeability to cell membranes may vary considerably with the cell type, dye concentrations and other staining conditions. ‡ Available in aqueous solution for those wishing to avoid potentially hazardous and mutagenic powders. § After oxidation to ethidium. ** Prior to photolysis; after photolysis the spectra of the dye/DNA complexes are similar to those of ethidium bromide–DNA complexes.

Figure 8.1.32 Live and dead kangaroo rat (PtK2) cells stained with ethidium homodimer-1 and the esterase substrate calcein AM, both of which are provided in our LIVE/DEAD[®] Viability/Cytotoxicity Kit (L3224). Live cells fluoresce a bright green, whereas dead cells with compromised membranes fluoresce red-orange.

Figure 8.1.33 A mixed population of trinitrophenyl-sensitized and nonsensitized bovine pulmonary artery endothelial cells that have been probed with anti-dinitrophenyl-KLH antibody (A6430), incubated with rabbit complement and then stained using the LIVE/DEAD[®] Reduced Biohazard Viability/Cytotoxicity Kit #1 (L7013). With this kit, the membrane-permeant SYTO[®] 10 dye labels the nucleic acids of live cells with green fluorescence, and the membrane-impermeant DEAD Red[™] dye labels nucleic acids of membrane-compromised cells with red fluorescence. Subsequent aldehyde-based fixation inactivates pathogens without distorting the original staining pattern. This multiple-exposure image was acquired with bandpass optical filters appropriate for fluorescein and Texas Red[®] dyes.

LIVE/DEAD® Viability/Cytotoxicity Kit (L3224, Section 15.3, Figure 8.1.32) and EthD-2 (as Dead Red™ nucleic acid stain) a suitable dead-cell indicator in our LIVE/DEAD® Reduced Biohazard Cell Viability Kit #1 (L7013, Section 15.3, Figure 8.1.33). These dyes have also been used to detect DNA in solution,⁶¹ although they are not as sensitive or as easy to use as our Quant-iT™ PicoGreen® dsDNA reagent (Section 8.3).

Ethidium Monoazide: A Photocrosslinking Reagent

Nucleic acids can be covalently photolabeled by various DNA intercalators. Ethidium monoazide (E1374, Figure 8.1.34) is a fluorescent photoaffinity label that, after photolysis, binds covalently to nucleic acids both in solution and in cells that have compromised membranes.^{62–66} The quantum yield for covalent photolabeling by ethidium monoazide is unusually high (>0.4).

The membrane-impermeant ethidium monoazide is reported to only label dead cells and is therefore particularly useful for assaying the viability of pathogenic cells (Section 15.2). A mixed population of live and dead cells incubated with this reagent can be illuminated with a visible-light source, washed, fixed and then analyzed in order to determine the viability of the cells at the time of photolysis.⁶⁷ This method not only reduces some of the hazards inherent in working with pathogenic cells, but also is compatible with immunocytochemical analyses requiring fixation. We have developed alternative assays for determining the original viability of fixed samples and provide these in the LIVE/DEAD® Reduced Biohazard Cell Viability Kit #1 (L7013) and the LIVE/DEAD® Fixable Dead Cell Stain Kits, which are described in Section 15.3.

In addition to its utility as a viability indicator, ethidium monoazide has been used to irreversibly label the DNA of *Candida albicans* in order to investigate phagocytic capacity of leukocytes.⁶⁸ Ethidium monoazide has also been employed to "footprint" drug-binding sites on DNA,⁶⁹ to probe for ethidium-binding sites in DNA⁷⁰ and transfer RNA (tRNA)⁶⁵ and to selectively photoinactivate the expression of genes in vertebrate cells.⁷¹

Acridine Orange: A Dual-Fluorescence Nucleic Acid Stain

We offer highly purified, flow cytometry-grade acridine orange, a dye that interacts with DNA and RNA by intercalation or electrostatic attractions. In condensed chromatin, however, the bulk of DNA is packed in a way that does not allow efficient acridine orange intercalation.⁷² This cationic dye (Figure 8.1.35) has green fluorescence with an emission maximum at 525 nm when bound to DNA. Upon association with RNA, its emission is shifted to ~650 nm (red fluorescence). Acridine orange is available as a solid (A1301) and, for ease of handling, as a 10 mg/mL aqueous solution (A3568).

AT-Selective Acridine Homodimer

The water-soluble acridine homodimer bis-(6-chloro-2-methoxy-9-acridinyl)spermine (A666, Figure 8.1.36) is one of several acridine dimers that have been described in the literature. This dye has extremely high affinity for AT-rich regions of nucleic acids, making it particularly useful for chromosome banding.^{73,74} Acridine homodimer emits a blue-green fluorescence when bound to DNA, yielding fluorescence that is proportional to the fourth power of the AT base-pair content.⁷⁵ Because of its greater brightness and photostability, acridine homodimer has been recommended as an alternative to quinacrine for Q banding.⁷³

Figure 8.1.40 Absorption and fluorescence emission spectra of Hoechst 33258 bound to DNA.

Figure 8.1.41 4',6-Diamidino-2-phenylindole, dihydrochloride (DAPI, D1306).

AT-Selective ACMA

ACMA (9-amino-6-chloro-2-methoxyacridine, A1324, Figure 8.1.37) is a DNA intercalator that selectively binds to poly(d(AT)) with a binding affinity constant of $2 \times 10^5 \text{ M}^{-1}$ at pH 7.4.^{76,77} Excitation of the ACMA–DNA complex (excitation/emission maxima $\sim 419/483 \text{ nm}$) is possible with most UV-light sources, making it compatible for use with both shorter- and longer-wavelength dyes. ACMA also apparently binds to membranes in the energized state and becomes quenched if a pH gradient forms.⁷⁸ It has been extensively employed to follow cation and anion movement across membranes^{78–81} and to study the proton-pumping activity of various membrane-bound ATPases^{82,83} (Section 20.3).

Indoles and Imidazoles: Classic Minor Groove–Binding Dyes

DNA-Selective Hoechst Dyes

The bisbenzimidazole dyes—Hoechst 33258 (Figure 8.1.38), Hoechst 33342 (Figure 8.1.39) and Hoechst 34580—are cell membrane-permeant, minor groove-binding DNA stains (Figure 8.1.1) that fluoresce bright blue upon binding to DNA. Hoechst 33342 has slightly higher membrane permeability than Hoechst 33258,⁵³ but both dyes are quite soluble in water (up to 2% solutions can be prepared) and relatively nontoxic. These Hoechst dyes, which can be excited with the UV spectral lines of the argon-ion laser and by most conventional fluorescence excitation sources, exhibit relatively large Stokes shifts (Figure 8.1.40) (excitation/emission maxima $\sim 350/460 \text{ nm}$), making them suitable for multicolor labeling experiments. Hoechst 34580⁸⁴ has somewhat longer-wavelength spectra than the other Hoechst dyes when bound to nucleic acids.

The Hoechst 33258 and Hoechst 33342 dyes have complex, pH-dependent spectra when not bound to nucleic acids, with a much higher fluorescence quantum yield at pH 5 than at pH 8. Their fluorescence is also enhanced by surfactants such as sodium dodecyl sulfate⁸⁵ (SDS). These dyes appear to show a wide spectrum of sequence-dependent DNA affinities and bind with sufficient strength to poly(d(AT)) sequences that they can displace several known DNA intercalators.⁸⁶ They also exhibit multiple binding modes and distinct fluorescence emission spectra that are dependent on dye:base pair ratios.⁸⁷ Hoechst dyes are used in many cellular applications, including cell-cycle and apoptosis studies (Section 15.4, Section 15.5), and they are common nuclear counterstains (Section 12.5). Hoechst 33258, which is selectively toxic to malaria parasites,⁸⁸ is also useful for flow cytometric screening of blood samples for malaria parasites and for assessing their susceptibility to drugs.^{89–91}

The Hoechst 33258 and Hoechst 33342 dyes are available as solids (H1398, H1399), as high-purity solids (H21491, H21492) and, for ease of handling, as 10 mg/mL aqueous solutions (H3569, H3570). The Hoechst 34580 dye is available as a solid (H21486).

AT-Selective DAPI

DAPI (4',6-diamidino-2-phenylindole; D1306, D3571, D21490; Figure 8.1.41) shows blue fluorescence (Figure 8.1.42) upon binding DNA and can be excited with a mercury-arc lamp or with the UV lines of the argon-ion laser. Like the Hoechst dyes, the blue-fluorescent DAPI stain apparently associates with the minor groove of dsDNA (Figure 8.1.43), preferentially binding to AT clusters;⁹² there is evidence that DAPI also binds to DNA sequences that contain as few as two consecutive AT base pairs, perhaps employing a different binding mode.^{93–95} DAPI is thought to employ an intercalating binding mode with RNA that is AU selective.⁹⁶

The selectivity of DAPI for DNA over RNA is reported to be greater than that displayed by ethidium bromide and propidium iodide.⁹⁷ Furthermore, the DAPI–RNA complex exhibits a longer-wavelength fluorescence emission maximum than the DAPI–dsDNA complex ($\sim 500 \text{ nm}$ versus $\sim 460 \text{ nm}$) but a quantum yield that is only about 20% as high.⁹⁸

Binding of DAPI to dsDNA produces an ~ 20 -fold fluorescence enhancement, apparently due to the displacement of water molecules from both DAPI and the minor groove.⁹⁹ Although the Hoechst dyes may be somewhat brighter in some applications, their photostability when bound to dsDNA is less than that of DAPI. In the presence of appropriate salt concentrations, DAPI usually does not exhibit fluorescence enhancement upon binding to ssDNA or GC base pairs.¹⁰⁰ However, the fluorescence of DAPI does increase significantly upon binding to detergents,¹⁰¹ dextran sulfate,¹⁰² polyphosphates and other polyanions.¹⁰³ A review by Kapuscinski discusses the mechanisms of DAPI binding to nucleic acids, its spectral properties and its uses

Figure 8.1.42 Neural somata labeled with NeuroTrace[®] 530/615 red-fluorescent Nissl stain (N21482). Nuclei in this mouse cerebellum section were counterstained with DAPI (D1306, D3571, D21490). The image is a composite of two micrographs acquired using filters appropriate for tetramethylrhodamine and DAPI.

Figure 8.1.43 X-ray crystal structure of DAPI (D1306, D3571, D21490) bound to DNA; the image was derived from data submitted to the Protein Data Bank (number PDB 1D30, www.rcsb.org/pdb) (Nucleic Acids Res (2000) 28:235). X-ray crystallography shows that DAPI binds to DNA in the minor groove (J Biol Struct Dyn (1989) 7:477).

Figure 8.1.46 Absorption and fluorescence emission spectra of 7-aminoactinomycin D (7-AAD) bound to DNA.

Figure 8.1.47 Panel of confocal micrographs showing cells from wheat root tips in seven stages of the cell cycle. DNA was stained with 7-aminoactinomycin D (A1310), and microtubules were labeled with an anti- β -tubulin antibody in conjunction with a fluorescein-labeled secondary antibody. Cells vary in width from about 15 μm to about 25 μm . The stages are (from top left): interphase cortical microtubule array; pre-prophase band of microtubules (predicts future plane of division); metaphase mitotic spindle; telophase, showing early phragmoplast and cell plate; fully developed phragmoplast during cytokinesis; late cytokinesis (plane of division matching plane of earlier pre-prophase band); and restoration of cortical arrays in daughter cells. Figure 8.1.48 Hydroxystilbamidine, methanesulfonate (H22845).

in flow cytometry and for chromosome staining.¹⁰⁴ DAPI is an excellent nuclear counterstain, showing a distinct banding pattern in chromosomes (Figure 8.1.44), and we have included it in our SelectFX® Nuclear Labeling Kit (S33025, Section 12.5). DAPI is quite soluble in water but has limited solubility in phosphate-buffered saline.

We also offer DAPI premixed with our ProLong® Gold and SlowFade® Gold antifade reagents (P36931, P36935, S36938, S36939; Section 23.1). This combination of nucleic acid dye and antifade reagent permits simultaneous staining and protection of the stained sample from photobleaching.

Other Nucleic Acid Stains

7-Aminoactinomycin D and Actinomycin D: Fluorescent Intercalators

7-AAD (7-aminoactinomycin D, A1310; Figure 8.1.45) is a fluorescent intercalator that undergoes a spectral shift upon association with DNA. 7-AAD–DNA complexes can be excited by the argon-ion laser and emit beyond 610 nm (Table 8.4, Figure 8.1.22, Figure 8.1.46), making this nucleic acid stain useful for multicolor fluorescence microscopy (Figure 8.1.47), confocal laser-scanning microscopy and immunophenotyping by flow cytometry.^{105–110} 7-AAD appears to be generally excluded from live cells, although it has been reported to label the nuclear region of live cultured mouse L cells and salivary gland polytene chromosomes of *Chironomus thummi* larvae.¹¹¹ 7-AAD binds selectively to GC regions of DNA,¹¹² yielding a distinct banding pattern in polytene chromosomes and chromatin.^{111,113} This sequence selectivity has been exploited for chromosome banding studies.¹¹⁴

Actinomycin D (A7592) is a nonfluorescent intercalator that exhibits high GC selectivity and causes distortion at its binding site.¹¹⁵ Binding of the nonfluorescent actinomycin D to nucleic acids changes the absorbance of the dye.¹¹⁶ Like 7-AAD, actinomycin D has been used for chromosome banding studies.¹¹⁷ Binding of actinomycin D to ssDNA is reported to inhibit reverse transcriptase and other polymerases.¹¹⁸

Hydroxystilbamidine

The trypanocidal drug hydroxystilbamidine (H22845, Figure 8.1.48) is an interesting probe of nucleic acid conformation; its nucleic acid staining properties were first described in 1973.¹¹⁹ Hydroxystilbamidine, a nonintercalating dye, exhibits AT-selective binding that is reported to favor regions of nucleic acids that have secondary structure. The interaction between hydroxystilbamidine and DNA has been investigated using binding isotherms¹²⁰ and temperature-jump relaxation studies.¹²¹

Hydroxystilbamidine has some unique spectral properties upon binding nucleic acids. At pH 5, the free dye exhibits UV excitation maxima at ~330 nm and ~390 nm, with dual emission at ~450 nm and ~600 nm (Figure 8.1.49). Although the red-fluorescent component remains present when bound to DNA, it is never observed when the dye is bound to RNA, permitting potential discrimination to be made between these two types of nucleic acids. The enhancement of its metachromatic fluorescence upon binding to DNA is proportional to the square of the AT base-pair content. Hydroxystilbamidine is reported to exhibit red fluorescence when bound to calf thymus DNA and T5 DNA, orange fluorescence with *Micrococcus lysodeikticus* DNA and blue-violet fluorescence on poly(d(AT)).¹¹⁹ It has been used for the treatment of myeloma, binding selectively to myeloma cells in the bone marrow.¹²²

Murgatroyd described the use of hydroxystilbamidine's metachromatic fluorescence properties for the selective permanent staining of DNA (with yellow fluorescence), mucosubstances and elastic fibers in paraffin sections.¹²³ He also reported that hydroxystilbamidine (as its isethionate salt, which we do not currently offer) is nonmutagenic in *Salmonella typhimurium* by the Ames test.¹²³

Long-Wavelength LDS 751 Dye

LDS 751 (L7595, Figure 8.1.50) is a cell-permeant nucleic acid stain that has been used to discriminate intact nucleated cells from nonnucleated and damaged nucleated cells,^{124,125} as well as to identify distinct cell types in mixed populations of neutrophils, leukocytes and monocytes by flow cytometry.¹²⁶ LDS 751, which has its peak excitation at ~543 nm on dsDNA, can be excited by the argon-ion laser at 488 nm and is particularly useful in multicolor analyses due to its long-wavelength emission maximum (~712 nm). Binding of LDS 751 to dsDNA results in an ~20-fold fluorescence enhancement. When LDS 751 binds to RNA, we have observed a significant red shift

in its excitation maximum to 590 nm and blue shift in its emission maxima to 607 nm, which may permit its use to discriminate DNA and RNA in cells. A report has ascribed the name LDS 751 to a dye called styryl 8;¹²⁷ however, their chemical structures are not the same.

NeuroTrace® Fluorescent Nissl Stains

The Nissl substance, described by Franz Nissl more than 100 years ago, is unique to neuronal cells.¹²⁸ Composed of an extraordinary amount of rough endoplasmic reticulum, the Nissl substance reflects the unusually high protein synthesis capacity of neuronal cells. Various fluorescent or chromophoric "Nissl stains" have been used for this counterstaining, including acridine orange,¹²⁹ ethidium bromide,¹²⁹ neutral red (N3246, Section 15.2), cresyl violet,¹³⁰ methylene blue, safranin-O and toluidine blue-O.¹³¹ We have developed five fluorescent Nissl stains (Table 14.2) that not only provide a wide spectrum of fluorescent colors for staining neurons, but also are far more sensitive than the conventional dyes:

- NeuroTrace® 435/455 blue-fluorescent Nissl stain (N21479)
- NeuroTrace® 500/525 green-fluorescent Nissl stain (N21480)
- NeuroTrace® 515/535 yellow-fluorescent Nissl stain (N21481)
- NeuroTrace® 530/615 red-fluorescent Nissl stain (Figure 8.1.42) (N21482)
- NeuroTrace® 640/660 deep red-fluorescent Nissl stain (N21483)

In addition, the Nissl substance redistributes within the cell body in injured or regenerating neurons. Therefore, these Nissl stains can also act as markers for the physiological state of the neuron. Staining by the Nissl stains is completely eliminated by pretreatment of tissue specimens with RNase; however, these dyes are not specific stains for RNA in solutions. The strong fluorescence (emission maximum ~515–520 nm) of NeuroTrace® 500/525 green-fluorescent Nissl stain (N21480) makes it a preferred dye for use as a counterstain in combination with orange- or red-fluorescent neuroanatomical tracers such as Dil¹³² (D282, D3911, V22885; Section 14.4).

Figure 8.1.49 Fluorescence spectra of hydroxystilbamidine bound to different forms of DNA. Hydroxystilbamidine (H22845) was incubated with either calf thymus DNA (red) or a hybrid of poly(d(A)) and poly(d(T)) homopolymers (blue) in 50 mM sodium acetate, pH 5.0. The fluorescence emission spectra changes when the dye is bound to AT-rich DNA versus calf-thymus genomic DNA.

Figure 8.1.50 LDS 751 (L7595).

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

1. ND = not determined.
2. A666 in MeOH: Abs = 418 nm (EC = 12,000 cm⁻¹M⁻¹), Em = 500 nm.
3. Spectra represent aqueous solutions of nucleic acid-bound dye. EC values are derived by comparing the absorbance of the nucleic acid-bound dye with that of free dye in a reference solvent (H₂O or MeOH).
4. Acridine orange bound to RNA: Abs ~460 nm, Em ~650 nm. (Methods Cell Biol (1994) 41:401, Cytometry (1982) 2:201)
5. Spectra of this compound are in methanol acidified with a trace of HCl.
6. This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
7. Although this compound is soluble in water, preparation of stock solutions in water is not recommended because of possible adsorption onto glass or plastic.
8. This product is essentially nonfluorescent except when bound to DNA or RNA.
9. This compound is susceptible to oxidation, especially in solution. Store solutions under argon or nitrogen. Oxidation may be induced by illumination.
10. Dihydroethidium has blue fluorescence (Em ~420 nm) until oxidized to ethidium. The reduced dye does not bind to nucleic acids. (FEBS Lett (1972) 26:169)
11. DAPI in H₂O: Abs = 342 nm (EC = 28,000 cm⁻¹M⁻¹), Em = 450 nm. The fluorescence quantum yield of DAPI bound to dsDNA is 0.34, representing an ~20-fold increase relative to the free dye in H₂O. (Photochem Photobiol (2001) 73:585)
12. This product is specified to equal or exceed 98% analytical purity by HPLC.
13. This product is supplied as a ready-made solution in DMSO with sodium borohydride added to inhibit oxidation.
14. E1169 in H₂O: Abs = 493 nm (EC = 9100 cm⁻¹M⁻¹). E3599 in H₂O: Abs = 498 nm (EC = 10,800 cm⁻¹M⁻¹). Both compounds are very weakly fluorescent in H₂O. QY increases >40-fold on binding to dsDNA.
15. E1374 spectral data are for the free dye. Fluorescence is weak, but intensity increases ~15-fold on binding to DNA. After photocrosslinking to DNA, Abs = 504 nm (EC ~4000 cm⁻¹M⁻¹), Em = 600 nm. (Nucleic Acids Res (1978) 5:4891, Biochemistry (1980) 19:3221)
16. MW is for the hydrated form of this product.
17. The fluorescence quantum yield of Hoechst 33258 bound to dsDNA is 0.42, representing an ~30-fold increase relative to the free dye in H₂O. (Photochem Photobiol (2001) 73:585)
18. The fluorescence quantum yield of Hoechst 33342 bound to dsDNA is 0.38, representing an ~10-fold increase relative to the free dye in H₂O. (Photochem Photobiol (2001) 73:585)
19. H7593 in H₂O: Abs = 482 nm (EC = 5500 cm⁻¹M⁻¹), Em = 625 nm (weakly fluorescent).
20. Nucleic acid-bound hydroxystilbamidine has a second fluorescence emission peak at ~450 nm. The relative amplitudes of the two emission peaks are dependent on the nucleotide content of the nucleic acid. (Biochemistry (1973) 12:4827)
21. The active ingredient of this product is an organic dye with MW <1000. The exact MW and extinction coefficient values for this dye are proprietary.
22. Propidium iodide in H₂O: Abs = 493 nm (EC = 5900 cm⁻¹M⁻¹), Em = 636 nm (weakly fluorescent). Fluorescence is enhanced >10-fold on binding to dsDNA.
23. MW: The preceding ~ symbol indicates an approximate value, not including counterions.
24. The fluorescence quantum yield (QY) of SYTO® 13 dye bound to dsDNA is 0.56 (measured at 22°C).
25. Ethidium bromide in H₂O: Abs = 480 nm (EC = 5600 cm⁻¹M⁻¹), Em = 620 nm (weakly fluorescent). Fluorescence is enhanced >10-fold on binding to dsDNA.

PRODUCT LIST 8.1 NUCLEIC ACID STAINS

Cat. No.	Product	Quantity
A666	acridine homodimer (bis-(6-chloro-2-methoxy-9-acridinyl)spermine)	10 mg
A1301	acridine orange	1 g
A3568	acridine orange *10 mg/mL solution in water*	10 mL
A7592	actinomycin D	10 mg
A1310	7-aminoactinomycin D (7-AAD)	1 mg
A1324	9-amino-6-chloro-2-methoxyacridine (ACMA)	100 mg
B3582	BOBO™-1 iodide (462/481) *1 mM solution in DMSO*	200 µL
B3586	BOBO™-3 iodide (570/602) *1 mM solution in DMSO*	200 µL
D1306	4',6-diamidino-2-phenylindole, dihydrochloride (DAPI)	10 mg
D21490	4',6-diamidino-2-phenylindole, dihydrochloride (DAPI) *FluoroPure™ grade*	10 mg
D3571	4',6-diamidino-2-phenylindole, dilactate (DAPI, dilactate)	10 mg
D1168	dihydroethidium (hydroethidine)	25 mg
D23107	dihydroethidium (hydroethidine) *5 mM stabilized solution in DMSO*	1 mL
D11347	dihydroethidium (hydroethidine) *special packaging*	10 x 1 mg
E1169	ethidium homodimer-1 (EthD-1)	1 mg
E3599	ethidium homodimer-2 (EthD-2) *1 mM solution in DMSO*	200 µL
E1374	ethidium monoazide bromide (EMA)	5 mg
H7593	hexidium iodide	5 mg
H1398	Hoechst 33258, pentahydrate (bis-benzimide)	100 mg
H3569	Hoechst 33258, pentahydrate (bis-benzimide) *10 mg/mL solution in water*	10 mL
H21491	Hoechst 33258, pentahydrate (bis-benzimide) *FluoroPure™ grade*	100 mg
H1399	Hoechst 33342, trihydrochloride, trihydrate	100 mg
H3570	Hoechst 33342, trihydrochloride, trihydrate *10 mg/mL solution in water*	10 mL
H21492	Hoechst 33342, trihydrochloride, trihydrate *FluoroPure™ grade*	100 mg
H21486	Hoechst 34580	5 mg
H22845	hydroxystilbamidine, methanesulfonate	10 mg
J11372	JOJO™-1 iodide (529/545) *1 mM solution in DMSO*	200 µL
J11373	JO-PRO™-1 iodide (530/546) *1 mM solution in DMSO*	1 mL
L7595	LDS 751	10 mg

8.2 Labeling Oligonucleotides and Nucleic Acids

Figure 8.2.1 Human metaphase chromosomes hybridized to centromere probes labeled with ChromaTide® OBEA-dCTP nucleotides. Probes specific to the α satellite sequences from human chromosome 17, chromosome 15 and chromosome 1 were labeled using nick translation with ChromaTide® Alexa Fluor® 488-7-OBEA-dCTP (green, C21555), ChromaTide® Alexa Fluor® 594-7-OBEA-dCTP (red) and ChromaTide® Alexa Fluor® 647-12-OBEA-dCTP (pink, C21559), respectively. The probes were hybridized to metaphase spreads from peripheral blood lymphocyte cultures. The chromosomes were counterstained with Hoechst 33342 (blue) (H1399, H3570, H21492).

Figure 8.2.2 A microarray hybridized to Alexa Fluor® 546 dye-labeled cDNA. cDNA was labeled by reverse transcription from *Vibrio cholerae* total RNA using ChromaTide® Alexa Fluor® 546-14-dUTP (C11404). Labeled cDNA was then hybridized to a *V. cholerae* O1 El Tor microarray. The array was imaged with ScanArray® 5000XL scanner (PerkinElmer LAS, Inc.). The image was contributed by Kimberly Chong and Gary Schoolnik, Stanford University.

To facilitate the preparation of optimally labeled nucleic acids, we offer several modified nucleotides, as well as a wide selection of nucleic acid labeling kits that include reactive versions of Molecular Probes® fluorophores. Our available technologies include:

- ChromaTide® dUTP, ChromaTide® OBEA-dCTP and ChromaTide® UTP nucleotides, which provide researchers with a large selection of fluorophore- and hapten-labeled nucleotides that can be enzymatically incorporated into DNA or RNA probes for FISH (fluorescence *in situ* hybridization), DNA arrays/microarrays and other hybridization techniques.
- Unlabeled aminoalkyl derivatives of dUTP and UTP, as well as unlabeled and labeled aminohexylacrylamide (aha) derivatives of dUTP and dCTP, that are easy to incorporate into nucleic acids for subsequent conjugation with any of our amine-reactive probes (Chapter 1).
- ARES™ DNA Labeling Kits, which employ a versatile, two-step method for labeling DNA with fluorescent dyes to achieve a uniformity and consistency of labeling that is difficult to obtain with conventional enzymatic incorporation of labeled nucleotides.¹
- FISH Tag™ DNA and RNA Kits, which provide a complete workflow solution for creating labeled DNA and RNA probes for use in fluorescence *in situ* hybridization (FISH) applications.
- ULYSIS® Nucleic Acid Labeling Kits, which employ a fast, simple and reliable chemical method for labeling nucleic acids without enzymatic incorporation of labeled nucleotides.
- Alexa Fluor® Oligonucleotide Amine Labeling Kits, which use familiar chemical labeling of amine-terminated oligonucleotides to prepare the best singly labeled fluorescent oligonucleotide conjugates.

ChromaTide® Nucleotides

We offer a series of uridine triphosphates (UTP), deoxyuridine triphosphates (dUTP) and deoxycytidine triphosphates (OBEA-dCTP) conjugated to an extensive selection of fluorophores and haptens, including our intensely fluorescent Alexa Fluor® dyes (Table 8.5). These ChromaTide® nucleotides are useful for generating labeled nucleic acids for molecular biology and molecular cytogenetics applications, including chromosome and mRNA fluorescence *in situ* hybridization (FISH) experiments²⁻⁵ (Figure 8.2.1), gene expression and mutation detection on arrays and microarrays⁶⁻¹⁶ (Figure 8.2.2), and *in situ* PCR and RT-PCR. Our diverse fluorescent labels provide the ideal tools for multicolor techniques such as spectral karyotyping,¹⁷⁻²³ multi-locus FISH analysis,²⁴ chromosome painting²⁵ and comparative genome hybridization.^{26,27}

Figure 8.2.3 Structure of ChromaTide® BODIPY® FL-14-dUTP (C7614). This structure is representative of our other labeled ChromaTide® aminoalkynyl dUTP nucleotides. Fluorophore labels are attached via a four-atom aminoalkynyl spacer (between arrows A and B) to either deoxyuridine triphosphate (dUTP) or uridine triphosphate (UTP).

Structures of the ChromaTide® Nucleotides

The ChromaTide® UTP and dUTP nucleotides are modified at the C-5 position of UTP or dUTP via a unique aminoalkynyl linker (Figure 8.2.3). The C-5 position of UTP and dUTP is not involved in Watson–Crick base-pairing and so interferes little with probe hybridization. The aminoalkynyl linker between the fluorophore and the nucleotide in the ChromaTide® UTP and dUTP nucleotides is designed to reduce the fluorophore's interaction with enzymes or target binding sites. In addition to this four-atom bridge, several of these nucleotides contain a seven- to 10-atom spacer that further separates the dye from the base. The number in the product's name (e.g., the "12" in ChromaTide® fluorescein-12-dUTP) indicates the net length of the spacer in atoms. Longer spacers typically result in brighter conjugates and increased hapten accessibility for secondary detection reagents.

The ChromaTide® OBEA-deoxycytidine triphosphates (OBEA-dCTP) are modified at the N-4 position of cytosine using a 2-aminoethoxyethyl (OBEA) linker (Figure 8.2.4). The Alexa Fluor® 546 and Alexa Fluor® 647 OBEA-dCTP conjugates (C21555, C21559) also have a built-in spacer that reduces possible steric interference caused by the presence of the dye.

Figure 8.2.4 Structure of ChromaTide® Alexa Fluor® 488-7-OBEA-dCTP (C21555). This structure is representative of our labeled ChromaTide® OBEA-dCTP nucleotides. Fluorophore labels are attached via the OBEA spacer (between arrows A and B) to deoxycytidine triphosphate (dCTP).

Table 8.5 Molecular Probes® ChromaTide® nucleotides and aha-dUTP and aha-dCTP nucleotides.

Cat. No.	dUTP, aha-dUTP, aha-dCTP, OBEA-dCTP or UTP Nucleotide *	Ex/Em †	Applications ‡

* All products are supplied as either 25 µL (dUTPs and UTPs) or 50 µL (dCTPs) of a 1 mM solution in TE buffer. † Excitation (Ex) and emission (Em) maxima, in nm, for the labeled nucleotide. ‡ Except where otherwise noted, the following applications were tested: PCR, Taq polymerase for DNA amplification; TDT, terminal deoxynucleotidyl transferase for 3'-end labeling of dsDNA; RP, Klenow polymerase for labeling DNA by random hexamer priming; RT, murine leukemia virus (MLV) reverse transcriptase for synthesizing DNA from an RNA template; NT, nick translation using DNase I and DNA polymerase I. ChromaTide® UTP nucleotides were incorporated into RNA by standard transcription reactions using the indicated RNA polymerases (SP6, T3, T7). We also offer unlabeled aha-dUTP (50 µL of a 50 mM solution in TE buffer, A32761) and unlabeled aha-dCTP (50 µL of a 50 mM solution in TE buffer, A32769; 500 µL of a 2 mM solution in TE buffer, A32768).

Fluorescent ChromaTide® Nucleotides

The spectral diversity of the ChromaTide® UTP, ChromaTide® dUTP and ChromaTide® OBEA-dCTP nucleotides (Table 8.5) gives researchers significant flexibility in choosing a label that is compatible with a particular optical detection system or multicolor experiment. Probes made from the fluorescent ChromaTide® nucleotides can be imaged directly; alternatively, some fluorophores can be used as a hapten for signal amplification (Section 7.4). In many cases, the TSA™ (Section 6.2) or ELF® technologies (Section 6.3) can be used individually or together²⁸ to significantly amplify the signal of dye-labeled hybridization probes in cells and tissues and on microarrays.

The Alexa Fluor® conjugates of UTP, OBEA-dCTP and dUTP provide fluorophore labels with demonstrably superior fluorescence properties, as compared with conventional dyes. The Alexa Fluor® 488, Alexa Fluor® 568 and Alexa Fluor® 594 nucleotides are spectrally similar to fluorescein, Lissamine rhodamine B and Texas Red® conjugates, respectively, but the Alexa Fluor® conjugates exhibit superior spectral and chemical properties. ChromaTide® OBEA-dCTP nucleotides have been prepared from four of our brightest and most photostable dyes—Alexa Fluor® 488, Alexa Fluor® 546, Alexa Fluor® 594 and Alexa Fluor® 647 dyes—with spectra virtually identical to those of fluorescein, Cy®3, Texas Red® and Cy®5 dyes, respectively.

The ChromaTide® Alexa Fluor® dUTP and ChromaTide® Alexa Fluor® OBEA-dCTP nucleotides are highly water soluble, as are the DNA probes that contain them. Thus, Alexa Fluor® dye-labeled DNA probes do not aggregate or precipitate, even in high-salt hybridization solutions. Fluorescence of the Alexa Fluor® conjugates is not pH sensitive in the range used for hybridization or microscopy mounting media. Additionally, the enhanced photostability of these conjugates makes them ideal for imaging applications.

Using ChromaTide® Nucleotides in Enzymatic Labeling Methods

The ChromaTide® nucleotides can be incorporated into DNA and RNA using conventional enzymatic labeling techniques (Table 8.5). Protocols for many of these techniques are provided with the ChromaTide® nucleotides; please note that not all ChromaTide® nucleotides have been tested in all applications. Enzymes that we have used successfully include:

- Taq polymerase in polymerase chain reaction (PCR) assays
- DNA polymerase I in nick-translation and primer-extension assays
- Klenow polymerase in random-primer labeling
- Terminal deoxynucleotidyl transferase (TdT) for 3'-end labeling
- Reverse transcriptase for synthesizing DNA from RNA templates
- SP6 RNA polymerase, T3 RNA polymerase and T7 RNA polymerase for *in vitro* transcription

ChromaTide® nucleotides have also been used in the TUNEL assay for detecting DNA fragmentation in apoptotic cells^{29–32} (Section 15.5, Figure 8.2.5). Microinjected fluorescent nucleotides have been utilized to follow the dynamics of chromosome formation and cell proliferation in live cells.^{33–35}

Amine-Modified Nucleotides

Unlabeled and Labeled aha-dUTP and aha-dCTP

5-Aminoethylacrylamido-dUTP (aha-dUTP) and 5-aminoethylacrylamido-dCTP (aha-dCTP) can be used to produce amine-modified DNA by conventional enzymatic incorporation methods such as reverse transcription, nick translation, random primed labeling or PCR. The amine-modified DNA can then be labeled with any amine-reactive dye or hapten. This two-step technique permits a uniform and high degree of DNA labeling that is difficult to obtain by other methods. The protocol provided with the aha-dUTP and aha-dCTP nucleotides yields a labeling efficiency of ~5–8 dyes per 100 bases, which we have found to be optimal for fluorescence *in situ* hybridization (FISH), dot blot hybridization and especially microarray applications, in which the consistency of labeling between samples is critical for accurate interpretation of results. The aha-dUTP and aha-dCTP nucleotides are available as 50 µL of a 50 mM solution (A32761, A32769) in 10 mM Tris, 1 mM EDTA, pH 7.5 (TE); aha-CTP is also available as 500 µL of a 2 mM solution (A32768). We provide a wide variety of amine-reactive reagents for labeling amine-modified DNA, including succinimidyl esters of our Alexa Fluor® dyes, conventional fluorophores, biotin and dinitrophenyl (DNP) (Chapter 1).

The labeled aha-dUTP and aha-dCTP nucleotides can be used to generate labeled nucleic acid hybridization probes for many molecular biology and molecular cytogenetics applications, including two-color microarray assays, northern and Southern blots, colony and plaque

Figure 8.2.5 HL-60 cells treated with camptothecin for three hours. The DNA strand nicks characteristic of apoptosis were detected with the TUNEL (terminal deoxynucleotidyl transferase-mediated dUTP nick end-labeling) assay using the fluorescently labeled nucleotide ChromaTide® BODIPY® FL-14-dUTP (C7614). Image contributed by Zbigniew Darzynkiewicz, Cancer Research Institute, New York Medical College.

Figure 8.2.6 Fluorescein-aha-dUTP (F32767).

hybridizations, DNA sequencing, primer extension, DNA and RNA amplification and bead-based separation techniques. In these applications, the labeled samples can be detected by the intrinsic fluorescence of the labeled probe or with enzyme-conjugated secondary detection reagents in conjunction with fluorescent, chemiluminescent or colorimetric substrates. These nucleotides are modified at the C-5 position of uridine and cytosine, respectively, with a unique hexylacrylamide linker, which serves as a spacer between the nucleotide and the dye or hapten (Figure 8.2.6). This spacer reduces interactions between the nucleotide and the dye or hapten, producing brighter conjugates and increased hapten accessibility for secondary detection reagents. The Alexa Fluor® 555 aha-dUTP and aha-dCTP nucleotides (A32762, A32770), with excitation/emission maxima of 555/570 nm, and the Alexa Fluor® 647 aha-dUTP and aha-dCTP nucleotides (A32763, A32771), with excitation/emission maxima of 650/670 nm, respectively, are compatible with commonly used microarray scanners. These fluorescent nucleotides provide greater signal correlation (R^2) values than do the spectrally similar Cy*3 and Cy*5 dye pair, thereby improving the resolution of two-color microarray gene expression assays.³⁶ The exceptionally bright and photostable Alexa Fluor® dyes are also essentially insensitive to pH and are highly water soluble.

We also offer biotin aha-dUTP and aha-dCTP (B32766, B32772) and fluorescein aha-dUTP (F32767) nucleotides, which can be used to generate nucleic acid probes that can be detected with streptavidin conjugates (Section 7.6, Table 7.9) or labeled anti-fluorescein antibodies (Section 7.4), respectively. Nucleic acid probes labeled with biotin have generally been the most common nonisotopic probes used in hybridization techniques. Biotinylated probes are readily detected with fluorophore or enzyme conjugates of avidins or streptavidins, providing amplification of the signal (Figure 8.2.7). The signal from biotin-labeled hybridization probes can be considerably amplified, while retaining excellent spatial resolution, using tyramide signal amplification technology (Section 6.2, Figure 8.2.8) or Enzyme-Labeled Fluorescence (ELF®) technology (Section 6.3, Figure 8.2.9). In addition, biotinylated nucleic acids can be adsorbed onto streptavidin agarose or CaptAvidin™ agarose (S951, C21386; Section 7.6) or detected with NANOGOLD® or Alexa Fluor® FluoroNanogold™ streptavidin^{37–39} (N24918, A24926, A24927; Section 7.6).

Aminoallyl dUTP

Aminoallyl dUTP⁴⁰ (5-aminoallyl-2'-deoxyuridine 5'-triphosphate, A21664) can be incorporated into DNA using conventional enzymatic incorporation techniques, as described above for the ChromaTide® dUTP nucleotides.⁴¹ The resulting amine-modified nucleic acid can then be labeled using the amine-reactive dyes¹ described in Chapter 1. Lacking bulky dye groups, the aminoallyl-modified nucleotides can be incorporated to extremely high and consistent levels. Subsequent reaction of the amine-modified nucleic acid with an excess of amine-reactive reagent achieves correspondingly high and consistent labeling efficiency, regardless of the labeling reagent chosen. We typically obtain labeling efficiencies of ~5–8 dyes per 100 bases. This two-step labeling method also eliminates the need to optimize an enzymatic reaction to accommodate different dye-modified nucleotides, which may incorporate at very different rates. This

Figure 8.2.7 Labeled paint probes hybridized to human metaphase chromosomes. A biotinylated chromosome 5 probe was detected with Alexa Fluor® 594 streptavidin (S11227), and a digoxigenin-labeled chromosome 2 probe detected with mouse anti-digoxigenin in combination with Alexa Fluor® 488 goat anti-mouse IgG antibody (A11001). Image contributed by Joop Wiegant, Leiden University Medical Center, Leiden, The Netherlands.

Figure 8.2.9 *lacZ* mRNA in transformed mouse fibroblasts (CRE BAG 2 cells) hybridized with a singly biotinylated, complementary oligonucleotide. Hybrids were then detected by incubation with a streptavidin–alkaline phosphatase conjugate in combination with the ELF® 97 alkaline phosphatase substrate, both of which are provided in our ELF® 97 mRNA *In Situ* Hybridization Kit (E6604, E6605). Cells were counterstained with DAPI (D1306, D3571, D21490) and photographed using a longpass optical filter appropriate for DAPI.

Figure 8.2.8 Fluorescence *in situ* hybridization detected by tyramide signal amplification. Chromosome spreads were prepared from the cultured fibroblast cell line MRC-5 and hybridized with a biotinylated α -satellite probe specific for chromosome 17. The probe was generated by nick translation in the presence of biotinylated dUTP. For detection by TSA, hybridized chromosome spreads were labeled using TSA™ Kit #22 (T20932) with HRP-conjugated streptavidin and Alexa Fluor® 488 tyramide (left) or using TSA™ Kit #23 (T20933) with HRP-conjugated streptavidin and Alexa Fluor® 546 tyramide (right). After counterstaining with DAPI (D1306, D3571, D21490), images were obtained using filters appropriate for DAPI, FITC or TRITC.

Figure 8.2.12 DNA microarray hybridized to DNA labeled using the ARES™ DNA Labeling Kits. Total human RNA was labeled by reverse transcription using either ARES™ Alexa Fluor® 555 DNA Labeling Kit (A21677) or ARES™ Alexa Fluor® 647 DNA Labeling Kit (A21676). Labeled DNA was hybridized to a microarray containing human housekeeping genes. After hybridization, the array was imaged using a ScanArray®5000XL microarray scanner (PerkinElmer LAS, Inc.) using the appropriate lasers and filter sets. The image was pseudocolored so that white areas show the most intense signal and blue areas show the least intense signal.

labeling method is ideal for both FISH probes (Figure 8.2.10, Figure 8.2.11) and microarray-based experiments (Figure 8.2.12). Aminoallyl dUTP labeling is the basis of both our ARES™ DNA Labeling Kits and FISH Tag™ DNA Kits (see below), which provide aminoallyl dUTP, amine-reactive dyes and carefully tested protocols.

Alexa Fluor® Amine-Reactive Dye Decapacks for Labeling Amine-Modified DNA and RNA

For labeling amine-modified DNA or RNA probes in microarray-based experiments, we offer three amine-reactive Alexa Fluor® dyes conveniently packaged in 10 single-use vials and rigorously tested for the ability to efficiently label amine-modified DNA:

- Alexa Fluor® 488 reactive dye decapack (A32750)
- Alexa Fluor® 555 reactive dye decapack (A32756)
- Alexa Fluor® 647 reactive dye decapack (A32757)
- A set containing both the Alexa Fluor® 555 and Alexa Fluor® 647 reactive dye decapacks (A32755), for two-color experiments

These specially packaged amine-reactive dyes can be used in conjunction with our amino-hexylacrylamido-dUTP (aha-dUTP, A32760) or aminoallyl dUTP (A21664) nucleotides or with commercially available aminoallyl nucleotide-based nucleic acid labeling kits. With excitation/emission maxima of 495/519 nm, 555/565 nm and 650/668 nm, respectively, the Alexa Fluor® 488, Alexa Fluor® 555 and Alexa Fluor® 647 succinimidyl esters match the most popular wavelength channels used to scan microarrays. We have found that when single-stranded DNA is labeled with equivalent levels of Alexa Fluor® 647 dye or Cy®5 dye using aminoallyl

Figure 8.2.10 Fluorescence *in situ* hybridization (FISH) mapping of a BAC clone on human metaphase chromosomes. FISH was performed using a BAC clone labeled using the ARES™ Alexa Fluor® 488 DNA Labeling Kit (A21665). The chromosomes were counterstained with DAPI (D1306, D3571, D21490). Image contributed by Nallasivam Palanisamy, Cancer Genetics Inc.

Figure 8.2.11 Expression of snail RNA in an early-stage fruit fly embryo visualized by FISH. A 1.7 kb RNA probe corresponding to the snail gene was labeled by *in vitro* transcription using aminoallyl UTP (A21663) followed by reaction with Alexa Fluor® 488 carboxylic acid, succinimidyl ester (A20000, A20100). The probe was hybridized to *Drosophila melanogaster* embryos and imaged using confocal laser-scanning microscopy. Image contributed by David Kosman and Ethan Bier, University of California, San Diego.

Figure 8.2.13 Fluorescence emission of DNA labeled with Alexa Fluor® dyes versus Cy® dyes. DNA was amine modified by reverse transcription in the presence of aminoallyl dUTP (A21664). The modified DNA was then labeled with Alexa Fluor® 555 or Alexa Fluor® 647 succinimidyl ester (A21677, A21676) or with Cy®3 or Cy®5 reactive dye to a level optimal for hybridization. The fluorescence emission spectra for DNA samples labeled to the same degree show that the Alexa Fluor® dye-labeled DNA was consistently brighter than the spectrally similar Cy® dye-labeled DNA.

dUTP incorporation, the fluorescence emission from the Alexa Fluor® 647 dye-labeled DNA is several times more intense than that of Cy® 5 dye-labeled DNA; similarly, Alexa Fluor® 555 dye-labeled DNA is consistently brighter than spectrally similar Cy® 3 dye-labeled DNA (Figure 8.2.13). Furthermore, the Alexa Fluor® 555/Alexa Fluor® 647 dye pair has been shown to display higher signal correlation coefficients than the Cy® 3/Cy® 5 dye pair in two-color DNA microarray assays.³⁶

ARES™ DNA Labeling Kits

ARES™ DNA Labeling Kits (Table 8.6) provide a versatile two-step method for labeling DNA with our Alexa Fluor® dyes¹ (Figure 8.2.14). This method achieves uniformity and consistency of labeling that is difficult to obtain with conventional enzymatic incorporation of labeled nucleotides. In the first step, an amine-modified nucleotide, 5-(3-aminoallyl)-dUTP, is enzymatically incorporated into DNA. This step permits relatively uniform labeling of the probe with primary amine groups. The aminoallyl dUTP substrate used in this reaction is taken up efficiently by reverse transcription or nick translation, for which we provide the protocols; other enzymatic methods are also likely to be compatible. In the second step, the amine-modified DNA is chemically labeled using an amine-reactive Alexa Fluor® dye. This chemical reaction varies little in its efficiency from dye to dye, so that it is possible to use any combination of the ARES™ Kits and obtain consistent labeling for every DNA sample. The labeling protocols provided generally result in about one dye per 12–20 bases, which we have determined to be optimal for fluorescence *in situ* hybridization (FISH) and dot-blot hybridization. Nucleic acids labeled using this method are ideal for FISH (Figure 8.2.15) or microarray experiments (Figure 8.2.12).

Figure 8.2.15 Fluorescent probes generated with ARES™ DNA Labeling Kits hybridized to human metaphase chromosome spreads. Centromere probes specific for chromosomes 17, 1 and 15 were prepared by nick translation and labeled with kits containing green-fluorescent Alexa Fluor® 488 (A21665), red-orange-fluorescent Alexa Fluor® 546 (A21667) and red-fluorescent Alexa Fluor® 594 (A21669) dyes. DNA was counterstained with the blue-fluorescent Hoechst 33342 dye (H1399, H3570, H21491), and the slides were mounted using the ProLong® Antifade Kit (P7481). This multiple-exposure image was obtained with bandpass filter sets appropriate for fluorescein, rhodamine, Texas Red® dye and DAPI.

Figure 8.2.14 Schematic diagram of the labeling method provided in our ARES™ DNA Labeling Kits. The ARES™ DNA Labeling Kits use a two-step method to label DNA. Step 1) The aminoallyl dUTP is enzymatically incorporated. Step 2) A reactive fluorophore is used to label the incorporated aminoallyl group.

* Excitation (Ex) and Emission (Em) maxima, in nm. † Also available are the FISH Tag™ DNA Multicolor Kit (F32951) and the FISH Tag™ RNA Multicolor Kit (F32956), each containing four different amine-reactive Alexa Fluor® dyes.

Figure 8.2.16 Change in signal brightness with level of labeling for Alexa Fluor® versus Cy® dye-labeled DNA. Chromosome 17 α -satellite DNA was amine-modified by nick translation in the presence of varying ratios of aminoallyl dUTP (A21664) to dTTP. The pools of modified DNA were split into equal parts and labeled with Alexa Fluor® 555 or Alexa Fluor® 647 succinimidyl ester (A21677, A21676) or with Cy®3 or Cy®5 reactive dye. The degree of labeling was calculated for each reaction; each probe was then hybridized to human metaphase chromosomes and the brightness of each signal measured. The brightness of the signal was plotted against the degree of labeling for each dye. At higher levels of labeling, the Alexa Fluor® dyes become brighter, whereas the corresponding Cy® dyes become quenched.

Figure 8.2.17 Aminoallyl dUTP (5-(3-aminoallyl)-2'-deoxyuridine 5'-triphosphate, trisodium salt; A21664).

In addition to 5-(3-aminoallyl)-dUTP, the ARES™ DNA Labeling Kits provide amine-reactive Alexa Fluor® dyes, which exhibit spectral properties that are superior to conventional dyes for labeling nucleic acids (Figure 8.2.16). Each kit contains sufficient reagents for 5–10 labelings of 1–5 μ g DNA each, including:

- 5-(3-Aminoallyl)-dUTP
- Amine-reactive fluorescent dye and an appropriate solvent
- Sodium bicarbonate
- Nuclease-free H₂O
- Detailed protocols for labeling DNA using reverse transcriptase or nick translation

The 5-(3-aminoallyl)-dUTP (A21664, Figure 8.2.17) and amine-reactive dyes are also available as stand-alone reagents. Enzymatic incorporation of 5-(3-aminoallyl)-dUTP permits incorporation of almost any amine-reactive dye in Chapter 1 into nucleic acids.⁴⁰

FISH Tag™ DNA and FISH Tag™ RNA Kits

The FISH Tag™ DNA and FISH Tag™ RNA Kits (Table 8.6) employ the same aminoallyl nucleotide labeling method as the ARES™ DNA labeling Kit but provide a complete workflow solution for fluorescence *in situ* hybridization (FISH) applications. Each FISH Tag™ Kit provides all of the reagents needed for enzymatically incorporating the amine-modified nucleotide (aminoallyl dUTP or aminoallyl UTP) into DNA or RNA, followed by fluorescent labeling with an amine-reactive Alexa Fluor® dye and purification of the labeled probe using PureLink™ nucleic acid purification technology.

The FISH Tag™ DNA Kits are supplied with one of four spectrally distinct Alexa Fluor® dyes or with all four of these dyes in the FISH Tag™ DNA Multicolor Kit:

- FISH Tag™ DNA Green Kit with Alexa Fluor® 488 dye (F32947)
- FISH Tag™ DNA Orange Kit with Alexa Fluor® 555 dye (F32948)
- FISH Tag™ DNA Red Kit with Alexa Fluor® 594 dye (F32949)
- FISH Tag™ DNA Far-Red Kit with Alexa Fluor® 647 dye (F32950)
- FISH Tag™ DNA Multicolor Kit (F32951)

Each kit provides sufficient reagents for 10 labelings, as well as detailed instructions for synthesizing amine-modified DNA by nick translation of template DNA, labeling with an amine-reactive Alexa Fluor® dye and purifying the fluorescent DNA probe. Kit contents include:

- Alexa Fluor® amine-reactive dye
- Dimethylsulfoxide (DMSO)
- Dithiothreitol (DTT), glycogen, sodium bicarbonate and nuclease-free water
- DNA nucleotide mix, containing the optimal ratio of aminoallyl dUTP:dTTP
- DNA polymerase 1
- DNase 1
- Nick translation buffer
- Binding, wash and elution buffers
- Spin columns and collection tubes, for purifying both the amine-modified DNA and the fluorescent DNA probe
- *SlowFade*® Gold antifade reagent, for use in the hybridization/imaging protocol
- Detailed protocols

The FISH Tag™ RNA Kits are also supplied with one of four spectrally distinct Alexa Fluor® dyes or with all four of these dyes in the FISH Tag™ RNA Multicolor Kit:

- FISH Tag™ RNA Green Kit with Alexa Fluor® 488 dye (F32952)
- FISH Tag™ RNA Orange Kit with Alexa Fluor® 555 dye (F32953)

- FISH Tag™ RNA Red Kit with Alexa Fluor® 594 dye (F32954)
- FISH Tag™ RNA Far-Red Kit with Alexa Fluor® 647 dye (F32955)
- FISH Tag™ RNA Multicolor Kit (F32956)

Each kit provides sufficient reagents for 10 labelings, as well as detailed instructions for synthesizing amine-modified RNA by *in vitro* transcription of template DNA (containing a T3, T7 or SP6 promoter), labeling with an amine-reactive Alexa Fluor® dye and purifying the fluorescent RNA probe. Kit contents include:

- Alexa Fluor® amine-reactive dye
- Dimethylsulfoxide (DMSO)
- Dithiothreitol (DTT), glycogen, sodium bicarbonate and nuclease-free water
- RNA nucleotide mix, containing the optimal ratio of aminoallyl UTP:UTP
- T7, T3 and SP6 RNA polymerases
- DNase 1
- T3/T7 and SP6 transcription buffers
- RNaseOUT™ ribonuclease inhibitor
- Binding, wash and elution buffers
- Spin columns and collection tubes, for purifying both the amine-modified RNA and the fluorescent RNA probe
- *SlowFade*® Gold antifade reagent, for use in the hybridization/imaging protocol
- Detailed protocols

ULYSIS® Nucleic Acid Labeling Kits

The ULYSIS® Alexa Fluor® Nucleic Acid Labeling Kits (Table 8.6) provide a simple, reliable method for producing fluorescent hybridization probes by combining our Alexa Fluor® fluorophores with the versatile, patented Universal Linkage System (ULS®) platinum-based chemistry developed by KREATECH Biotechnology BV. The ULS® technology is based on the use of a platinum dye reagent that forms a stable adduct with the *N*-7 position of guanine and, to a lesser extent, adenine bases in DNA, RNA, peptide–nucleic acid conjugates (PNA) and oligonucleotides (Figure 8.2.18). In protein contexts, ULS® reagents are reactive with cysteine residues and other thiols.⁴² The labeling reaction typically takes only 15 minutes, and separation of the labeled nucleic acids from the unreacted ULS® reagent can be accomplished through use of a simple spin-column procedure (Figure 8.2.19). DNA longer than ~1000 base pairs requires a 10-minute DNase digestion before labeling, which both optimizes labeling and fragments the probe for efficient hybridization.

Figure 8.2.18 Schematic diagram of the labeling method provided in our ULYSIS® Nucleic Acid Labeling Kits. The ULS® reagent in the ULYSIS® Nucleic Acid Labeling Kits reacts with the *N*-7 position of guanine residues to provide a stable coordination complex between the nucleic acid and the fluorophore label.

Figure 8.2.19 Nucleic acid labeling method provided in our ULYSIS® Nucleic Acid Labeling Kits.

Figure 8.2.20 A paint probe for chromosome 2 was labeled with the ULYSIS® Alexa Fluor® 546 Nucleic Acid Labeling Kit (U21652) and hybridized to human metaphase chromosomes. Image contributed by Joop Wiegant, Leiden University Medical Center, Leiden, The Netherlands.

Figure 8.2.21 Human metaphase chromosomes hybridized to fluorescent probes from two overlapping microdissection libraries. Probes specific to chromosome regions 1p34–35 and 1p36 were labeled using the ULYSIS® Oregon Green® 488 (U21659) and Alexa Fluor® 594 (U21654) Nucleic Acid Labeling Kits, respectively. The chromosomes were counterstained with DAPI (D1306, D3571, D21490). Image contributed by Jingwei Yu, Colorado Genetics Laboratory.

Figure 8.2.22 ULYSIS® reagent-labeled RNA hybridized to a microarray. Poly(A)⁺ RNA samples from the spleen of an irradiated or unirradiated mouse were labeled using the Alexa Fluor® 594 ULS® reagent or Alexa Fluor® 546 ULS® reagent, respectively. The labeled samples were mixed and hybridized to a cDNA microarray. The image was contributed by Rahul Mitra (Baylor College of Medicine) and Mini Kapoor, Thomas H. Burrows, and Rachel Grier (MD Anderson Cancer Center).

In addition to ULYSIS® Alexa Fluor® Nucleic Acid Labeling Kits, we offer the ULYSIS® Oregon Green® 488 Nucleic Acid Labeling Kit. Each of these ULYSIS® Kits provides sufficient reagents for 20 labelings of 1 µg DNA each, including:

- ULS® labeling reagent and appropriate solvent
- Labeling buffer
- Deoxyribonuclease I (DNase I), for digesting DNA longer than 1000 base-pairs prior to labeling
- DNase I storage and reaction buffers
- Control DNA from calf thymus
- Nuclease-free H₂O
- Detailed protocols for preparing fluorescent DNA hybridization probes for chromosome *in situ* hybridization and dot-blot hybridization

Probes labeled using the ULYSIS® Kits are stable indefinitely and hybridize effectively to target DNA. The ULS® method has been used to prepare labeled probes for dot, northern and Southern blot analysis, RNA and DNA *in situ* hybridization, multicolor fluorescence *in situ* hybridization (FISH; Figure 8.2.20, Figure 8.2.21), comparative genome hybridization (CGH) and microarray analysis (Figure 8.2.22).

Labeled Oligonucleotides

Panomer™ 9 Random Oligodeoxynucleotides

RNA samples can be labeled by reverse transcription using fluorophore-labeled random oligonucleotides as primers in combination with unlabeled deoxynucleotide triphosphates. Panomer™ 9 random-sequence oligodeoxynucleotides are covalently labeled on the 5'-terminus with one of four different Alexa Fluor® dyes:

- Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 488 conjugate (P21680)
- Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 546 conjugate (P21681)
- Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 555 conjugate (P21687)
- Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 647 conjugate (P21686)

The Panomer™ 9 oligonucleotides are also useful as primers for synthesizing labeled DNA via Klenow DNA polymerase or reverse transcriptase. In these reactions, the primer provides the fluorescent label, whereas unlabeled nucleotides are incorporated by the enzyme. This labeling strategy allows for efficient and unbiased incorporation of nucleotides because the bulky dye molecule does not interfere with nucleotide incorporation. However, because the resulting DNA fragments contain only a single label, the detection sensitivity will typically be lower than that achieved by incorporating fluorophore- or hapten-labeled nucleotides.

Alexa Fluor® Oligonucleotide Amine Labeling Kits

The Alexa Fluor® Oligonucleotide Amine Labeling Kits (Table 8.6) provide the reagents required for labeling synthetic oligonucleotides that have amine groups incorporated at their 5'- or 3'-terminus. Following purification by standard chromatographic or electrophoretic procedures, these singly labeled oligonucleotides can serve as hybridization or ligation probes for a variety of applications.^{43–45}

Each Alexa Fluor® Oligonucleotide Amine Labeling Kit contains sufficient reagents for three labelings of 50 µg each of an amine-modified oligonucleotide, including:

- Three vials of amine-reactive dye
- Dimethylsulfoxide (DMSO)
- Three vials of labeling buffer
- Labeling protocol

Labeling Amine-, Thiol- or Phosphate-Modified Oligonucleotides

Amine or thiol groups can be incorporated into a chemically synthesized oligonucleotide. These groups can then be directly conjugated to an amine-reactive (Chapter 1) or thiol-reactive (Chapter 2) fluorophore or hapten. For labeling amine-modified DNA or RNA probes in microarray-based experiments, we offer three amine-reactive Alexa Fluor® dyes conveniently packaged in 10 single-use vials and rigorously tested for the ability to efficiently label amine-modified DNA:

- Alexa Fluor® 488 reactive dye decapack (A32750)
- Alexa Fluor® 555 reactive dye decapack (A32756)
- Alexa Fluor® 647 reactive dye decapack (A32757)
- A set containing both the Alexa Fluor® 555 and Alexa Fluor® 647 reactive dye decapacks (A32755), for two-color experiments

For use in fluorescence resonance energy transfer (FRET) applications (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2), amine-modified oligonucleotides can be labeled with our non-fluorescent, amine-reactive QSY® 7, QSY® 9 and QSY® 21 dyes (Section 1.6). These QSY® quencher dyes have absorption in the visible and near-infrared spectrum, making them excellent energy transfer acceptors from a wide variety of dyes that emit in the visible range, including fluoresceins, Oregon Green® dyes, rhodamines, Texas Red®, Cy®3 and several of the Alexa Fluor® dyes.⁴⁶ Conjugates of the QSY® 35 dye (Section 1.8) have somewhat shorter-wavelength absorption and are useful as quenchers of UV light-excited fluorescent dyes. Oligonucleotide conjugates of the nonfluorescent dabcyI succinimidyl ester (D2245) have also been extensively used for FRET-based and quencher-based assays.^{47–50}

A fluorophore or hapten containing an aliphatic amine may be conjugated to the 3'- or 5'-phosphate group of an oligonucleotide by using the zero-length crosslinker EDAC (E2247, Section 3.4) in an *N*-methylimidazole buffer at pH 9. This reaction results in a phosphoramidate bond that is stable in most molecular biology assays. The method can be used in combination with T4 polynucleotide kinase to fluorescently label oligonucleotides lacking a 5'-phosphate, or to double-label radioactively labeled oligonucleotides. We have found that this reaction is very efficient—labeling over 90% of the oligonucleotides that contain a phosphate group—and much easier than conventional methods for modifying terminal phosphate groups, which typically require multistep synthesis.^{51–53} For this reaction we recommend cadaverine-conjugated fluorophores (Section 3.4, Table 3.2).

It has also been reported that DNA can be reacted quantitatively with carbonyl diimidazole and a diamine (such as ethylenediamine) or a carbohydrazide to yield a phosphoramidate that has a free primary amine; the amine can then be modified with amine-reactive reagents^{51–55} of the type described in Chapter 1. Fluorescent or biotinylated amines have been coupled to the 5'-phosphate of tRNA using dithiodipyridine and triphenylphosphine.⁵⁶ Wang and Giese⁵⁷ have reported a general method that employs an imidazole derivative prepared from our BODIPY® FL hydrazide (D2371, Section 3.3) to label phosphates, including nucleotides, for capillary electrophoresis applications.

Amine-Reactive SYBR® Dye

The amine-reactive succinimidyl ester of the SYBR® 101 dye (S21500) can be coupled with amine-derivatized oligonucleotides. The

conjugates may fluoresce green as the result of intramolecular or intermolecular association of the dye with the nucleic acid backbone; however, changes in intensity and fluorescence polarization may occur during hybridization reactions. Similar amine-reactive versions of the cyanine dyes have been utilized to label peptide–nucleic acid conjugates (PNA) and to detect their hybridization to target nucleic acids in solution.^{58–61}

Dyes for Sequencing Applications

We are a major manufacturer of several dyes that are used directly or indirectly in nucleic acid sequencing and provide these dyes in reactive forms for preparing conjugates (Table 8.7). Because the electrophoretic separation step during sequencing is highly sensitive to the chemical structure of the fragments, the use of single-isomer labels is essential. In addition to providing high-purity reactive succinimidyl esters of the common FAM™, JOE™, TAMRA™ and ROX™ dyes, we prepare amine-reactive single isomers of carboxyrhodamine 6G (CR 6G). The 6-isomer of the CR 6G dye has spectroscopic and electrophoretic properties that are superior to the JOE™ dye often used for automated DNA sequencing. Please go to www.invitrogen.com/handbook/customorganics for information about availability of any of our reactive dyes in bulk.

Certain BODIPY® dyes (Section 1.4) have been shown to be very useful for DNA sequencing,^{62–64} in part because the dyes have a minimal effect on the mobility of the fragment during electrophoresis and also exhibit well-resolved spectra with narrow bandwidths. BODIPY® dyes, which are all high-purity single isomers, exhibit high extinction

* FAM™ = carboxyfluorescein; CR 6G = carboxyrhodamine 6G; JOE™ = 6-carboxy-4',5'-dichloro-2',7'-dimethoxyfluorescein; TAMRA™ = carboxytetramethylrhodamine; ROX™ = carboxy-X-rhodamine; BODIPY® = a substituted 4,4-difluoro-4-bora-3a,4a-diazas-indacene derivative; SE = succinimidyl ester; SSE = water-soluble sulfosuccinimidyl ester. † These are the most widely used isomers for DNA sequencing.^{1–4} ‡ These BODIPY® derivatives were reported to be useful for automated DNA sequencing, in part because the dyes have a minimal effect on the mobility of the fragment during electrophoresis and also exhibit well-resolved spectra with narrow bandwidths.⁵ § Excitation (Ex) and emission (Em) maxima in nm.

1. Anal Biochem (1994) 223:39; 2. Nucleic Acids Res (1992) 20:2471; 3. Proc Natl Acad Sci U S A (1989) 86:9178; 4. Genome Res (1996) 6:995; 5. Science (1996) 271:1420.

coefficients, excellent quantum yields and fluorescence emission that is quite photostable and insensitive to pH. BODIPY[®] FL-X, BODIPY[®] TMR-X and BODIPY[®] TR-X succinimidyl esters are reactive versions of the BODIPY[®] fluorophores with emission properties similar to those of fluorescein, (Section 1. 4) tetramethylrhodamine and Texas Red[®] dyes, respectively; BODIPY[®] 630/650-X and BODIPY[®] 650/665-X succinimidyl esters provide long-wavelength amine-reactive fluorophores that match filter sets optimized for the Alexa Fluor[®] 647 and Cy⁵ dyes. Oligonucleotide conjugates of the BODIPY[®] FL, BODIPY[®] R6G, BODIPY[®] 564/570 and BODIPY[®] FL, BODIPY[®] R6G, BODIPY[®] 564/570 and BODIPY[®] 581/591 dyes have been found to be particularly useful for automated DNA sequencing.^{62–64}

Figure 8.2.23 Aldehyde-reactive probe (ARP) used to detect DNA damage. The biotin hydroxylamine ARP (A10550) reacts with aldehyde groups formed when reactive oxygen species depurinate DNA. This reaction forms a covalent bond linking the DNA to biotin. The biotin can then be detected using fluorophore- or enzyme-linked streptavidin.

Other Labeling Methods for Nucleic Acids

Labeling Nascent DNA and RNA for Cell Proliferation Studies

Cells can naturally incorporate the thymidine analog 5-bromo-2'-deoxyuridine (BrdU, B23151; Section 15.4) into their DNA during cell division, making this nucleoside analog an excellent marker of both cell cycle and cell proliferation.⁶⁵ Analysis of incorporated BrdU can be either by detection with an antibody to BrdU-modified DNA or by modification of the fluorescence of a nucleic acid stain. For instance, the fluorescence of TO-PRO[®]-3 and LDS 751 is considerably enhanced by the presence of BrdU in DNA,⁶⁶ whereas that of the Hoechst dyes is specifically quenched.⁶⁷ 5-Bromo-2'-deoxyuridine 5'-triphosphate (BrdUTP, B21550; Section 15.4) is commonly used in TUNEL-based methods to detect proliferating or apoptotic cells.^{30,31} BrdUTP is a substrate for reverse transcriptase^{68,69} and Klenow polymerase,^{70,71} and has been used in a sensitive nonisotopic assay for detecting HIV-1-associated reverse transcriptase activity.^{68,72} Similarly, the corresponding brominated ribonucleotide, 5-Bromouridine 5'-triphosphate (BrUTP, B21551; Section 15.4) is an excellent substrate for RNA polymerase⁷³ and has been used to monitor nucleolar transcription *in situ*.^{74,75}

The Click-iT[®] EdU cell proliferation assay (Section 15.4) provides a superior alternative to bromodeoxyuridine (BrdU) or ³H-thymidine incorporation methods for measuring new DNA synthesis.^{76,77} The alkynyl nucleoside analog EdU (5-ethynyl-2'-deoxyuridine; A10044, E10187; Section 3.1) is incorporated into DNA during the synthesis phase (S phase) of the cell cycle and is subsequently detected by copper (I)-catalyzed click coupling to an azide-derivatized fluorophore⁷⁸ (Section 3.1). The small size of the click-coupled fluorophore compared to that of antibodies required for immunodetection of BrdU enables efficient penetration of complex samples without the need for harsh cell treatment, simplifying the assay considerably.

Similarly, the Click-iT[®] RNA assay employs the alkyne-modified nucleoside EU (5-ethynyl uridine, E10345; Section 3.1), which is supplied to cells and incorporated into nascent RNA.⁷⁹ The small size of the alkyne tag enables efficient incorporation by RNA polymerases without any apparent changes to the RNA levels of several housekeeping genes. Detection of incorporated EU is accomplished by copper (I)-catalyzed click coupling to an azide-derivatized fluorophore (Section 3.1). The multiplexing capability of the assays makes them ideal for toxicological profiling or interrogation of disease models using high-content imaging platforms.

Labeling Abasic Sites with ARP

Abasic sites in DNA can be generated spontaneously or through the action of free radicals, ionizing radiation or mutagens like MMS (methyl methanesulfonate). These apurinic and apyrimidinic sites are very common lesions in DNA and are thought to be important intermediates in mutagenesis. A quick and sensitive microplate assay for abasic sites can be performed using ARP (A10550, Figure 8.2.23), a biotin hydroxylamine that reacts with the exposed aldehyde group at abasic sites. Biotins bound to the abasic sites can be quantitated with our fluorescent- or enzyme-conjugated streptavidin complexes^{80–83} (Section 7.6, Table 7.9). ARP is permeant to cell membranes, permitting detection of abasic sites in live cells.^{84,85} Alexa Fluor[®] hydroxylamine derivatives (Section 3.3) may have utility similar to that of ARP but are not membrane permeant.

Labeling Cytidine Residues

DNA and RNA can be modified by reacting their cytidine residues with sodium bisulfite to form sulfonate intermediates that can then be directly coupled to hydrazides or aliphatic amines.^{86–88} For example, biotin hydrazides (Section 4.2) have been used in a bisulfite-mediated reaction to couple biotin to cytidine residues in oligonucleotides.⁸⁹ The fluorescent hydrazides, hydroxylamines and aliphatic amines listed in Table 3.2 might be useful in this reaction. The bisulfite-activated cytidylic acid can also be coupled to aliphatic diamines such as ethylenediamine.⁹⁰ The amine-modified DNA or RNA can then be modified with any of the amine-reactive dyes described in this section or in Chapter 1.

Specialized Methods for Nucleic Acid Modification

A few other specialized methods have been developed for nucleic acid modification. These include:

- Use of a fluorescent iodoacetamide or maleimide, along with T4 polynucleotide kinase and ATP- γ -S (ATP with a sulfur in the ter-

minal phosphate), to introduce a thiophosphate at the 5'-terminus of 5'-dephosphorylated RNA^{91,92} or DNA

- Introduction of 4-thiouridine at the 3'-terminus of DNA using calf thymus terminal deoxynucleotidyl transferase followed by treatment with ribonuclease and reaction with thiol-reactive probes^{93,94}
- Direct reaction of thiol-reactive reagents with 4-thiouridine residues in nucleic acids^{56,95–98}
- Selective oxidation of the 3'-terminus of RNA by sodium metaperiodate to a dialdehyde, which can be coupled with a fluorescent or biotin hydrazide or hydroxylamine reagent^{55,92,99–103}
- Direct reaction of amine- or thiol-reactive reagents with aminoacyl tRNA or thioacetylated aminoacyl tRNA^{56,104,105}
- Reaction of the X-base of tRNA with isothiocyanates¹⁰¹ or replacement of other uncommon bases in tRNA by fluorophores^{106–108}
- Photolabeling of plasmid DNA with fluorescent 4-azido-2,3,5,6-tetrafluorobenzyl derivatives¹⁰⁹
- Coupling of labeled diazonium salts to nucleic acids¹¹⁰

8.3 Nucleic Acid Quantitation in Solution

Through intensive research efforts in both chemical synthesis and bioassay development, we have developed rapid and exceptionally sensitive fluorescence-based assays for quantitation of nucleic acids in solution. The Quant-iT™ Assay Kits represent advanced quantitation systems for DNA, RNA or protein samples. These state-of-the-art assays are designed to deliver high sensitivity and specificity together with a streamlined protocol, prediluted standards and a ready-to-use buffer. The Quant-iT™ PicoGreen® dsDNA reagent, Quant-iT™ OliGreen® ssDNA reagent and Quant-iT™ RiboGreen® RNA reagent—optimized for double-stranded DNA, oligonucleotides and RNA, respectively—have a high affinity for nucleic acids and an extremely large fluorescence enhancement upon binding, making possible the direct detection of minute amounts of nucleic acids in complex solutions within minutes, usually without interference from other biomolecules. These reagents and quantitation assays provide the following advantages:

- **Sensitivity.** The PicoGreen® dye-, OliGreen® dye- and RiboGreen® dye-based fluorescence assays are up to 10,000-fold more sensitive than UV absorbance measurements and at least 400-fold more sensitive than assays that use the Hoechst 33258 dye¹ (H1398, H3569, H21491), requiring much less sample for quantitation.
- **Accuracy.** Unlike measurements of UV absorbance, these assays are not affected by the presence of proteins, free nucleotides or very short oligonucleotides, making quantitation of intact oligonucleotides and nucleic acids much more accurate in complex mixtures such as serum or whole blood.
- **Precision.** The average standard deviations of triplicate assays using these reagents are typically less than 5%.
- **Simplicity.** These assays have a very simple protocol that requires no separation steps, making them ideal for automated, high-throughput measurements.
- **Broad dynamic range.** Quantitation is accurate over four orders of magnitude for the PicoGreen® and OliGreen® assays, with a single dye concentration. The RiboGreen® assay is accurate over three orders of magnitude.
- **Instrument compatibility.** Quantitation assays can be performed using a fluorescence microplate reader with standard filters optimized for fluorescein-like dyes, a relatively inexpensive filter-based spectrofluorometer or a standard spectrofluorometer. Additionally, we offer a set of Quant-iT™ Assay Kits specifically designed for the Qubit® fluorometer.
- **Convenience.** Each reagent is available separately or in a kit that additionally contains a nuclease-free buffer and standards. The RiboGreen® RNA quantitation assay is also available in the RediPlate™ 96 format—a prepared 96-well microplate with standards included—for high-throughput applications.

Figure 8.3.1 DNA, RNA or protein quantitation with the Quant-iT™ Assay Kits (Q33120, Q33130, Q33140, Q33210).

Quant-iT™ Assay Kits for DNA and RNA

The Quant-iT™ family of assay kits provides state-of-the-art reagents designed for sensitive and selective quantitation of DNA, RNA or protein samples using a standard fluorescence microplate reader or the Qubit® fluorometer (Table 8.8). These kits have been specially formulated with ready-to-use buffers, prediluted standards and easy-to-follow instructions, allowing quantitation to be both accurate and extremely easy (Figure 8.3.1). Each Quant-iT™ assay is:

- **Ready to use.** Only the dye is diluted in the supplied buffer; dilution of standards or buffer is not required.
- **Easy to perform.** Just add the sample to the diluted dye and read the fluorescence.
- **Highly sensitive.** The Quant-iT™ protein assay is orders of magnitude more sensitive than UV absorbance measurements.
- **Highly selective.** Separate kits are available for quantitating DNA, RNA (see below) or protein (Section 9.2), with minimal interference from common contaminants.
- **Precise.** CVs are generally less than 5%.

Figure 8.3.2 DNA selectivity and sensitivity of the Quant-iT™ dsDNA high-sensitivity assay. Triplicate 10 μ L samples of DNA (O), *Escherichia coli* rRNA (Δ) or a 1:1 mixture of DNA and RNA (\blacksquare) were assayed with the Quant-iT™ dsDNA High-Sensitivity Assay Kit (Q33120). Fluorescence was measured at 485/530 nm and plotted versus the mass of nucleic acid for the DNA alone, the mass of nucleic acid for the RNA alone or the mass of the DNA component in the 1:1 mixture. The coefficient of variation (CV) of replicate DNA determinations was $\leq 2\%$. The inset, a separate experiment with octuplicate determinations, shows the extreme sensitivity of the assay for DNA. Background fluorescence has not been subtracted.

Figure 8.3.3 DNA selectivity and sensitivity of the Quant-iT™ dsDNA broad-range assay. Triplicate 10 μ L samples of DNA (O), *Escherichia coli* rRNA (Δ) or a 1:1 mixture of DNA and RNA (\blacksquare) were assayed with the Quant-iT™ dsDNA Broad-Range Assay Kit (Q33130). Fluorescence was measured at 485/530 nm and plotted versus the mass of nucleic acid for the DNA alone, the mass of nucleic acid for the RNA alone or the mass of the DNA component in the 1:1 mixture. The coefficient of variation (CV) of replicate DNA determinations was $\leq 3\%$. The inset, a separate experiment with octuplicate determinations, shows the sensitivity of the assay for DNA. Background fluorescence has not been subtracted.

Because the fluorescent dye in each Quant-iT™ Kit matches common fluorescence excitation and emission filter sets in microplate readers, these assay kits are ideal for high-throughput environments, as well as for small numbers of samples.

Quant-iT™ DNA Assay Kits

The Quant-iT™ DNA Assay Kits simplify DNA quantitation without sacrificing sensitivity. The Quant-iT™ dsDNA High-Sensitivity Assay Kit (Q33120) provides a linear detection range between 0.2 ng and 100 ng double-stranded DNA (dsDNA) (Figure 8.3.2), corresponding to initial experimental sample concentrations between 10 pg/ μ L and 100 ng/ μ L. This high-sensitivity DNA assay is ideal for quantitating PCR products, viral DNA, DNA fragments for subcloning and other applications requiring small amounts of DNA. The Quant-iT™ dsDNA Broad-Range Assay Kit (Q33130) provides a linear detection range between 2 ng and 1000 ng dsDNA (Figure 8.3.3), corresponding to initial experimental sample concentrations between 100 pg/ μ L and 1000 ng/ μ L. This broad-range DNA assay minimizes the need to dilute concentrated samples, such as genomic DNA and miniprep DNA, prior to high-throughput procedures. Both Quant-iT™ DNA assays are highly selective for dsDNA over RNA, and have shown to be accurate even in the presence of an equal mass of RNA. Moreover, their fluorescence signals are unaffected by many common contaminants, including free nucleotides, salts, solvents and proteins. Each Quant-iT™ DNA Assay Kit contains:

- Quant-iT™ DNA HS reagent (in Kit Q33120) or Quant-iT™ DNA BR reagent (in Kit Q33130)
- Quant-iT™ DNA HS buffer (in Kit Q33120) or Quant-iT™ DNA BR buffer (in Kit Q33130)
- A set of eight prediluted λ DNA standards between 0 and 10 ng/ μ L (in Kit Q33120) or between 0 and 100 ng/ μ L (in Kit Q33130)
- Easy-to-follow instructions for the high-sensitivity DNA assay or the broad-range DNA assay

Table 8.8 Selection guide for the Quant-iT™ Assay Kits.

Cat. No.	Kit	Target	Useful Range *	No. of Assays
Quant-iT™ Assay Kits for Use with the Qubit® Fluorometer †				
Q32851	Quant-iT™ dsDNA High-Sensitivity (HS) Assay Kit	dsDNA	0.2–100 ng	100
Q32854				500

O7582	(Ex/Em = 498/518 nm)			
R11490	Quant-iT™ RiboGreen® RNA Assay Kit and Reagent	RNA	20–1000 ng	2000
R11491	(Ex/Em = 500/525 nm)			

* The useful range assumes a 1–20 μ L sample volume in a 96-well microplate assay. † These kits are formulated for use with the Qubit® fluorometer (Q32857). Also available is the Qubit® Quantitation Starter Kit (Q32860), which contains the Qubit® fluorometer and four Quant-iT™ Assay Kits. ‡ Excitation (Ex) and emission (Em), in nm, of the Quant-iT™ detection reagent is indicated in parentheses.

Sufficient reagents are provided to perform 1000 assays, based on a 200 μL assay volume in a 96-well microplate format; this assay can also be adapted for use in cuvettes or 384-well microplates. Both the high-sensitivity assay and the broad-range assay can be detected using standard fluorescein filters, and the fluorescence signal is stable for three hours at room temperature.

Quant-iT™ RNA Assay Kit

The Quant-iT™ RNA Assay Kit (Q33140) provides the first homogeneous assay ever developed for quantitating RNA in the presence of DNA. This RNA assay exhibits a linear detection range between 5 ng and 100 ng RNA (Figure 8.3.4), corresponding to initial experimental sample concentrations between 250 $\text{pg}/\mu\text{L}$ and 100 $\text{ng}/\mu\text{L}$. We also offer the Quant-iT™ RNA Broad-Range Assay Kit (Q10213), with a linear detection range between 20 ng and 1000 ng. Because of the high selectivity of the Quant-iT™ RNA reagent for RNA over dsDNA, this assay enables accurate RNA quantitation even in the presence of an equal mass of DNA. The fluorescence signal is unaffected by many common contaminants, including free nucleotides, salts, solvents and proteins, making this assay ideal for measuring samples for microarray, RT-PCR and northern blot procedures. Each Quant-iT™ RNA Assay Kit contains:

- Quant-iT™ RNA reagent
- Quant-iT™ RNA buffer
- A set of eight prediluted *Escherichia coli* rRNA standards between 0 and 10 $\text{ng}/\mu\text{L}$
- Easy-to-follow instructions

Sufficient reagents are provided to perform 1000 assays, based on a 200 μL assay volume in a 96-well microplate format; this assay can also be adapted for use in cuvettes or 384-well microplates. The fluorescence signal exhibits excitation/emission maxima of 644/673 nm and is stable for three hours at room temperature.

Quant-iT™ Assay Kits for Use with the Qubit® Fluorometer

The Qubit® fluorometer (Figure 8.3.5) is designed to work seamlessly with the Quant-iT™ Assay Kits. Together, they form the Qubit® Quantitation Platform, an efficient combination of sophisticated, accurate and highly sensitive fluorescence-based quantitation assays for DNA, RNA and protein, along with an extremely user-friendly fluorometer. This powerful pairing offers:

- Selective quantitation—more accurate than UV absorbance readings
- High sensitivity—use as little as 1 μL of sample for quantitation
- Intuitive integrated platform—sophisticated quantitation in 5 minutes or less

In addition to providing quantitation results that are fast, easy and reliable, the Qubit® fluorometer features software that is fully upgradable. The Qubit® fluorometer incorporates sophisticated data analysis algorithms designed to produce accurate measurements and an intuitive user interface for seamless integration with the full range of Quant-iT™ Assay Kits. We offer the Qubit® fluorometer separately (Q32857; USB cable, Q32858; replacement international power cord, Q32859) or bundled in a starter kit that includes four different Quant-iT™ assay kits as well as a supply of 500 Qubit® assay tubes (Q32860); a set of 500 Qubit® assay tubes is also available separately (Q32856).

In addition to the Quant-iT™ Assay Kits described above for microplate readers, we offer a set of Quant-iT™ Assay Kits specifically formulated for use with the Qubit® fluorometer (Table 8.8). These Quant-iT™ Assay Kits are up to 1000 times as sensitive as UV absorbance readings, and as little as 1 μL of sample is all that's needed to get accurate, reliable quantitation. There are Quant-iT™ Assay Kits for a variety of quantitation needs:

- Quant-iT™ dsDNA Broad-Range (BR) and Quant-iT™ High-Sensitivity (HS) Assay Kits (Q32850, Q32853; Q32851, Q32854)—for sequencing samples, genomic DNA samples and routine cloning experiments
- Quant-iT™ ssDNA Assay Kit (Q10212)—for hybridization experiments, site-directed mutagenesis and antisense gene suppression
- Quant-iT™ RNA and Quant-iT™ RNA BR Assay Kits (Q32852, Q32855; Q10210, Q10211)—for microarray experiments, real-time PCR samples and northern blots
- Quant-iT™ Protein Assay Kits—for western blotting, activity assays and SDS-PAGE or 2D gel electrophoresis (Q33211, Q33212; Section 9.2)

Figure 8.3.4 RNA selectivity and sensitivity of the Quant-iT™ RNA assay. Triplicate 10 μL samples of *Escherichia coli* rRNA (Δ), DNA (O) or a 1:1 mixture of RNA and DNA (\blacksquare) were assayed with the Quant-iT™ RNA Assay Kit (Q33140). Fluorescence was measured at 630/680 nm and plotted versus the mass of nucleic acid for the RNA alone, the mass of the nucleic acid for the DNA alone or the mass of the RNA component in the 1:1 mixture. The coefficient of variation (CV) of replicate RNA determinations was $\leq 10\%$. The inset is an enlargement of the graph to show the sensitivity of the assay for RNA. Background fluorescence has not been subtracted.

Figure 8.3.5 The Qubit® fluorometer. The Qubit® fluorometer (Q32857) is designed to work seamlessly with the Quant-iT™ assays for DNA, RNA and protein quantitation. It features state-of-the-art optical components, sophisticated data analysis and an intuitive user interface. The result is an easier method to obtain much more accurate and sensitive quantitation than can be obtained with UV absorbance assays, increasing sample performance in downstream applications.

Figure 8.3.6 Fluorescence enhancement of the Quant-iT™ PicoGreen® dsDNA reagent upon to binding dsDNA, ssDNA and RNA. Samples containing 500 ng/mL calf thymus DNA, M13 ssDNA or *Escherichia coli* ribosomal RNA were added to cuvettes containing Quant-iT™ PicoGreen® dsDNA reagent (P7581, P7589, P11495, P11496) in TE buffer. Samples were excited at 480 nm, and the fluorescence emission spectra were collected using a spectrofluorometer. Emission spectra for samples containing dye and nucleic acids, as well as for dye alone (baseline), are shown.

Figure 8.3.7 Linear quantitation of calf thymus DNA from 25 pg/mL to 1000 ng/mL using the Quant-iT™ PicoGreen® dsDNA reagent (P7581, P7589, P11495, P11496). Samples in 10 mm × 10 mm cuvettes were excited at 480 nm. The fluorescence emission intensity was measured at 520 nm using a spectrofluorometer and plotted as a function of DNA concentration. The inset shows an enlargement of the results obtained with DNA concentrations between 0 and 750 pg/mL.

Quant-iT™ PicoGreen® dsDNA Quantitation Assay

The Quant-iT™ PicoGreen® dsDNA reagent² (P7581, P11495) and Kits (P7589, P11496) are designed to accurately quantitate as little as 25 pg/mL of dsDNA in a fluorometer or 250 pg/mL (typically 50 pg in a 200 μ L volume) in a fluorescence microplate reader. The PicoGreen® dsDNA quantitation assay is more than 10,000 times as sensitive as conventional UV absorbance measurements at 260 nm (an A_{260} of 0.1 corresponds to an ~ 5 μ g/mL dsDNA solution) and at least 400 times more sensitive than the Hoechst 33258 dye-based assay.³ It is even more sensitive than assays based on our YO-PRO®-1 and YOYO®-1 dyes, which have reported detection limits of approximately 2.5 ng/mL and 0.5 ng/mL,⁴ respectively.

Although the PicoGreen® reagent is not specific for dsDNA, it shows a >1000-fold fluorescence enhancement upon binding to dsDNA, and much less fluorescence enhancement upon binding to single-stranded DNA (ssDNA) or RNA, making it possible to quantitate dsDNA in the presence of equimolar amounts of ssDNA, RNA or proteins⁵⁻⁷ (Figure 8.3.6). The PicoGreen® reagent also selectively detects DNA–RNA hybrids in the presence of ssDNA and RNA. Differences in the emission lifetimes of the PicoGreen® complexes with dsDNA and ssDNA make it possible to quantitate the relative amounts of each species in solution by time-resolved measurements. By contrast, UV absorbance measurements cannot distinguish between dsDNA, ssDNA and RNA or proteins. Thus, the PicoGreen® reagent allows direct quantitation of PCR amplicons without purification from the reaction mixture and makes it possible to detect low levels of DNA contamination in recombinant protein products.^{6,8} In comparison to the Hoechst 33258 dye, which shows significant AT selectivity, the PicoGreen® reagent shows little if any AT- or GC-selectivity, enabling accurate DNA quantitation from many sources.

The protocol for the PicoGreen® dsDNA quantitation assay is simple and requires very few steps—the dye is simply added to the sample and incubated for five minutes, then the fluorescence is measured. In addition, the fluorescence signal from binding of the PicoGreen® reagent to dsDNA is linear over at least four orders of magnitude (Figure 8.3.7) with a single dye concentration, whereas assays using ethidium bromide, Hoechst 33258 or the YOYO®-1 dye exhibit a much more limited linear range.^{4,9,10} We have found that this linearity is maintained in the presence of several compounds commonly found in nucleic acid preparations, including salts, urea, ethanol, chloroform, detergents, proteins and agarose.⁵ The PicoGreen® reagent can be excited at 488 nm with an argon-ion laser, and is reported to be a superior nucleic acid stain for analysis of single DNA molecules in a flow cytometer.¹¹ A method that utilizes the PicoGreen® reagent for the absolute quantitation of cDNA using real-time PCR has been reported.¹²

The PicoGreen® assay is useful for quantitating DNA templates for PCR,¹³ labeling reactions, electrophoretic mobility-shift (bandshift) assays, DNA-footprinting assays and filter-binding assays, and for measuring yields from PCR reactions,¹⁴ DNA minipreps and maxipreps, cDNA synthesis and nuclease protection assays. The simplicity and selectivity of the assay also make it ideal for high-throughput automated quantitation assays used in forensic and genomics research. Furthermore, the PicoGreen® reagent has been used for:

- Genotyping by allele-specific PCR¹⁵
- Quantitating dsDNA samples before and after PCR amplification or after agarose gel electrophoresis^{8,16}
- Determining PCR amplification yields before sequencing¹⁴
- Automating quantitation of DNA isolated from biological samples or obtained from PCR reactions, prior to running DNA typing gels for high-throughput genotyping¹⁷
- Quantitating DNA from buccal scrapes prior to DNA profiling by short tandem repeat (STR) analysis¹⁸
- Identifying contaminating DNA in recombinant protein products¹⁹ or purified monoclonal antibody preparations^{20,21}
- Monitoring DNA strand breaks in plasmids and bacterial artificial chromosomes²²
- Quantitating the efficiency of DNA extraction from frozen and formalin-fixed tissue sections²³
- Detecting mammalian telomerase activity in tumor cells using the PCR-based TRAP assay²⁴⁻²⁶
- Developing assays for DNA polymerase

- Measuring the activity of reverse transcriptase or DNase I⁷
- Measuring supercoiled DNA forms in solution, based on their renaturation properties²⁸
- Monitoring plasmid production during fermentation and downstream processing²⁹
- Quantitating DNA denaturation as a measure for DNA damage in purified DNA preparations, cell lysates or homogenized solid tissues^{30–32}

Each vial of the Quant-iT™ PicoGreen® dsDNA reagent (P7581) contains a sufficient amount of dye for at least 200 assays using a 2 mL assay volume and a standard fluorometer, or 2000 assays using a 200 µL assay volume and a fluorescence microplate reader. The product is accompanied by a simple protocol that enables linear and reproducible quantitation of dsDNA. We also provide the PicoGreen® reagent in the Quant-iT™ PicoGreen® dsDNA Assay Kit (P7589), which contains:

- Quant-iT™ PicoGreen® dsDNA quantitation reagent
- Low-fluorescence, nucleic acid- and nuclease-free assay buffer concentrate, essential for the accurate measurement of dsDNA
- dsDNA standard solution for assay calibration
- Detailed protocols for dsDNA quantitation

This kit provides sufficient reagents for 200 assays using a 2 mL assay volume and a standard fluorometer or 2000 assays using a 200 µL assay volume and a fluorescence microplate reader. Both the stand-alone reagent and the kit are also available in special packaging, in which the Quant-iT™ PicoGreen® reagent is supplied as 10 vials of 100 µL aliquots for added convenience (P11495; Kit, P11496). The special packaging reduces thawing times, provides individual aliquots for each person performing the assay, and allows smaller amounts of dye to be taken into the field for analysis of water or other samples.

Figure 8.3.8 Linear quantitation of a synthetic 24-mer (an M13 sequencing primer) from 0.1 to 1000 ng/mL using the Quant-iT™ OliGreen® ssDNA reagent (O7582, O11492). Samples in 10 mm × 10 mm cuvettes were excited at 480 nm. The fluorescence emission intensity was measured at 520 nm using a spectrofluorometer and plotted as a function of oligonucleotide concentration. The inset shows an enlargement of the results obtained with oligonucleotide concentrations between zero and 2.0 ng/mL.

Quant-iT™ OliGreen® ssDNA Quantitation Assay

For researchers working with ssDNA and oligonucleotides, as well as for companies that synthesize oligonucleotides, we offer the Quant-iT™ OliGreen® ssDNA reagent (O7582) and Quant-iT™ OliGreen® ssDNA Assay Kit (O11492). Short, synthetic oligonucleotides are used in a number of molecular biology techniques, including DNA sequencing, site-directed mutagenesis, DNA amplification, antisense gene suppression and *in situ* and blot hybridization. The conventional methods for quantitating oligonucleotides are not very sensitive, often requiring highly concentrated samples, and are quite subject to interference from sample contaminants. The most commonly used technique for measuring oligonucleotide and ssDNA concentrations is the determination of absorbance at 260 nm (an A_{260} of 0.1 corresponds to an ~ 3 µg/mL solution of a synthetic 24-mer M13 sequencing primer).

The Quant-iT™ OliGreen® ssDNA reagent enables researchers to routinely quantitate as little as 100 pg/mL of ssDNA or oligonucleotide (200 pg in a 2 mL assay volume with a standard fluorometer) or 200 pg in a 200 µL assay volume using a fluorescence microplate reader (Figure 8.3.8). Thus, quantitation with the OliGreen® reagent is about 10,000 times more sensitive than quantitation with UV absorbance methods and at least 500 times more sensitive (and far faster, with a greater throughput) than detecting oligonucleotides on electrophoretic gels stained with ethidium bromide. Using an easy-to-follow protocol and fluorescein excitation and emission wavelengths, we have quantitated oligonucleotides that range from 10 to 50 nucleotides in length, as well as several sources of ssDNA, such as M13 and ϕ X174 viral DNA and denatured calf thymus DNA, and obtained similar sensitivity. The Quant-iT™ OliGreen® reagent has also been used to detect phosphodiester and phosphorothioate oligonucleotides.³³

Significant disadvantages of the UV absorbance method for oligonucleotide quantitation include the large relative contribution of free nucleotides to the signal and the interference caused by contaminants commonly found in nucleic acid preparations. By contrast, nucleotides and short oligonucleotides of six bases or less do not interfere with the OliGreen® ssDNA quantitation assay. However, the OliGreen® reagent does exhibit fluorescence enhancement when bound to dsDNA and RNA. Like the PicoGreen® assay, the linear detection range of the OliGreen® ssDNA

Figure 8.3.9 Linear quantitation of ribosomal RNA using the Quant-iT™ RiboGreen® RNA reagent (R11491, R11490). For the high-range assay, the RiboGreen® reagent was diluted 200-fold into 10 mM Tris-HCl, 1 mM EDTA, pH 7.5 (TE), and 100 µL of the reagent solution was added to microplate wells containing 100 µL ribosomal RNA in TE. For the low-range assay (see inset), the RiboGreen® reagent was diluted 2000-fold into TE, and 100 µL of the reagent solution was added to 100 µL of ribosomal RNA in TE. Samples were excited at 485 ± 10 nm, and the fluorescence emission intensity was measured at 530 ± 12.5 nm using a fluorescence microplate reader. Background fluorescence was not subtracted.

quantitation assay in a standard fluorometer extends over four orders of magnitude—from 100 pg/mL to 1 µg/mL—with a single dye concentration (Figure 8.3.8). The linearity of the Quant-iT™ OliGreen® assay is maintained in the presence of several compounds commonly found to contaminate nucleic acid preparations, including salts, urea, ethanol, chloroform, detergents, proteins, ATP and agarose; however, many of these compounds do affect the signal intensity to some extent, so standard curves should be generated using solutions that closely mimic those of the samples. The OliGreen® assay can even be performed using samples as complex as whole blood or serum.³³

Our experiments with homopolymers have demonstrated that the OliGreen® reagent may exhibit significant base selectivity. The Quant-iT™ OliGreen® reagent shows a large fluorescence enhancement when bound to poly(dT) but only a relatively small fluorescence enhancement when bound to poly(dG) and little signal with poly(dA) and poly(dC). Thus, it is important to use an oligonucleotide with similar base composition when generating the standard curve.

The remarkable properties of our Quant-iT™ OliGreen® reagent make it ideal for the fast and accurate detection and quantitation of:

- Antisense oligonucleotides
- Aptamers
- Genomic DNA isolated under denaturing conditions
- PCR primers
- Phosphorothioate and phosphodiester oligodeoxynucleotides³³
- Sequencing primers
- Single-stranded phage DNA

Each vial of Quant-iT™ OliGreen® ssDNA reagent (O7582) contains a sufficient amount of dye for at least 200 assays using a 2 mL assay volume and a standard fluorometer, or 2000 assays using a 200 µL assay volume and a fluorescence microplate reader. The product is accompanied by a simple protocol that ensures linear and reproducible quantitation of ssDNA. We also provide the Quant-iT™ OliGreen® reagent in the Quant-iT™ OliGreen® ssDNA Assay Kit (O11492), which contains:

- Quant-iT™ OliGreen® ssDNA quantitation reagent
- Low-fluorescence, nucleic acid- and nuclease-free assay buffer concentrate, essential for the accurate measurement of ssDNA
- Oligonucleotide standard (M13 sequencing primer) solution for assay calibration
- Detailed protocols for ssDNA quantitation

This kit provides sufficient reagents for 200 assays using a 2 mL assay volume and a standard fluorometer or 2000 assays using a 200 µL assay volume and a fluorescence microplate reader.

Quant-iT™ RiboGreen® RNA Quantitation Assay

Quant-iT™ RiboGreen® RNA Reagent and Kit

The Quant-iT™ RiboGreen® RNA reagent (R11491) is our premier stain for quantitating RNA in solution. Like the Quant-iT™ PicoGreen® dsDNA and Quant-iT™ OliGreen® ssDNA quantitation assays, the RiboGreen® RNA quantitation assay relies on a proprietary dye that exhibits a large fluorescence enhancement upon binding to nucleic acids. The extinction coefficient (EC) of the Quant-iT™ RiboGreen® reagent, as well as its quantum yield (QY) and fluorescence enhancement upon binding RNA, are all significantly greater than those of ethidium bromide.

- Quant-iT™ RiboGreen® reagent: $EC_{482} = 67,000 \text{ cm}^{-1}\text{M}^{-1}$, $QY = 0.65$, fluorescence enhancement >1000-fold.
- Ethidium bromide: $EC_{482} = 5,500 \text{ cm}^{-1}\text{M}^{-1}$, $QY < 0.3$, fluorescence enhancement <30-fold.

The Quant-iT™ RiboGreen® assay allows detection of as little as 1 ng/mL RNA in a standard fluorometer, fluorescence microplate reader or filter-based fluorometer using standard fluorescein excitation and emission settings (Figure 8.3.9). This sensitivity is at least 200-fold better than that achieved with ethidium bromide³⁴ and at least 1000-fold better than that achieved using

conventional absorbance measurements at 260 nm (an A_{260} of 0.1 corresponds to an $\sim 4 \mu\text{g/mL}$ RNA solution). Unlike UV absorbance measurements at 260 nm, the Quant-iT™ RiboGreen® reagent does not detect significant sample contamination by free nucleotides.³⁵ Thus, the Quant-iT™ RiboGreen® reagent more accurately measures the amount of intact RNA polymers in potentially degraded samples.

Using two different dye concentrations to cover its full dynamic range of three orders of magnitude, we have observed a linear correlation between the RNA concentration and fluorescence for 1.0 ng/mL to 50 ng/mL RNA using a 4000-fold dilution of the RiboGreen® reagent, and for 20 ng/mL to 1 $\mu\text{g/mL}$ using a 400-fold dilution of the dye (Figure 8.3.9). Assay linearity is maintained in the presence of several compounds commonly found in nucleic acid preparations, including salts, urea, ethanol, chloroform, detergents, proteins and agarose.³⁵

The Quant-iT™ RiboGreen® reagent is not appreciably selective for RNA—the dye also shows significant fluorescence enhancement upon binding to DNA. However, a simple DNase pretreatment of samples removes the contribution of DNA to the signal. The Quant-iT™ RiboGreen® reagent may also have some base selectivity; it exhibits about 60% less fluorescence when bound to poly(G) homopolymers and virtually no fluorescence when bound to poly(U) or poly(C) homopolymers compared with the fluorescence when bound to poly(A) homopolymers or to rRNA.³⁵

Using the Quant-iT™ RiboGreen® RNA reagent, we have reproducibly quantitated RNA from a wide variety of sources, including ribosomal RNA (rRNA), transfer RNA (tRNA), viral RNA, poly(A)⁺ fractions and total cellular RNA.³⁵ The RiboGreen® reagent is useful for:

- Fast and accurate measurements of RNA yields before generating cDNA
- Determination of RNA yields from *in vitro* transcription
- Accurate measurements of RNA before performing northern blot analysis,³⁶ S1 nuclease assays, RNase-protection assays, reverse-transcription PCR and differential-display PCR
- Assay of DNA-dependent RNA polymerase activity³⁷
- Detection of capillary electrophoresis-separated viral RNA that has been stained *in vitro*³⁸

Each vial of the Quant-iT™ RiboGreen® RNA reagent (R11491) contains a sufficient amount of dye for at least 200 high-range assays or 2000 low-range assays using a 2 mL assay volume and a standard fluorometer. With a fluorescence microplate reader and a 96-well microplate, the assay volume is reduced to 200 μL , allowing 2000 high-range assays or 20,000 low-range assays. Included with each vial of the Quant-iT™ RiboGreen® reagent is a simple protocol that permits linear and reproducible quantitation of RNA. We also provide the RiboGreen® reagent in the Quant-iT™ RiboGreen® RNA Assay Kit (R11490), which contains:

- Quant-iT™ RiboGreen® RNA reagent
- Low-fluorescence, nucleic acid- and nuclease-free assay buffer concentrate, essential for the accurate measurement of RNA
- Ribosomal RNA standard (16S and 23S rRNA from *Escherichia coli*) solution for assay calibration
- Detailed protocols

This kit provides sufficient reagents for at least 200 assays using a 2 mL assay volume and a standard fluorometer or at least 2000 assays using a 200 μL assay volume and a fluorescence microplate reader. The RNase-free TE buffer concentrate, which is essential to the success of the assay, is also available separately (T11493) and can be used to extend the number of low-concentration assays possible with the kit.

RediPlate™ 96 RiboGreen® RNA Quantitation Kit

The RiboGreen® assay is also available in a convenient RediPlate™ 96 RiboGreen® RNA Quantitation Kit in which the RiboGreen® reagent is predispensed into a 96-well microplate (R32700). The buffer and sample are simply added to the microplate wells—there is no need to handle the RiboGreen® reagent. After a 10-minute incubation, the microplate is ready to read in a fluorescence microplate reader. The RediPlate™ RiboGreen® assay has a linear range of ~ 15 –1000 ng/mL (~ 3 –200 ng in a 200 μL assay volume) with a single dye concentration (Figure 8.3.10). The microplate used in the RediPlate™ 96 RiboGreen® RNA Quantitation Kit is provided in a resealable foil packet, and it snaps apart into twelve strips to permit assays in any multiple

Figure 8.3.10 Dynamic range and sensitivity of the RediPlate™ 96 RiboGreen® RNA quantitation assay. The RNA standards provided in the RediPlate™ 96 RiboGreen® RNA Quantitation Kit (R32700) were added in quadruplicate to assay wells as described in the accompanying protocol, and fluorescence was measured in a fluorescence microplate reader using excitation at 485 ± 12.5 nm and fluorescence detection at 530 ± 15 nm. Fluorescence was plotted against the RNA concentration with no background subtraction. The inset shows the sensitivity of the assay at very low levels of RNA.

Figure 8.3.11 A RediPlate™ 96 microplate.

Figure 8.3.12 An environmental sample containing marine viruses (smallest dots), bacteria (larger, brighter dots) and a diatom (long thin cell with prominent nucleus) stained with SYBR® Green I nucleic acid stain (S7563, S7567, S7585). Image contributed by Jed Fuhrman, University of Southern California.

of eight (Figure 8.3.11). Eleven of the strips are preloaded with the RiboGreen® reagent; the remaining strip, marked with blackened tabs, contains a series of RNA standards for generating a standard curve. In addition to the 96-well microplate, each RediPlate™ RiboGreen® 96 RNA Quantitation Kit includes RNase-free reaction buffer and detailed instructions.

Other Stains for Nucleic Acid Quantitation in Solution

Cyanine Dyes and Phenanthridine Dyes for Nucleic Acid Quantitation in Solution

The dimeric cyanine dyes TOTO®-1 and YOYO®-1 are useful for sensitive fluorometric measurement of dsDNA, ssDNA and RNA in solution,⁴ although the PicoGreen®, OliGreen® and RiboGreen® reagents generally are faster, have greater sensitivity and show a linear response over a broader range of nucleic acid concentrations. The linear range of assays that use the TOTO®-1 and YOYO®-1 dyes for DNA quantitation encompasses about two orders of magnitude, with a sensitivity limit of about 0.5 ng/mL. The TOTO®-1, YOYO®-1 and YO-PRO®-1 nucleic acid stains have been used to quantitate PCR amplification products in a homogeneous human leukocyte antigen (HLA) typing method that requires no transfer or washing steps, thus minimizing the risk of sample contamination.^{39,40} Other dyes for nucleic acid quantitation in solution and their applications include:

- YOYO®-1 dye (Y3601, Section 8.1) for solution quantitation of oligonucleotides,⁴¹ PCR products⁴² and nuclear run-on assays⁴³
- YO-PRO®-1 dye (Y3603, Section 8.1) for quantitating dsDNA in a fluorescence microplate reader, with a reported sensitivity limit of about 2.5 ng/mL³
- YO-PRO®-1 dye for quantitating RNA isolated from *Xenopus* embryos⁴⁴
- YO-PRO®-1 dye and SYBR® Green I dye for direct counting of viruses in marine and freshwater environments⁴⁵⁻⁵⁰ (Figure 8.3.12)
- PO-PRO™-3 dye (P3585, Section 8.1) for quantitating DNA in a fluorescence microplate reader,⁵¹ with fluorescence measurements reported to be independent of base-pair composition
- Ethidium bromide for measuring the yield of PCR products⁵²
- Ethidium bromide and acridine homodimer (A666, Section 8.1) for quantitating covalently closed, circular DNA and for measuring the activity of polymerases, deoxynucleotidyl transferases, ligases, gyrases, topoisomerases and nucleases^{9,53,54}
- YOYO®-1 dye for measuring the activity of DNases⁵⁵
- SYBR® Gold nucleic acid gel stain (S11494, Section 8.4), for detecting DNA mutations in a simple PCR-based assay⁵⁶

Dyes such as the ethidium homodimers and our dimeric cyanine dyes—the TOTO®, YOYO®, BOBO™, POPO™, JOJO™ and LOLO™ dyes (Table 8.2)—exhibit a high affinity for double-stranded nucleic acids but label small single-stranded oligonucleotides less well. This characteristic of ethidium homodimer-1 (E1169, Section 8.1) was exploited to analyze short self-annealing oligonucleotides for their ability to hybridize.⁵⁷ Because our dimeric cyanine dyes and the Quant-iT™ PicoGreen® dsDNA quantitation reagent have extremely low intrinsic fluorescence in the absence of DNA, high fluorescence enhancements upon binding, higher quantum yields and much larger extinction coefficients than ethidium homodimer-1,^{3,58} they should prove superior in this application.

Hoechst 33258 Dye for Quantitating DNA in Solution

The Hoechst 33258 dye (H1398, H3569, H21491) has been extensively used to quantitate dsDNA in solution. Hoechst 33258 shows a fluorescence increase upon binding nucleic acids and a preference for binding to AT regions. Hoechst 33258 is selective (but not specific) for dsDNA over RNA in high-salt buffers and for dsDNA over ssDNA in low-salt buffers. The Hoechst 33258 dye can quantitatively detect from 10 ng/mL to ~10 µg/mL dsDNA when two different dye concentrations are used.¹⁰ While this assay uses principles that are similar to other fluorescent assays, newer dyes such as the Quant-iT™ PicoGreen® reagent provide much higher sensitivity, better selectivity and a much broader dynamic range with a single dye concentration.

The FluoReporter® Blue Fluorometric dsDNA Quantitation Kit (F2962) provides the protocols developed by Rago and colleagues¹ for analyzing cellular DNA with the blue-fluorescent Hoechst 33258 nucleic acid stain. The kit enables researchers to detect ~10 ng of isolated calf thymus DNA or ~1000 mouse NIH 3T3 cells in a 200 µL sample (substantially lower levels are detectable using our CyQUANT® Cell Proliferation Assay Kit described in Section 15.4). With this kit, quantitation of cellular DNA is rapid, and all manipulations can be carried out in microplate wells. The cells are lysed by freezing them in distilled water, which circumvents the requirement for extraction procedures used in other Hoechst 33258 dye-based protocols.^{10,59–62} The diluted dye solution is then added to lysed cells and the fluorescence is measured. Kit components include:

- Hoechst 33258 in dimethylsulfoxide (DMSO)/H₂O
- TNE buffer
- Detailed protocols

Each kit provides sufficient reagents for assaying 2000 samples using a fluorescence microplate reader.

Real-Time Quantitative PCR Using SYBR® Green I Nucleic Acid Gel Stain

Measurements of PCR products can be taken during the linear portion of the amplification reactions, allowing accurate quantitation of templates. Several methods exist for real-time quantitation of PCR products, including fluorescence resonance energy transfer techniques using fluorescently labeled primers or molecular beacon. Identification of PCR products during the reaction can also be monitored using SYBR® Green I nucleic acid gel stain (S7563, S7567, S7585); this method has been shown to be more precise than TaqMan® assays using labeled

oligonucleotide probes.⁶³ In addition, individual DNA molecules have been detected with on-line capillary PCR coupled with laser-induced fluorescence detection by adding SYBR® Green I stain to the reaction mixture.⁶⁴

SYBR® Green I stain binds preferentially to dsDNA, allowing accurate quantitation of double-stranded product in the presence of single-stranded oligonucleotide primers.⁶⁵ SYBR® Green I stain is stable to the extremes of temperature required for PCR reactions and does not interfere with Taq polymerase. Improved specificity for quantitating desired products can be achieved by using SYBR® Green I stain after the assay to measure the melting temperature of the products.^{66–74} Double-stranded DNA with no base mismatches will show a higher melting temperature than the nonspecific templates that contain mismatches. Real-time quantitative PCR experiments can be carried out using instruments specialized for the application^{75,76} or by quantitating amplification products manually at different time points.⁷⁷ Real-time quantitative PCR with SYBR® Green I stain has been used to develop reliable and simple assays for detecting genetic mutations, including duplications and deletions in mosquito drug-resistance genes,⁷⁸ chromosomal translocations in human disease genes,^{70,79} and base substitutions.^{67,80,81} It has also been used for the unequivocal identification of viral, bacterial or fungal pathogens.^{66,68,71,82–84} In addition, this method has been used successfully for quantitative reverse-transcription PCR.^{63,75}

Invitrogen has introduced the next generation of real-time PCR detection reagents, including the SYBR® GreenER qPCR reagent system, which produces the extremely reliable gene expression data from real-time quantitative PCR. SYBR® GreenER reagent is a novel dsDNA-binding dye that exhibits a brighter signal and significantly reduced PCR inhibition compared to the original SYBR® Green dye, but nearly identical spectral characteristics. More information about the SYBR® GreenER qPCR reagent system and the latest developments in real-time PCR detection can be found at www.invitrogen.com/handbook/qrtPCR.

PRODUCT LIST 8.3 NUCLEIC ACID QUANTITATION IN SOLUTION

Cat. No.	Product	Quantity
F2962	FluoReporter® Blue Fluorometric dsDNA Quantitation Kit *200–2000 assays*	1 kit
H1398	Hoechst 33258, pentahydrate (bis-benzimide)	100 mg
H3569	Hoechst 33258, pentahydrate (bis-benzimide) *10 mg/mL solution in water*	10 mL
H21491	Hoechst 33258, pentahydrate (bis-benzimide) *FluoroPure™ grade*	100 mg
Q33130	Quant-iT™ dsDNA Assay Kit, Broad Range, 1000 assays *2–1000 ng*	1 kit
Q33120	Quant-iT™ dsDNA Assay Kit, High Sensitivity, 1000 assays *0.2–100 ng*	1 kit
Q32850	Quant-iT™ dsDNA BR Assay Kit, 100 assays *for use with the Qubit® fluorometer* *2–1000 ng*	1 kit
Q32853	Quant-iT™ dsDNA BR Assay Kit, 500 assays *for use with the Qubit® fluorometer* *2–1000 ng*	1 kit
Q32851	Quant-iT™ dsDNA HS Assay Kit, 100 assays *0.2–100 ng* *for use with the Qubit® fluorometer*	1 kit
Q32854	Quant-iT™ dsDNA HS Assay Kit, 500 assays *0.2–100 ng* *for use with the Qubit® fluorometer*	1 kit
O11492	Quant-iT™ OliGreen® ssDNA Assay Kit *2000 assays*	1 kit
O7582	Quant-iT™ OliGreen® ssDNA reagent *2000 assays*	1 mL
P7589	Quant-iT™ PicoGreen® dsDNA Assay Kit *2000 assays*	1 kit
P11496	Quant-iT™ PicoGreen® dsDNA Assay Kit *2000 assays* *10 x 100 µL*	1 kit
P7581	Quant-iT™ PicoGreen® dsDNA reagent *2000 assays*	1 mL
P11495	Quant-iT™ PicoGreen® dsDNA reagent *2000 assays* *10 x 100 µL*	10 x 100 µL
R11490	Quant-iT™ RiboGreen® RNA Assay Kit *2000 assays*	1 kit
R11491	Quant-iT™ RiboGreen® RNA reagent *2000 assays*	1 mL
Q33140	Quant-iT™ RNA Assay Kit, 1000 assays *5–100 ng*	1 kit
Q32852	Quant-iT™ RNA Assay Kit, 100 assays *5–100 ng* *for use with the Qubit® fluorometer*	1 kit
Q32855	Quant-iT™ RNA Assay Kit, 500 assays *5–100 ng* *for use with the Qubit® fluorometer*	1 kit
Q10213	Quant-iT™ RNA Assay Kit, Broad Range, 1000 assays *20–1000 ng*	1 kit
Q10210	Quant-iT™ RNA BR Assay Kit, 100 assays *20–1000 ng* *for use with the Qubit® fluorometer*	1 kit
Q10211	Quant-iT™ RNA BR Assay Kit, 500 assays *20–1000 ng* *for use with the Qubit® fluorometer*	1 kit
Q10212	Quant-iT™ ssDNA Assay Kit, 100 assays *1–200 ng* *for use with the Qubit® fluorometer*	1 kit
Q32856	Qubit™ assay tubes *set of 500*	1 set
Q32857	Qubit® fluorometer	each
Q32859	Qubit™ fluorometer international power cord *replacement*	each
Q32858	Qubit™ fluorometer USB cable	each
Q32861	Qubit™ Quantitation Lab Starter Kit	1 kit
Q32860	Qubit™ Quantitation Starter Kit	1 kit
R32700	RediPlate™ 96 RiboGreen® RNA Quantitation Kit *one 96-well microplate*	1 kit
S7563	SYBR® Green I nucleic acid gel stain *10,000X concentrate in DMSO*	500 µL
S7567	SYBR® Green I nucleic acid gel stain *10,000X concentrate in DMSO*	1 mL
S7585	SYBR® Green I nucleic acid gel stain *10,000X concentrate in DMSO* *special packaging*	20 x 50 µL
T11493	20X TE buffer *RNase free*	100 mL

8.4 Nucleic Acid Detection on Gels, Blots and Arrays

Nucleic Acid Detection in Gels

Molecular Probes® fluorescent nucleic acid gel stains—SYBR® Gold, SYBR® Green I, SYBR® Green II and SYBR® Safe dyes—are high-sensitivity reagents for staining DNA and RNA in electrophoretic gels.¹ These gel stains provide greater sensitivity with lower background fluorescence than the conventional ethidium bromide gel stain. In addition, SYBR® Safe DNA gel stain showed very low mutagenic activity when tested by an independent, licensed testing laboratory, and it is not classified as hazardous waste or as a pollutant under U.S. Federal regulations.

SYBR® Gold Nucleic Acid Gel Stain

SYBR® Gold nucleic acid gel stain (S11494) is our most sensitive stain for detecting DNA or RNA in gels using a standard 300 nm UV transilluminator and Polaroid® 667 black-and-white print film. Although SYBR® Green I and SYBR® Green II gel stains are preferred for specific applications, several characteristics of SYBR® Gold stain represent a further improvement over our SYBR® Green I and SYBR® Green II gel stains for routine gel analysis. SYBR® Gold nucleic acid gel stain provides:

- **Maximum sensitivity.** Upon binding to nucleic acids, SYBR® Gold stain exhibits a >1000-fold fluorescence enhancement and a quantum yield of ~0.6.² By comparison, ethidium bromide exhibits <30-fold fluorescence enhancement upon binding nucleic acids³ and a quantum yield of ~0.15.⁴ Because of its superior fluorescence characteristics, SYBR® Gold stain is greater than 10-fold more sensitive than ethidium bromide for detecting DNA and RNA in gels using a 300 nm UV transilluminator and black-and-white photography (Figure 8.4.1). We routinely detect as little as 25 pg of dsDNA or 1 ng of RNA per band using a 300 nm UV transilluminator or a blue-light transilluminator—sensitivity levels even higher than those of silver staining.² For detecting glyoxalated RNA with 300 nm transillumination, SYBR® Gold stain is 25–100 times more sensitive than ethidium bromide (Figure 8.4.2) and thus represents a significant advance for protocols requiring sensitive RNA detection. SYBR® Gold stain has also proven to be more sensitive than SYBR® Green II RNA gel stain for detecting single-strand conformation polymorphism (SSCP) products.
- **Rapid gel penetration.** Staining gels with SYBR® Gold stain after electrophoresis followed by gel photography provides the optimal sensitivity. SYBR® Gold stain penetrates agarose gels faster and stains thick and high-percentage gels better than other post-electrophoresis stains.
- **Versatility.** SYBR® Gold stain is a universal nucleic acid gel stain that provides high detection sensitivity for dsDNA, ssDNA and RNA detection in many gel types, including high-percentage agarose, glyoxal/agarose, formaldehyde/agarose, native polyacrylamide- and urea-polyacrylamide gels. No wash step is required in order to achieve maximal sensitivities.²
- **Ease of use.** As a result of the low intrinsic fluorescence of the unbound dye, gel staining with SYBR® Gold dye shows extremely low background fluorescence and does not require a destaining step, even when staining agarose/formaldehyde gels. After incubating the gel in SYBR® Gold staining solution for 10–40 minutes (depending on the thickness and percentage of the agarose or polyacrylamide gel) the golden-yellow-fluorescent DNA or RNA bands are ready to be photographed.
- **Compatibility with other molecular biology techniques.** The presence of unbound SYBR® Gold dye in stained gels at standard staining concentrations does not interfere with restriction endonuclease or ligase activity or with subsequent PCR reactions. SYBR® Gold nucleic acid staining is compatible with both northern and Southern blotting—the stain transfers with the DNA or RNA to the blot and is washed off during incubation in the prehybridization mix.² SYBR® Gold stain is also easily removed from dsDNA by simple ethanol precipitation, leaving templates ready for subsequent manipulation or analysis.

Figure 8.4.1 Comparison of the sensitivity achieved using SYBR® Gold stain (S11494) with 300 nm transillumination (A) or silver stain to detect double-stranded DNA separated on native polyacrylamide gels (B).

Figure 8.4.2 Comparison of glyoxylated RNA stained with ethidium bromide and with SYBR® Gold nucleic acid gel stain (S11494). Identical 2-fold dilutions of glyoxylated *Escherichia coli* 16S and 23S ribosomal RNA were separated on 1% agarose minigels using standard methods and stained for 30 minutes with SYBR® Gold stain in TBE buffer (A) or 0.5 µg/mL ethidium bromide in 0.1 M ammonium acetate (B). Both gels were subjected to 300 nm transillumination and photographed using Polaroid® 667 black-and-white print film and a SYBR® photographic filter (S7569, A) or an ethidium bromide photographic filter (B).

Figure 8.4.3 Fluorescence excitation and emission spectra of SYBR® Gold nucleic acid gel stain (S11494) bound to double-stranded DNA.

Figure 8.4.4 Sensitive and direct visualization of single-strand conformation polymorphism (SSCP) in exon 1 of human K-ras using SYBR® Gold nucleic acid gel stain (S11494). Lane 1 contains wild-type DNA and lanes 2–4 contain DNA from various adenocarcinoma samples with mutant alleles. Image contributed by Valerie DeGroff and Chris Weghorst, Ohio State University.

Figure 8.4.5 DNA molecular weight ladders that have been electrophoresed on a 1% agarose gel and then stained for 30 minutes with a 1:10,000 dilution of SYBR® Green I nucleic acid gel stain (S7563, S7567, S7585). Lanes 1 and 8 contain *Hind*III-cut DNA; lanes 2 and 7, *Hae*III-cut *fx174* RF DNA; lanes 3 and 6, 1 kilobase pair DNA ladder (GIBCO®); lane 4, 100 base pair DNA ladder (GIBCO®); lane 5, *Eco*R-I-cut pUC19 DNA mixed with *Pst*I-cut *fx174* RF DNA. Gel staining was visualized using 254 nm epi-illumination.

- **Instrument compatibility.** Because the nucleic acid-bound SYBR® Gold dye exhibits excitation maxima at both ~495 nm and ~300 nm (the emission maximum is ~537 nm) (Figure 8.4.3), it is compatible with a wide variety of instrumentation, ranging from UV epi- and transilluminators and blue-light transilluminators, to mercury-arc lamp- and argon-ion laser-based gel scanners. Short-wavelength (254 nm) epi-illumination is not required to obtain high sensitivity with SYBR® Gold stain. For optimal sensitivity with black-and-white print film and UV illumination, SYBR® Gold dye-stained gels should be photographed through a SYBR® photographic filter (S7569, see below).

SYBR® Gold dye should prove invaluable in applications such as agarose/formaldehyde gel electrophoresis prior to northern blot analysis, denaturing gradient gel electrophoresis (DGGE) and single-strand conformation polymorphism (SSCP) studies (Figure 8.4.4), as well as routine gel analysis. The high signals of the dye-DNA complex and the remarkable photostability observed with 300 nm transilluminators will make it easier to cut out low-abundance bands for subsequent manipulation, including subcloning, bandshift assays or other dsDNA template-based reactions. SYBR® Gold nucleic acid stain is useful for methylation-sensitive single-strand conformation analysis⁵ (MS-SSCA). It is also reportedly more sensitive and easier to use than silver staining in the telomeric repeat amplification protocol⁶ (TRAP). In the electrophoretic analysis of DNA forms in liposomes, the dye showed 40-fold greater sensitivity and more consistent staining between different isoforms of DNA compared with ethidium bromide.⁷ In addition, it has been used to monitor the formation of crosslinked peptide-DNA complexes.⁸

Each 500 µL vial of SYBR® Gold nucleic acid gel stain (S11494) contains sufficient reagent to stain at least 100 agarose or polyacrylamide minigels. SYBR® Gold nucleic acid stain is accompanied by detailed instructions for use of the dye in staining nucleic acids. Answers to frequently asked questions about all our SYBR® dyes are available in a separate information sheet.

SYBR® Green I Nucleic Acid Gel Stain

SYBR® Green I nucleic acid gel stain⁹ (S7563, S7567, S7585) is an extremely sensitive fluorescent stain for detecting nucleic acids in agarose and polyacrylamide gels (Figure 8.4.5). As with SYBR® Gold stain, this remarkable sensitivity can be attributed to a combination of unique dye characteristics. SYBR® Green I stain exhibits exceptional affinity for DNA and a large fluorescence enhancement upon binding to DNA—at least an order of magnitude greater than that of ethidium bromide when detected by photography. Also, the fluorescence quantum yield of the SYBR® Green I dye-DNA complex (~0.8) is over five times greater than that of the ethidium complex of DNA (~0.15). Furthermore, SYBR® Green I stain has been shown to be significantly less mutagenic than EtBr by Ames testing.¹⁰ SYBR® Green I stain is somewhat less sensitive than our SYBR® Gold stain, but has some important characteristics that make it the preferred reagent for certain applications:

- **Preferential DNA staining.** SYBR® Green I nucleic acid stain has a much greater fluorescence enhancement when bound to dsDNA and oligonucleotides than when bound to RNA. With a standard 300 nm UV transilluminator and photographic detection, as little as 60 pg dsDNA per band can be detected with SYBR® Green I stain^{11–13} (Figure 8.4.6), whereas SYBR® Green I

Figure 8.4.6 Comparison of dsDNA detection in native gels using SYBR® Green I nucleic acid gel stain and ethidium bromide. Identical 3-fold dilutions of bacteriophage lambda DNA digested with *Hind*III restriction endonuclease were electrophoresed on 1% agarose gels. Gels were stained for 30 minutes with a 1:10,000 dilution of SYBR® Green I nucleic acid gel stain (S7563, S7567, S7585) and not destained (A and B) or with 5 µg/mL ethidium bromide for 30 minutes and destained for a further 30 minutes in water (C). Gel staining was visualized using 254 nm epi-illumination (A) or 300 nm transillumination (B and C) and then photographed using Polaroid® 667 black-and-white print film and a SYBR® photographic filter (A and B, S7569) or an ethidium bromide gel stain photographic filter (C).

stain is not much more sensitive than ethidium bromide for staining RNA. This quality makes SYBR® Green I dye the ideal gel stain for applications in which RNA in the sample may obscure the results, such as when visualizing DNA fragmentation ladders from apoptotic cells^{14,15} (Figure 8.4.7). Fluorescence of nucleic acid-bound SYBR® Green I dye is also of sufficient sensitivity to allow detection and discrimination of viruses by flow cytometry.¹⁶

- **Sensitivity for oligonucleotide detection.** We have determined that SYBR® Green I nucleic acid gel stain is nearly two orders of magnitude more sensitive than ethidium bromide for staining oligonucleotides in gels, provided that the gel is photographed according to the provided protocol. Using 254 nm epi-illumination, it is possible to detect 1–2 ng of a synthetic 24-mer on 5% polyacrylamide gels (Figure 8.4.8).
- **Exceptionally low background.** SYBR® Green I stain shows very low background fluorescence in the gel, making it the preferred dye for some laser-scanning instruments, in which background fluorescence can produce unacceptable noise levels.
- **Spectral compatibility with lasers and filter sets.** SYBR® Green I stain has a UV-excitation peak of ~250 nm (Figure 8.4.9). Thus, higher sensitivity can be achieved with SYBR® Green I stain using 254 nm transillumination, as compared with the more common 300 nm transillumination. However, the visible excitation peak of SYBR® Green I dye-stained nucleic acids near 497 nm is very close to the principal emission lines of many laser-scanning instruments. Because nucleic acid-bound SYBR® Green I dye exhibits spectral characteristics (excitation/emission maxima ~497/520 nm) very similar to those of fluorescein, it is compatible with most common filter sets used in laser scanners.

Like SYBR® Gold stain, SYBR® Green I dye is very easy to use—the staining procedure can be completed in 10–40 minutes (somewhat longer for thicker gels), with no destaining step required prior to photography. Presence of typical staining concentrations of SYBR® Green I dye does not significantly inhibit the ability of several restriction endonucleases to cleave DNA.¹¹ This property makes staining with SYBR® Green I dye compatible with in-gel subcloning protocols.¹⁷ SYBR® Green I stain is also easily removed from dsDNA by simple ethanol precipitation. For optimal sensitivity with black-and-white print film and UV illumination, gels stained with SYBR® Green dye should be photographed through a SYBR® photographic filter (S7569); a CCD camera also provides good detection sensitivity.

The ultrasensitivity of SYBR® Green I dye makes it useful for detecting the products of DNA and RNA amplification reactions by gel electrophoresis,¹⁸ restriction mapping small amounts of DNA and detecting the products of bandshift¹⁹ and nuclease-protection assays. PCR amplification products that are at the limit of detection using ethidium bromide are easily detected using SYBR® Green I dye. Reverse-transcription PCR (RT-PCR) reaction products have been detected with high sensitivity following gel electrophoresis and staining with SYBR® Green I dye, allowing the cycle number to be lowered, which reduces heteroduplex formation during amplification.²⁰ SYBR® Green I stain was used to detect RT-PCR products amplified from B cells,²¹ *Xenopus laevis* embryos²² and smooth muscle cells.²³ Using a laser scanner and SYBR® Green I stain, researchers have developed a high-throughput RT-PCR DNA profiling assay in multiwell agarose gels.²⁴ SYBR® Green I dye was used to stain DNA in high-resolution gels capable of resolving 100–200 base-pair DNA fragments and differing by as few as two base pairs.²⁵ Use of SYBR® Green I stain also eliminates the need to label PCR products with radioisotopes in a kinetic PCR assay.^{26–28} The high chemical stability of SYBR® Green I nucleic acid stain and the dye's selective sensitivity for detecting double-stranded products made in the presence of single-stranded oligonucleotide

Figure 8.4.9 Fluorescence excitation and emission spectra of dsDNA-bound SYBR® Green I nucleic acid gel stain (S7563, S7567, S7585).

Figure 8.4.7 DNA extracts from camptothecin-treated HL-60 cells separated on an agarose gel and stained with SYBR® Green I nucleic acid gel stain (S7563, S7567, S7585). The 200 to 5000 bp DNA fragments characteristic of apoptotic cells (which appear as "ladders") are clearly visualized with this sensitive nucleic acid stain. Cell preparations were gifts of Zbigniew Darzynkiewicz, Cancer Research Institute, New York Medical College.

Figure 8.4.8 Comparison of single-stranded oligonucleotide detection using SYBR® Green I nucleic acid gel stain and ethidium bromide. Identical 3-fold dilutions of a synthetic, single-stranded 24-mer were electrophoresed on 10% polyacrylamide gels. Gels were stained for 30 minutes with a 1:10,000 dilution of SYBR® Green I nucleic acid gel stain (S7563, S7567, S7585) and not destained (A and B), or with 5 µg/mL ethidium bromide for 30 minutes and destained for a further 30 minutes in water (C). Gel staining was visualized using 254 nm epi-illumination (A) or 300 nm transillumination (B and C), and then photographed using Polaroid® 667 black-and-white print film and a SYBR® photographic filter (S7569, A and B) or an ethidium bromide gel stain photographic filter (C).

primers make SYBR® Green I stain the preferred dye for real-time quantitative analysis of PCR products in a solution assay (Section 8.3).

In other gel-based techniques, SYBR® Green I nucleic acid gel stain has enabled researchers to eliminate silver staining and radioactivity from their protocols. SYBR® Green I dye staining was shown to be as sensitive as silver staining—as well as being more rapid, less laborious and less expensive—in a nonradioactive method for detecting hyper-variable simple sequence repeats in electrophoretic gels.²⁹ SYBR® Green I dye staining has replaced conventional silver staining techniques for routine identity testing in some forensics laboratories. In addition, SYBR® Green I stain is as sensitive as silver staining, but less expensive, for detecting STR (short tandem repeat) polymorphisms,^{30,31} and mitochondrial DNA deletions.³²

Likewise, in a gel assay for detection of telomerase activity (telomeric repeat amplification protocol or TRAP) in human cells and tumors, SYBR® Green I dye staining was found to be more sensitive than silver staining and gave results comparable to those achieved with a radioisotope-based TRAP assay.^{33,34} Moreover, unlike silver stains, SYBR® Green I stain does not label proteins carried over from the reaction mixture. SYBR® Green I dye staining has also been shown to be as sensitive as ³H-labeled thymidine for detecting double-strand breaks in mammalian cells.³⁵ It may be possible to further increase the sensitivity of some of these reported applications of SYBR® Green I stain by using SYBR® Gold nucleic acid gel stain (see above).

Each milliliter of our concentrated SYBR® Green I nucleic acid gel stain (S7563, S7567, S7585) contains sufficient reagent to stain at least 100 agarose or polyacrylamide minigels. Reuse of the staining solution can significantly increase the number of gels stained per vial. In some applications, such as preparative agarose gel electrophoresis, the amount of SYBR® Green I dye used per gel can be significantly reduced if the dye is added directly to the loading buffer. However, because the dye affects

DNA mobility and dissociates from the smaller DNA fragments during electrophoresis, this method should not be used for size determination or for DNA fragments less than ~100 base pairs in length.³⁶

SYBR® Green II RNA Gel Stain

SYBR® Green II RNA gel stain (S7564, S7568, S7586) is a highly sensitive dye for detecting RNA or ssDNA in agarose or polyacrylamide gels (Figure 8.4.10, Figure 8.4.11). Some outstanding features of SYBR® Green II RNA gel stain include its high binding affinity for RNA and its large fluorescence enhancement and exceptionally high quantum yield upon binding to RNA. Although it is not a specific stain for RNA, SYBR® Green II dye exhibits a larger fluorescence quantum yield when bound to RNA (~0.54) than to dsDNA (~0.36). This property is unusual among nucleic acid stains; most show far greater quantum yields and fluorescence enhancements when bound to double-stranded nucleic acids. Moreover, the fluorescence quantum yield of the SYBR® Green II complex of RNA is over seven times greater than that of the ethidium bromide–RNA complex³⁷ (~0.07). The affinity of SYBR® Green II RNA gel stain for RNA is also higher than that of ethidium bromide, and its fluorescence enhancement upon binding to RNA is well over an order of magnitude greater. Like SYBR® Green I stain, our SYBR® Green II stain gives the greatest sensitivity on 254 nm transillumination or laser scanners. However, the best sensitivity for RNA detection using 300 nm transillumination is achieved with SYBR® Gold dye (see above). Other important properties of SYBR® Green II RNA gel stain include:

- Sensitivity.** Using 254 nm epi-illumination, Polaroid® 667 black-and-white print film and a SYBR® photographic filter (S7569), we have been able to detect as little as 100 pg of ribosomal RNA (rRNA) per band on native 1% agarose gels and <1 ng rRNA per band on 5% polyacrylamide gels stained with SYBR® Green II RNA gel stain. The detection limit of SYBR® Green II dye–stained native gels excited with 300 nm transillumination is approximately 500 pg per band, as compared with about 1.5 ng for ethidium bromide–stained gels¹³ (Figure 8.4.10).

Figure 8.4.10 Comparison of RNA detection in nondenaturing gels using SYBR® Green II RNA gel stain and ethidium bromide. Identical 2-fold dilutions of *Escherichia coli* ribosomal RNA were electrophoresed on 1% agarose gels using Tris-borate buffer. Gels were stained for 20 minutes with a 1:10,000 dilution of SYBR® Green II RNA gel stain (S7564, S7568, S7586) and not destained (A and B), or with 5 µg/mL ethidium bromide for 20 minutes and destained for a further 20 minutes in water (C). Gel staining was visualized using 254 nm epi-illumination (A) or 300 nm transillumination (B and C), and then photographed using Polaroid® 667 black-and-white print film and a SYBR® photographic filter (A and B, S7569) or an ethidium bromide gel stain photographic filter (C).

Figure 8.4.11 A 2-fold dilution series of *Escherichia coli* 16S and 23S ribosomal RNA (rRNA) that has been electrophoresed on a nondenaturing 1% agarose gel and then stained with our SYBR® Green II RNA gel stain (S7564, S7568, S7586). Gel staining was visualized with 254 nm epi-illumination.

- **Ease of use.** Like SYBR® Green I and SYBR® Gold stains, SYBR® Green II RNA gel stain has a very low intrinsic fluorescence, eliminating the need to destain gels.
- **Compatibility with urea and formaldehyde gels.** Fluorescence of SYBR® Green II dye–RNA complexes does not appear to be quenched in the presence of urea or formaldehyde, so that denaturing gels do not have to be washed free of the denaturant prior to staining.
- **Broad linear dynamic range.** When used on a laser scanner, SYBR® Green II stain shows a dynamic range of over five orders of magnitude—far greater than the linear dynamic range of ethidium bromide—allowing more accurate quantitation of bands in the gel.³⁸
- **Compatibility with northern blots.** SYBR® Green II dye staining is compatible with agarose/formaldehyde gels. The formaldehyde does not have to be removed prior to staining, and the sensitivity of SYBR® Green II dye staining is 5–10 times better than that of ethidium bromide on these gels. In addition, staining agarose/formaldehyde gels with SYBR® Green II dye does not interfere with transfer of the RNA to filters or subsequent hybridization in northern blot analysis, provided that 0.1% to 0.3% SDS is included in the prehybridization and hybridization buffers.³⁹ Thus, SYBR® Green II stain can be used to normalize the hybridization signal to the amount of RNA loaded on the gel.^{38,40,41}

SYBR® Green II RNA gel stain facilitates the detection of viroid RNAs and other multicopy cellular RNA species. This gel stain has been used to visualize the migration behavior of 5S rRNA species after electrophoresis through a denaturing gradient gel, a method that was used to discriminate among different acidophile species in a mixed culture.⁴² SYBR® Green II RNA gel stain should also improve the analysis of small aliquots from an RNA preparation, leaving the researcher with more material to carry out the primary experiment, be it northern blotting, start-site mapping or cDNA preparation.

In addition to its use for detecting RNA, SYBR® Green II RNA gel stain is useful for single-strand conformation polymorphism (SSCP) analysis,^{43,44} which demands extremely sensitive detection techniques.⁴⁵ Many of the nonradioisotopic SSCP methods currently in use, such as silver staining or chemiluminescence-mediated signal amplification, require long, complex procedures.^{46–49} An SSCP assay using precast polyacrylamide minigels and SYBR® Green II stain not only provides the precise temperature control required for the assay,⁵⁰ but it is more rapid and less labor-intensive than assays that use silver staining for detection.⁵¹ In another report, SYBR® Green II RNA gel stain was used to detect *Ki-ras* mutants by SSCP analysis and was reported to yield 10-fold better sensitivity than standard silver-staining techniques.⁴⁴ SYBR® Green II stain is compatible with amplification by PCR; after SSCP analysis, SYBR® Green II dye-stained bands can be excised out of the gel and used in cycle-sequencing.⁵² SYBR® Green II nucleic acid stain also provides high-sensitivity staining for rRNA separated by high-resolution denaturing gradient electrophoresis (DGGE), making it possible to discriminate between closely related species of bacteria.⁴²

SYBR® Green Nucleic Acid Gel Stains: Special Packaging and a Starter Kit

In addition to providing SYBR® Green nucleic acid gel stains packaged as 500 μ L or 1 mL stock solutions in DMSO (S7563, S7564, S7567, S7568), we make both SYBR® Green I and SYBR® Green II available as

a set of 20 individual vials, each containing 50 μ L of the DMSO stock solution (S7585, S7586). This convenient packaging makes it easy to supply members of the laboratory with an aliquot of stock solution, or to share stock with other laboratories. Special packaging also minimizes potential losses due to contamination, spills and light exposure. Each milliliter of the concentrated gel stain provides sufficient reagent to prepare 10 liters of a staining solution. Although best results are obtained with freshly diluted dye, properly prepared staining solution can be stored for up to a week, if kept refrigerated and protected from light, and can be reused 2–3 times with little loss of signal. SYBR® Green nucleic acid stains are accompanied by detailed instructions for their use in staining gels; answers to frequently asked questions about all SYBR® dyes are available in a separate information sheet.

Our SYBR® Green Nucleic Acid Gel Stain Starter Kit (S7580) is designed for laboratories that want to sample these products. The kit includes single 50 μ L vials of both SYBR® Green I and SYBR® Green II stains and a SYBR® gel stain photographic filter, along with complete directions for their use.

SYBR® Safe DNA Gel Stain

SYBR® Safe DNA gel stain (S33100, S33101, S33102, S33111, S33112) provides sensitive DNA detection with significantly reduced mutagenicity, making it safer than ethidium bromide for staining DNA in agarose or acrylamide gels. Not only is SYBR® Safe stain less mutagenic than ethidium bromide, but the detection sensitivity of SYBR® Safe gel stain is comparable to that of ethidium bromide and 400 times greater than that of colorimetric stains for detecting DNA in electrophoretic gels. SYBR® Safe stain is provided as a premixed solution that can directly replace ethidium bromide in standard protocols; SYBR® Safe stain can either be cast into the gel or be used as a post-electrophoresis stain. DNA bands stained with SYBR® Safe DNA gel stain can be detected using a standard UV transilluminator, a visible-light transilluminator or a laser scanner. SYBR® Safe stain is also suitable for detecting RNA in gels. Bound to nucleic acids, SYBR® Safe stain has fluorescence excitation maxima at 280 nm and 502 nm, and an emission maximum at 530 nm (Figure 8.4.12). SYBR® Safe DNA gel stain offers:

- **Increased safety.** SYBR® Safe DNA gel stain has tested negative in three mammalian cell-based assays for genotoxicity, is less mutagenic than ethidium bromide in standard Ames tests and is not classified as hazardous waste under U.S. Federal regulations (SYBR® Safe DNA Gel Stain—Note 8.1).

Figure 8.4.12 Normalized fluorescence excitation and emission spectra of SYBR® Safe DNA gel stain (S33100, S33101, S33110), determined in the presence of double-stranded DNA.

- **Better performance.** SYBR® Safe DNA gel stain is as sensitive as ethidium bromide and 400 times as sensitive as colorimetric stains for detecting DNA in electrophoretic gels.
- **Convenience.** SYBR® Safe stain is provided as a ready-to-use solution in 0.5X TBE or 1X TAE; it can be cast directly in the gel or used as a post-electrophoresis stain (Figure 8.4.13).
- **Quick staining protocol.** Simply incubate the gel in staining solution for 30 minutes; no destaining is required.

Furthermore, we have demonstrated a vast improvement in cloning efficiency with DNA fragments isolated from agarose gels using SYBR® Safe stain and blue light versus the same DNA fragments isolated using ethidium bromide and UV light. In the experiment, a 1.25 kilobase gene

was amplified by PCR. Seven equal amounts of the PCR product were electrophoresed on duplicate agarose gels; one gel was visualized with SYBR® Safe stain and blue-light illumination, while the other gel was visualized with ethidium bromide and UV illumination. Bands were excised after defined exposure times, then purified using the Invitrogen™ PureLink™ Gel Extraction Kit. The purified product was then used in a Gateway® BxP cloning reaction. A portion of each reaction product was transformed into One Shot® TOP10 chemically competent bacteria; three serial dilutions were plated, and colonies were counted using an Alpha Innotech imaging system. The results showed an 80% reduction in transformation efficiency after only 30 seconds of exposure to ethidium bromide and UV light; after only 2 minutes of exposure, the number of transformants was nearly zero. In contrast, the transformation

NOTE 8.1

SYBR® Safe DNA Gel Stain

SYBR® Safe stain tests negative in standardized mammalian cell tests for genotoxicity. Certified testing has shown that SYBR® Safe DNA gel stain does not induce transformations in primary cultures of Syrian hamster embryo (SHE) cells when compared with solvent alone (Table 1). This test has a high concordance (>80%) with rodent carcinogenesis assays;¹ thus, a negative test strongly indicates that the SYBR® Safe stain is noncarcinogenic. In contrast, ethidium bromide tests positive in the SHE cell assay,² consistent with its known activity as a strong mutagen.

In addition, SYBR® Safe stain does not cause mutations in mouse lymphoma cells at the TK locus, nor does it induce chromosomal aberrations in cultured human peripheral blood lymphocytes, with or without S9 metabolic activation, using standardized tests with appropriate controls (Table 1).

- SYBR® Safe stain is less mutagenic than ethidium bromide in the standard Ames test.
- Compared with ethidium bromide, SYBR® Safe DNA gel stain causes fewer mutations in the Ames test, as measured in several different strains of *Salmonella typhimurium*. Weakly positive results for SYBR® Safe stain in this test occurred in four out of seven strains and only with activation by a mammalian S9 fraction (Figure 1).
- SYBR® Safe stain is not classified as hazardous waste.
- SYBR® Safe DNA gel stain has been extensively tested for environmental safety. According to the test results (Table 2), this stain is not classified as hazardous waste under U.S. Federal regulations (Resource Conservation and Recovery Act (RCRA)). Contact your safety officer for proper disposal procedures.

Figure 1 Summary of Ames test results for mutagenicity of SYBR® Safe DNA gel stain and ethidium bromide. Samples were pretreated with a mammalian S9 fraction and then tested using the indicated test strain. With strains TA97a, TA98, TA100 and TA102, an increase in revertants of more than 2-fold over background is a positive result for mutagenicity in this test. With strains TA1535, TA1537 and TA1538, an increase in revertants of more than 3-fold over background is a positive result. All tests were performed by Covance Laboratories, Inc., Vienna, VA, an independent testing laboratory.

1. Toxicol Sci (2001) 60:28; 2. Mutat Res (1999) 439:37.

Table 1 Summary of mammalian cell test results for SYBR® Safe DNA gel stain.

Test *	Cell Type	With S9 Activation †	Without S9 Activation
Transformation	Syrian hamster embryo (SHE) cells	NA	Negative
Chromosomal aberrations	Cultured human peripheral blood lymphocytes	Negative	Negative
Forward mutation	L5178YTK+/- mouse lymphoma cells	Negative	Negative

* All tests were performed by Covance Laboratories Inc., Vienna, VA, an independent testing laboratory. † Mammalian S9 fraction obtained from Aroclor 1254-induced rat liver. NA = Not applicable.

Table 2 Environmental safety test results.

Analysis *	Method	Results
Ignitability	EPA 1010	Not ignitable (>212°F)
Corrosivity	EPA 150.1	Not corrosive (pH = 8.25)
Reactivity	EPA 9010B/9030A	No reactivity detected
Corrosivity (by Corrositex®)	DOT-E 10904	Category 2 noncorrosive
Aquatic toxicity	Fathead minnow CA Title 22 acute screening	Not classified as hazardous or toxic to aquatic life

* All tests were independently confirmed by AMEC Earth and Environmental San Diego Bioassay Laboratory, San Diego, CA.

efficiency attained using SYBR® Safe stain and blue light remained at virtually 100% of the control value throughout the entire 16-minute time course of the experiment.

SYBR® Safe DNA gel stain is supplied ready-to-use in two different sizes and in two different buffers. The 1 L unit size in 0.5X TBE or 1X TAE (S33100, S33111) provides sufficient reagent to stain ~20 minigels; the 4 L unit size in 0.5X TBE or 1X TAE (S33101, S33112) provides sufficient reagent to stain ~80 minigels and is supplied in a cube-shaped container with a removable spigot. We also offer a 400 µL unit size of 10,000X concentrate in DMSO (S33102). SYBR® Safe DNA Gel Stain Starter Kit (S33110) is a convenient packaging of the 1 L unit size of SYBR® Safe stain in 0.5X TBE plus one SYBR® Safe photographic filter (S37100).

Ethidium Bromide

Ethidium bromide (EtBr, 15585-011) is the most commonly used dye for DNA and RNA detection in gels.³ It binds to single-, double- and triple-stranded DNA.^{53–55} Ethidium bromide has also been used to detect protein–DNA complex formation in bandshift assays⁵⁶ and to observe single DNA molecules undergoing gel electrophoresis.^{57,58} We offer a 10 mg/mL aqueous solution of ethidium bromide (15585-011), which can be used as provided or diluted to the desired concentration.

Cyanine Monomers for Staining DNA in Electrophoretic Gels

Although SYBR® dyes are now the preferred gel stains, at least six of the monomeric cyanine dyes—TO-PRO®-1, YO-PRO®-1, BO-PRO®-1, PO-PRO®-1, JO-PRO®-1 and LO-PRO®-1 (Section 8.1, Table 8.2)—are also sensitive reagents for staining gels after electrophoresis and are compatible with UV trans- or epi-illumination or with laser-excited gel scanners. Their range of absorption maxima may make them superior to SYBR® dyes when using some lasers as excitation sources. We have determined that the limit of detection of dsDNA with some of these dyes is about 60 pg/band, using 254 nm epi-illumination and Polaroid® 667 black-and-white print film photography.

Our TO-PRO®-3 dye (T3605) can detect less than 0.1 ng/band DNA in an ultrathin-layer agarose gel-based electrophoretogram when excited by an inexpensive 640 nm red diode laser.⁵⁹ Preloading of the gel buffer with the TO-PRO®-3 dye has been recommended for this application when analyzing migrating allele-specific PCR fragments.^{60,61}

Cyanine and Ethidium Dimers for Staining DNA Prior to Electrophoresis

The extraordinary stability of the nucleic acid complexes formed with our dimeric cyanine dyes or ethidium homodimers^{62–64} (Table 8.2) allows the dye–DNA association to remain stable during electrophoresis. Thus, samples can be prestained with subsaturating nanomolar dye concentrations before electrophoresis^{65,66} (Figure 8.4.14), thereby reducing the hazards inherent in handling large volumes of ethidium bromide staining solutions.^{63,67} The fluorescence intensities of both the EthD-1–DNA and TOTO®-1–DNA complexes are directly proportional to the amount of DNA in a band; however, TOTO®-1 dye staining has less effect on the electrophoretic mobility of DNA fragments than does EthD-1. Furthermore, unlike EthD-1-labeled DNA, in which up to two-thirds of the bound dye can be transferred to excess unlabeled DNA, the extent of transfer of TOTO®-1 dye to unlabeled DNA is reported to be only about 15–20%, even when the TOTO®-1–DNA complexes are incubated for up to 10 hours with a 100-fold excess of uncomplexed dsDNA.^{62,68,69} This property is valuable for multiplexed electrophoretic separations,⁶² especially because our cyanine nucleic acid stains are available in so many visually distinct colors. If two DNA populations are stained with spectrally distinct cyanine dimer dyes and run in the same lane, simultaneous two-color detection can potentially eliminate errors caused by lane-to-lane variations in electrophoretic mobility. Binding of the TOTO®-1 dye (T3600), YOYO®-1 dye (Y3601) and ethidium homodimer-1 (E1169) to DNA initially results in inhomogeneous binding that yields double bands in DNA gel electrophoresis.⁷⁰ These double bands can be avoided by incubating complexes for times long enough to allow binding to come to equilibrium or by heating samples to 50°C for at least two hours. Binding of our other dimeric nucleic acid stains (Table 8.2) to DNA does not seem to give this problem.

An extremely sensitive confocal laser-based gel scanner has been exploited in multiplexed electrophoretic separations to detect as little as four picograms per band of TOTO®-1 dye- and YOYO®-1 dye-stained dsDNA;^{62,66,69,71} although sophisticated equipment is required for achieving these low detection limits, such equipment is not essential for detecting somewhat larger

Figure 8.4.13 DNA fragments were electrophoresed through an agarose gel, then stained with SYBR® Safe DNA gel stain (S33100, S33101, S33110).

Figure 8.4.14 Lambda bacteriophage *Hind*III fragments were prestained with various nucleic acid dyes, run on a 0.7% agarose gel and visualized using a standard 300 nm UV transilluminator. From left to right, the dyes used were: POPO™-1 (P3580), BOBO™-1 (B3582), YOYO®-1 (Y3601), TOTO®-1 (T3600), JOJO™-1 (J11372), POPO™-3 (P3584), LOLO™-1 (L11376), BOBO™-3 (B3586), YOYO®-3 (Y3606) and TOTO®-3 (T3604) nucleic acid stains. The longest-wavelength stains are barely visible to the eye but can be detected with infrared-enhanced films and imaging equipment.

quantities of these nucleic acid–dye complexes. TOTO[®]-1 dye has been used to label DNA prior to electrophoresis in order to detect cystic fibrosis mutant alleles with a laser-excited fluorescence gel scanner,⁷² as well as to detect DNA amplification products on agarose gels with standard UV transillumination.⁷³ TOTO[®]-1 dye has also been used to label nine DNA fragments of the dystrophin gene that were simultaneously generated using the polymerase chain reaction.⁷⁴ The resolution obtained by gel electrophoresis of these labeled fragments compared favorably to that observed using fluorophore-labeled primers. TOTO[®]-3 and POPO[™]-1 dyes (T3604, P3580; Section 8.1) have been similarly used to analyze DNA with a xenon lamp–based luminescence analyzer.⁷⁵

Ethidium homodimer-1 (EthD-1, E1169) has been used for fluorescence detection of 30–60 picograms DNA per band on polyacrylamide gels using a confocal laser–based scanning system.^{63,67} Ethidium homodimer-2 (EthD-2, E3599), which has a higher affinity for nucleic acids than does ethidium homodimer-1, may also be useful for this application.

Electrophoretic Mobility-Shift (Bandshift) Assay (EMSA) Kit

The Electrophoretic Mobility-Shift Assay (EMSA) Kit (E33075) provides a fast and quantitative fluorescence-based method to detect both nucleic acids and proteins in the same gel (Figure 8.4.15), doubling the information that can be obtained from bandshift assays.¹⁹ This kit uses two fluorescent dyes for detection—SYBR[®] Green EMSA nucleic acid gel stain for RNA or DNA and SYPRO[®] Ruby EMSA protein gel stain for proteins. Because the nucleic acids and proteins are stained in the gel after electrophoresis, there is no need to prelabel the DNA or RNA with a radioisotope, biotin or a fluorescent dye before the binding reaction, and therefore there is no possibility that the label will interfere with protein binding. Staining takes only about 20 minutes for the nucleic acid stain, and about 4 hours for the subsequent protein stain, yielding results much faster than radioisotope labeling (which may require multiple exposure times) or chemiluminescence-based detection (which requires blotting and multiple incubation steps).

This kit also makes it possible to perform ratiometric measurements of nucleic acid and protein in the same band, providing more detailed information on the binding interaction. The signals from the two stains are linear over a broad range, allowing accurate determination of the amount of nucleic acid and protein, even in a single band, with detection limits of ~1 ng for nucleic acids and ~20 ng for proteins. Both stains can be detected using a standard 300 nm UV illuminator, a 254 nm

Figure 8.4.15 Titration of lac operator DNA with lac repressor protein. Increasing amounts of lac repressor protein were mixed with 40 ng of lac operator DNA, incubated for 20 minutes and then separated on a 6% nondenaturing polyacrylamide gel. The gel was stained with SYBR[®] Green EMSA stain (green) followed by SYPRO[®] Ruby EMSA stain (red), components of the Electrophoretic Mobility-Shift Assay Kit (E33075). After each staining, the image was documented using an FLA-3000 laser-based scanner (Fuji[®]) and the digital images pseudocolored and overlaid. Yellow bands indicate areas stained with both stains.

epi-illuminator or a laser scanner (Figure 8.4.15). Digital images can easily be overlaid for a two-color representation of nucleic acid and protein in the gel. The EMSA Kit contains sufficient reagents for 10 nondenaturing polyacrylamide minigel assays, including:

- SYBR[®] Green EMSA nucleic acid gel stain
- SYPRO[®] Ruby EMSA protein gel stain
- Trichloroacetic acid, for preparing the working solution of SYPRO[®] Ruby EMSA protein gel stain
- Concentrated EMSA gel-loading solution
- Concentrated binding buffer
- Detailed protocols

Other Nucleic Acid Stains for Gel-Staining Applications

DAPI (D1306, D3571, D21490; Section 8.1) reportedly provides a significantly more sensitive means of detecting dsDNA in agarose gels than ethidium bromide.⁷⁶ Selective detection of dsDNA in the presence of dsRNA in gels with DAPI has been reported.⁷⁷ Likewise, the Hoechst 33258 and Hoechst 33342 dyes (Section 8.1) have been used to detect DNA in the presence of RNA in agarose gels.⁷⁸ DNA conformational changes during gel electrophoresis have been investigated with acridine orange^{79,80} (A1301, A3568; Section 8.1).

Safe Imager[™] Blue-Light Transilluminator

The Safe Imager[™] 2.0 blue-light transilluminator (G6600) is a blue-light transilluminator designed for viewing stained gels on the laboratory bench top. Light from the LED source inside the transilluminator passes through a blue filter, producing light with a narrow emission peak centered at approximately 470 nm. This 470 nm transillumination is effective for the excitation of the SYBR[®] Safe DNA gel stain, as well as many of our other nucleic acid and protein stains such as the SYBR[®] Gold, SYBR[®] Green I and SYBR[®] Green II nucleic acid stains and the SYPRO[®] Ruby, SYPRO[®] Orange, Coomassie Fluor[™] Orange and Pro-Q[®] Diamond protein stains. Sensitivity obtained using this instrument is comparable to that obtained with a standard UV transilluminator. Unlike UV transilluminators, however, the Safe Imager[™] blue-light transilluminator does not produce UV light and therefore does not require UV-protective equipment during use. Moreover, as compared to UV transillumination, blue-light transillumination results in dramatically increased cloning efficiencies.

The Safe Imager[™] 2.0 blue-light transilluminator is supplied with viewing glasses (S37103), amber filter (G6601) and an international power cord (G6602), each of which is also available separately. The Safe Imager[™] viewing glasses allow the user to visualize gel bands on the Safe Imager[™] transilluminator without the use of the Safe Imager[™] amber filter, thereby facilitating band excision.

SYBR[®] Photographic Filters

We offer a number of fluorescent reagents for staining nucleic acids and proteins in gels and on blots. Preeminent among these stains are our SYBR[®] Gold, SYBR[®] Green and SYBR[®] Safe nucleic acid gel stains (Section 8.4) and our SYPRO[®] protein stains for gels and blots (Section 9.3). To achieve optimal sensitivity with these exceptional fluorescent dyes, it is *essential* to photograph the gel or blot because the camera's

integrating capability can make bands visible that are not detected by eye. Photographs should be taken using a photographic filter with spectral properties closely matched to those of the fluorescent dye used. We offer 75 mm × 75 mm gelatin filters (Figure 8.4.16) optimized for photographing stained gels or blots with a Polaroid® camera and Polaroid® 667 black-and-white print film. Note that these gelatin filters are generally not suitable for use with portable or stationary gel-documentation systems or with CCD cameras.

SYBR® Photographic Filter

To achieve optimal sensitivity using Polaroid® 667 black-and-white print film and UV illumination, DNA or RNA gels stained with SYBR® Gold, SYBR® Green I and SYBR® Green II nucleic acid gel stains should be photographed through the SYBR® photographic filter (S7569, Figure 8.4.17).

SYBR® Safe Photographic Filter

The SYBR® Safe photographic filter (S37100) is ideal for black-and-white photography of gels stained with the SYBR® Safe DNA gel stain. Note that the SYBR® Safe photographic filter is identical to the SYPRO® photographic filter (Figure 8.4.18).

Figure 8.4.16 Molecular Probes® 75 mm × 75 mm gelatin photographic filters for use with Polaroid® black-and-white print film photography.

Capillary Electrophoresis and Channel Electrophoresis

Capillary Electrophoresis

Capillary gel electrophoresis (CGE) performs separations of nucleic acids in a manner analogous to standard slab-gel electrophoresis, but with the advantages of faster run times, higher resolution and greater sensitivity. The use of on-line detection by laser-induced fluorescence (LIF) increases the sensitivity by several orders of magnitude over UV detection, eliminates the time spent staining and photographing the gel and allows for the possibility of automated sample processing. CGE-LIF is widely used for the separation and identification of DNA fragments and has increased the efficiency of DNA typing and forensics analyses.^{81,82} Researchers are using several of our high-sensitivity nucleic acid stains with CGE for resolving similar-length DNA fragments.⁸³

In CGE applications, the nucleic acid stain can be chosen to match available laser excitation sources;⁸⁴⁻⁸⁹ furthermore, multiple dyes can be used to prestain samples, which can then be used for multiplexed capillary electrophoresis.⁹⁰

- SYBR® Green I nucleic acid gel stain exhibits a large linear detection range and high resolution of DNA fragments from 100 to 1000 base pairs in length. A clinically applicable high-throughput screen was developed using SYBR® Green I stain to detect mutations in the methylenetetrahydrofolate reductase gene.^{91,92}
- SYBR® Gold stain has sufficient sensitivity to detect electrophoretically separated nucleic acids from single cells.⁹³
- Quant-iT™ OliGreen® ssDNA reagent (O7582, O11492; Section 8.3) has been employed to detect short single-stranded oligonucleotides using CGE with laser-induced fluorescence detection; formation of the fluorescent oligonucleotide complexes is accomplished on the column.⁹⁴
- Both TOTO®-1 dye (T3600) and ethidium bromide (15585-011) have been used with capillary array electrophoresis for high-speed, high-throughput parallel separation of DNA fragments.^{95,96}
- YOYO®-1 dye (Y3601) has been used with CGE to quantitate DNA complexes in polymerase chain reaction (PCR) mixtures.^{84,97}
- Hepatitis B viral fragments have been detected by incorporation of submicromolar concentrations of either POPO™-3 dye (P3584) or ethidium homodimer-2 (E3599) in the detection buffer.⁹⁸ Sensitivity was as great as 3.9×10^{-16} M (390 attomolar) and increased with fragment length.
- YO-PRO®-1 dye (Y3603) has been used to develop a more rapid screening technique for identifying hypervariable regions in mitochondrial DNA. RFLP fragments were generated after PCR amplification and detected in CGE-LIF.⁹⁹ Automated CGE-LIF with the YO-PRO®-1 dye made it possible to replace time-consuming slab gel methods of analyzing variable number of tandem repeats (VNTR) in DNA typing labs.¹⁰⁰⁻¹⁰² YO-PRO®-3 dye (T3605) has proven useful for identifying single-sequence-repeat polymorphisms with high accuracy, using as little as 80 zeptomoles of sample DNA.¹⁰³

Figure 8.4.17 Transmittance profile of the SYBR® photographic filter (S7569).

Figure 8.4.18 Transmittance profile of the SYBR® Safe photographic filter (S37100) and the SYPRO® photographic filter (S6656), which are identical.

- CGE using ethidium bromide, SYBR® Green I or SYBR® Gold stain has been used in single-nucleotide polymorphism (SNP) analysis, making it possible to analyze as many as 96 samples in parallel.^{104,105}
- CGE-LIF has been used for short tandem repeat (STR) genotyping using nucleic acids stained by an on-column labeling technique with either TO-PRO®-1, YO-PRO®-1, TOTO®-1 or YOYO®-1.¹⁰⁶
- YO-PRO®-1 dye and ethidium bromide have both been used in heteroduplex analysis (HDA) by CGE.¹⁰⁷
- The use of CGE-LIF with the YO-PRO®-1 dye makes it possible to accurately quantitate RNA transcripts from competitive RT-PCR.¹⁰⁸ CGE-LIF with the YO-PRO®-1 dye can also detect fragmented DNA from apoptotic cells, making it possible to use 1000–2000-fold fewer cells than are needed for ladder detection on conventional slab gels.¹⁰⁹

Figure 8.4.19 DNA microarrays stained with nucleic acid stains for quality control. DNA microarrays were stained with dilutions of SYBR® Green II dye (left, green; S7568, S7564, S7586), POPO™-3 dye (center, orange, P3584) or SYTO® 59 dye (right, magenta, S11341) in aqueous buffer. The microarrays were imaged on a ScanArray® 5000XL microarray scanner (PerkinElmer LAS, Inc.) using the appropriate lasers and filters. Staining reveals the variable amounts of DNA spotted onto the different microarrays.

Figure 8.4.20 Panomer™ 9 oligodeoxynucleotides for quality control of microarray spotting. Three microarrays were made using three different spotting protocols. Each microarray was then hybridized to a Panomer™ 9 oligonucleotide, conjugated with either the Alexa Fluor® 488 dye (top) or the Alexa Fluor® 546 dye (middle and bottom), washed and imaged using a ScanArray® 5000XL microarray scanner (PerkinElmer LAS, Inc.). One representative spot from each slide was selected for comparison purposes. The spots were analyzed using Metamorph software (Universal Imaging, Inc.), and the data is presented as a three-dimensional graph with high-intensity areas as peaks and low-intensity areas as valleys. For further clarification, the graphs are color coded so that the highest intensity areas are red and the lowest intensity areas are blue. The comparison shows that the Panomer™ 9 oligodeoxynucleotides are ideal for microanalysis of spot morphology on DNA microarrays.

- Using POPO™-3 dye (P3584) or ethidium homodimer-2, researchers have been able to detect as little as 3.9×10^{-13} M duck hepatitis B virus.¹¹⁰

As an alternative to using nucleic acid stains for CGE, amine- or thiol-derivatized oligonucleotides can be chemically derivatized pre- or post-separation with many of the dyes described in Chapter 1 and Chapter 2. The thiol-reactive Alexa Fluor®, BODIPY®, fluorescein and Oregon Green® dyes are particularly suitable for labeling thiolated oligonucleotides and for applications that use ultrasensitive laser-scanning techniques.¹¹¹ Several papers have been published on the separation of fluorescent oligonucleotides by capillary electrophoresis.¹¹²

Channel Electrophoresis

Similar in concept to capillary electrophoresis, channel electrophoresis on microchips has the potential to provide even higher throughput by using completely automated nucleic acid analysis. Our intensely fluorescent nucleic acid dyes make sensitive on-line detection possible. SYBR® Green I dye was used to detect amplified DNA on a nanoliter device that mixes DNA samples, amplifies DNA fragments and separates the products in a channel for on-line detection.¹¹³ TO-PRO®-1 dye (T3602) was used to detect DNA fragments from bacterial DNA that had been extracted, amplified and separated in channels on the same microchip.¹¹⁴ YOYO®-1 dye (Y3601) has been used to detect as little as a few zeptomoles (10^{-21} mole) of DNA fragments on a chip device,¹¹⁵ and YO-PRO®-1 dye (Y3603) made it possible to distinguish triplet repeat DNA fragments in a 6 mm channel in only 12 seconds.¹¹⁶ A novel radial microchip device simultaneously separates 96 DNA samples pre-stained with YOYO®-1 dye.¹¹⁷ The TO-PRO®-3 dye has been used to detect DNA in a polycarbonate channel electrophoresis device.¹¹⁸ Fluorescence-based sequencing using dye-labeled primers (see above) in capillary electrophoresis chips allowed sequencing of ~200 bases in as little as 10 minutes.¹¹⁹

Quality Control Testing on Microarrays and Blots

Whether using northern blots, macroarrays on membranes or microarrays on glass slides, it is important to normalize the signal to the amount of nucleic acid on the solid support. Differences in purification, loading and transfer may create differences in RNA levels on blots and, even with sophisticated robotics, direct spotting techniques for creating arrays of nucleic acids on solid supports vary widely in reproducibility (Figure 8.4.19, Figure 8.4.20). A method to qualitatively determine the amount of nucleic acid on a support is desirable for quality control purposes. Quantitative data that can be used for signal normalization is even more useful, making it possible to validate perceived changes in RNA expression between samples, despite differences in the nucleic acid levels on the solid support. Often, hybridization of a "constitutively expressed" RNA sequence is used for normalization on northern blots. However, it is sometimes discovered that the level of such RNA sequences is not constant through changing physiological states of a cell or tissue. Direct measurement of the levels of nucleic acid spotted on the slide provides a reliable method for normalization and can also be used to assess the amount of nucleic acid remaining on a support after stripping off a probe and before reusing the blot or array.

In addition to providing a means of normalizing hybridization signals, staining denatured DNA or RNA directly on filter membranes after blotting protocols provides for more accurate comparison of the sample

to molecular weight markers and eliminates guesswork about transfer efficiency. However, direct staining on blotting membranes has not been widely used because the most common methods for detecting denatured DNA or RNA—ethidium bromide¹²⁰ or methylene blue staining—give rise to high background fluorescence. Silver staining or gold staining followed by silver enhancement provides 10- to 100-fold better sensitivity than ethidium bromide but is expensive, time-consuming and tedious. Also, because of the affinity of gold for sulfur, only agarose gels containing less than 0.1% sulfate are suitable for use with gold staining; higher amounts of sulfate invariably result in unacceptably high background signals.

Nucleic Acid Stains for Standardizing Microarrays

The simplest technique for comparing the amounts of DNA spotted onto arrays is to use a fluorescent nucleic acid stain. Molecular Probes® nucleic acid stains exhibit a strong fluorescence signal when bound to nucleic acids, providing an easy and effective method for measuring the amount of nucleic acids on solid supports (Figure 8.4.19). Nucleic acid stains that have been used effectively for microarrays include:

- POPO™-3 dye (P3584)
- SYBR® Green II RNA stain (S7568, S7564, S7586)
- SYTO® 59 dye (S11341, Section 8.1)

Other dyes in these families (Section 8.1) should also prove useful in this application. When staining nucleic acids on solid supports with nucleic acid stains, it is important to choose a dye that matches the light

Figure 8.4.21 DNA microarray hybridized to Panomer™ 9 random oligodeoxynucleotides. A DNA microarray slide was hybridized sequentially with one of three different Panomer™ 9 random oligodeoxynucleotides at room temperature for two minutes. After each hybridization, the slide was washed first in 2X SSC and 0.2% SDS and then in 1X SSC. After drying, the slide was imaged on a ScanArray® 5000XL microarray reader (PerkinElmer LAS, Inc.), using appropriate lasers and filter sets. After imaging, the Panomer™ 9 oligodeoxynucleotide was stripped from the microarray by incubation in deionized water for one minute at room temperature and the microarray was hybridized to another Panomer™ 9 oligodeoxynucleotide. From left to right, the images show the array hybridized to Panomer™ 9 oligodeoxynucleotides labeled with Alexa Fluor® 488 dye (P21680), Alexa Fluor® 546 dye (P21681) and Alexa Fluor® 647 dye (P21686). Each image has been pseudocolored to indicate the different dyes. The hybridization results reveal the variable amounts of DNA spotted onto this microarray.

sources and filter sets available in the image analysis system or the array reader. For example, the POPO™-3 dye has a maximum fluorescence excitation at 534 nm and a maximum fluorescence emission at 570 nm, which is compatible with filter sets for the Alexa Fluor® 546 dye, Alexa Fluor® 555 dye or Cy®3 dyes. In one case in which POPO™-3 staining was used to determine the number of spots on the microarray that contained PCR products, 1281 of 9216 spots did not display a significant POPO™-3 signal due to poor growth of the bacterial clones, failure of the PCR amplification or improper printing of the spots due to irregularities on the array.¹²¹ When testing dyes to use for normalization of signals, it is important to carefully test several dilutions of the dye to determine the one that gives the best linear response over the range of DNA in the spot. It is also important to determine any effects of the dye on subsequent hybridization.

Panomer™ Random-Sequence Oligonucleotides

Fluorescently labeled random-sequence oligonucleotides—such as the Panomer™ 9 random oligodeoxynucleotides—provide an alternative method for assessing the level of nucleic acids immobilized on solid supports:

- Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 488 conjugate (P21680)
- Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 546 conjugate (P21681)
- Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 555 conjugate (P21687)
- Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 647 conjugate (P21686)

This method assays the capability of spotted DNA to hybridize, making it possible to determine if hybridization efficiency varies across the array¹²² (Figure 8.4.21). These nine-base, random-sequence Panomer™ oligodeoxynucleotides are covalently labeled on the 5'-end with a fluorescent dye. The variety of available fluorescent dyes makes it possible to use any fluorescence channel of interest and to compare relative signal intensities per spot in several different channels (Figure 8.4.22). It is also possible to use Panomer™ 9 oligodeoxynucleotides for quality control of spotting techniques or to assay the stability of DNA spots after the array is subjected to washing, boiling, hybridization or other conditions (Figure 8.4.21).

Figure 8.4.22 Microarray spotted with Panomer™ 9 oligodeoxynucleotides labeled with Alexa Fluor® 546 dye (P21681) and Alexa Fluor® 647 dye (P21686). Equal amounts of two Panomer™ 9 random oligodeoxyribonucleotides were spotted directly onto microscope slides and the fluorescence documented using two different channels (left and right panels) of a ScanArray® 5000XL microarray reader (PerkinElmer LAS, Inc.). The Alexa Fluor® 546 Panomer™ 9 random oligodeoxyribonucleotide signal (left panel) was completely separated from the Alexa Fluor® 647 Panomer™ 9 random oligodeoxyribonucleotide signal (right panel).

PRODUCT LIST 8.4 NUCLEIC ACID DETECTION ON GELS, BLOTS AND ARRAYS

Cat. No.	Product	Quantity
E33075	Electrophoretic Mobility-Shift Assay (EMSA) Kit *with SYBR® Green and SYPRO® Ruby EMSA stains* *10 minigel assays*	1 kit
E1169	ethidium homodimer-1 (EthD-1)	1 mg
E3599	ethidium homodimer-2 (EthD-2) *1 mM solution in DMSO*	200 µL
P21680	Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 488 conjugate	10 nmol
P21681	Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 546 conjugate	10 nmol
P21687	Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 555 conjugate	10 nmol
P21686	Panomer™ 9 random oligodeoxynucleotide, Alexa Fluor® 647 conjugate	10 nmol
P3584	POPO™-3 iodide (534/570) *1 mM solution in DMF*	200 µL
S37102	Safe Imager™ blue-light transilluminator	each
S37104	Safe Imager™ international power cord *replacement*	each
S37103	Safe Imager™ viewing glasses	each
S11494	SYBR® Gold nucleic acid gel stain *10,000X concentrate in DMSO*	500 µL
S7563	SYBR® Green I nucleic acid gel stain *10,000X concentrate in DMSO*	500 µL
S7567	SYBR® Green I nucleic acid gel stain *10,000X concentrate in DMSO*	1 mL
S7585	SYBR® Green I nucleic acid gel stain *10,000X concentrate in DMSO* *special packaging*	20 x 50 µL
S7564	SYBR® Green II RNA gel stain *10,000X concentrate in DMSO*	500 µL
S7568	SYBR® Green II RNA gel stain *10,000X concentrate in DMSO*	1 mL
S7586	SYBR® Green II RNA gel stain *10,000X concentrate in DMSO* *special packaging*	20 x 50 µL
S7580	SYBR® Green Nucleic Acid Gel Stain Starter Kit	1 kit
S7569	SYBR® photographic filter	each
S33102	SYBR® Safe DNA gel stain *10,000X concentrate in DMSO*	400 µL
S33100	SYBR® Safe DNA gel stain in 0.5X TBE	1 L
S33101	SYBR® Safe DNA gel stain in 0.5X TBE	4 L
S33111	SYBR® Safe DNA gel stain in 1X TAE	1 L
S33112	SYBR® Safe DNA gel stain in 1X TAE	4 L
S33110	SYBR® Safe DNA Gel Stain Starter Kit *with 1 L of SYBR® Safe DNA gel stain in 0.5X TBE (S33100) and one photographic filter (S37100)*	1 kit
S37100	SYBR® Safe photographic filter	each
T3602	TO-PRO®-1 iodide (515/531) *1 mM solution in DMSO*	1 mL
T3605	TO-PRO®-3 iodide (642/661) *1 mM solution in DMSO*	1 mL
T3600	TOTO®-1 iodide (514/533) *1 mM solution in DMSO*	200 µL
T3604	TOTO®-3 iodide (642/660) *1 mM solution in DMSO*	200 µL
15585-011	UltraPure™ Ethidium Bromide *10 mg/ml*	10 mL
Y3603	YO-PRO®-1 iodide (491/509) *1 mM solution in DMSO*	1 mL
Y3601	YOYO®-1 iodide (491/509) *1 mM solution in DMSO*	200 µL

9.1 Introduction to Protein Detection

Proteomics: A Rapidly Developing Field

For decades, polyacrylamide gel electrophoresis and related blotting techniques have formed the core technologies for protein analysis. Traditionally, these technologies have been paired with chromogenic dye-based protein detection techniques, such as silver or Coomassie brilliant blue staining. With the rapid growth of proteomics,^{1,2} however, the limitations and experimental disadvantages of absorption-based detection technologies and labor-intensive silver staining techniques have become glaringly apparent. The field of proteomics requires new, highly quantitative electrophoresis and blotting techniques that can interface seamlessly with improved microanalysis methods and that can perform in an increasingly high-throughput environment. These requirements are particularly important for quantitative proteomics and multiplexing techniques.

Fluorescence- or luminescence-based detection technologies offer the opportunity for multicolor labeling, making multiplexed analysis possible (Figure 9.1.1). In particular, Molecular Probes® fluorescent and luminescent protein stains enable the identification of specific protein modifications (for example, phosphorylation, glycosylation and epitope tags) within the context of the entire protein profile. Simultaneous measurement of several variables greatly increases the amount of data that can be collected in a single experiment. In addition, directly comparing multiple measurements leads to more controlled experiments, more accurate data and fewer ambiguities. The detection characteristics of our protein stains greatly streamline protocols for proteome analysis and promise to bring to proteomics the same capability for rapid, large-scale data acquisition that fluorescence has brought to genomics and other fields.

Molecular Probes® Detection Technology for Proteomics

We are meeting the demands of the rapidly expanding field of proteomics through the development of fluorescence- and luminescence-based detection methods for proteins in solutions and on gels, blots and microarrays. We are continuing to develop new reagents and detection methods for proteins and their modifications, such as phosphorylation, glycosylation and epitope tags, as well as improved methods of separating and analyzing peptides and proteins. Our advanced technologies are compatible with modern needs for sensitivity, specificity, sequencing compatibility and automatability. Application of our unique detection reagents requires minimal investment in labor, as compared with older technologies, while significantly increasing throughput, reducing total cost and improving accuracy. Furthermore, the greater sensitivity and linearity of most of our premier reagents makes it possible to do quantitative proteomics and perform comparative protein expression measurements on very small samples.

In this chapter, Section 9.2 includes Molecular Probes® reagents and kits (including the Quant-iT™, NanoOrange®, CBQCA and EZQ® reagents) for quantitating total protein in solution. Section 9.3 includes the important SYPRO® stains for detecting and quantitating total

protein on gels and blots. Reagents for the qualitative and quantitative detection of phosphorylation, glycosylation and other post-translational modifications are described in Section 9.4 and include:

- Click-iT® reagents for detecting nascent protein synthesis, as well as post-translational modifications
- Pro-Q® Diamond phosphoprotein gel and blot stains—a breakthrough technology for selectively detecting phosphoproteins in gels and on blots
- Pro-Q® Emerald 300 and Pro-Q® Emerald 488 glycoprotein gel and blot stains—effective and easy-to-use stains for detecting periodate-oxidized glycoproteins in gels and on blots

Section 9.5 describes reagents used in the synthesis of fluorophore- or hapten-labeled peptides and fluorogenic protease substrates, as well as in peptide analysis and sequencing.

Figure 9.1.1 Two-dimensional protein gels of tumor versus normal cells stained for glycoproteins and total proteins. Lysates from rat liver tumor cells (top panels) or rat normal liver cells (bottom panels) were run on identical 2D gels. Following electrophoresis, the gels were stained with the Pro-Q® Emerald 300 glycoprotein detection reagent (left panels) (available in the Pro-Q® Emerald 300 Kits P21855 and P21857). After documentation of the fluorescence signal, the gel was stained with the SYPRO® Ruby protein gel stain (right panels) (S12000, S12001, S21900).

9.2 Protein Quantitation in Solution

Several colorimetric methods have been described for quantitating proteins in solution, including the widely used Bradford, Lowry and BCA (bicinchoninic acid) assays (Table 9.1). Because they rely on absorption-based measurements, however, these methods are inherently limited in both sensitivity and effective range. We have developed four unique fluorometric methods for quantitating proteins in solution—the Quant-iT™ Protein Assay Kit (Q33210), the

NanoOrange® Protein Quantitation Kit (N6666), the CBQCA Protein Quantitation Kit (C6667) and the EZQ® Protein Quantitation Kit (R33200)—that outperform these conventional methods (Table 9.1). We also offer the Qubit® fluorometer (Q32857), which is designed to work seamlessly with the Quant-iT™ Assay Kits, as well as several other fluorescent reagents useful for protein detection in solution.

Table 9.1 A comparison of reagents for detecting and quantitating proteins in solution.

Assay	Detection Wavelength(s) (nm) *	Sensitivity and Effective Range	Mechanism of Action	Notes
Quant-iT™ protein quantitation assay (Q33210, Q33211, Q33212)	470/570	Quasi-linear from 0.5 to 4 µg in a 200 µL assay volume, with a sample volume of 1–20 µL	Binds to detergent coating on proteins and hydrophobic regions of proteins; the unbound dye is nonfluorescent	<ul style="list-style-type: none"> Extremely fast and easy—just add sample to diluted dye and read fluorescence High sensitivity Little protein-to-protein variation Compatible with salts, solvents, 2-mercaptoethanol, amino acids and DNA, but not detergents
NanoOrange® protein quantitation assay (N6666)	470/570	10 ng/mL to 10 µg/mL	Binds to detergent coating on proteins and hydrophobic regions of proteins; the unbound dye is nonfluorescent	<ul style="list-style-type: none"> High sensitivity Little protein-to-protein variation Rapid assay with a simple procedure Compatible with reducing agents, but not detergents
CBQCA protein quantitation assay (C6667)	450/550	10 ng/mL to 150 µg/mL	Reacts with primary amine groups on proteins in the presence of cyanide or thiols; the unreacted dye is nonfluorescent	<ul style="list-style-type: none"> High sensitivity Sensitivity depends on the number of amines present Linear over an extended range of protein concentration Compatible with detergents and lipophilic proteins Not compatible with buffers containing amines or thiols
EZQ® protein quantitation assay (R33200)	280 and 450/618	50 µg/mL to 5 mg/mL, with a sample volume of 1 µL	Binds electrostatically to basic amino acids, supplemented by additional hydrophobic interactions	<ul style="list-style-type: none"> Ideal for determining protein concentration prior to electrophoresis Solid-phase format designed for high-throughput analysis Little protein-to-protein variation Compatible with detergents, reducing agents, urea and tracking dyes
Bradford assay ¹ (Coomassie brilliant blue)	595	1 µg/mL to 1.5 mg/mL	Directly binds specific amino acids and protein tertiary structures; the dye's color changes from brown to blue	<ul style="list-style-type: none"> High protein-to-protein variation Not compatible with detergents Rapid assay Useful when accuracy is not crucial
BCA method ² (bicinchoninic acid)	562	0.5 µg/mL to 1.2 mg/mL	Cu ²⁺ is reduced to Cu ⁺ in the presence of proteins at high pH; the BCA reagent chelates Cu ⁺ ions, forming purple-colored complexes	<ul style="list-style-type: none"> Compatible with detergents, chaotropes and organic solvents Not compatible with reducing agents The sample must be read within 10 minutes
Lowry assay ³ (biuret reagent plus Folin–Ciocalteu reagent)	750	1 µg/mL to 1.5 mg/mL	Cu ²⁺ is reduced to Cu ⁺ in the presence of proteins at high pH; the biuret reagent chelates the Cu ⁺ ion, then the Folin–Ciocalteu reagent enhances the blue color	<ul style="list-style-type: none"> Lengthy procedure with carefully timed steps Not compatible with detergents or reducing agents
Fluorescamine ^{4–7} (F2332, F20261)	390/475	0.3 µg/mL to 13 µg/mL	Reacts with primary amine groups on proteins; unbound dye is nonfluorescent	<ul style="list-style-type: none"> Sensitivity depends on the number of amines present Reagent is unstable Not compatible with amine-containing buffers
OPA ^{8–10} (o-phthalaldehyde) (P2331MP)	340/455	0.2 µg/mL to 25 µg/mL	Reacts with primary amine groups on proteins in the presence of 2-mercaptoethanol; unbound dye is nonfluorescent	<ul style="list-style-type: none"> Sensitivity depends on the number of amines present Not compatible with amine-containing buffers Low cost
UV absorption ¹¹	280	10 µg/mL to 50 µg/mL or 50 µg/mL to 2 mg/mL	Peptide bond absorption; tryptophan and tyrosine absorption	<ul style="list-style-type: none"> Sensitivity depends on the number of aromatic amino acid residues present Nondestructive Low cost

* Excitation and emission wavelength maxima or absorption wavelength maximum, in nm.

Quant-iT™ Protein Assay Kits

Overview of the Quant-iT™ Assay Kits

The Quant-iT™ family of assay kits provides state-of-the-art reagents for sensitive and selective quantitation of protein, DNA or RNA (Table 8.8) samples using a standard fluorescence microplate reader (Figure 9.2.1) or the Qubit® fluorometer. These kits have been specially formulated with ready-to-use buffers, prediluted standards and easy-to-follow instructions, to help make quantitation both accurate and extremely easy. Each Quant-iT™ assay is:

- **Ready to use.** Only the dye is diluted in the supplied buffer; no dilution of standards or buffer required.
- **Easy to perform.** Just add the sample to the diluted dye and read the fluorescence.
- **Highly sensitive.** The Quant-iT™ assays are orders of magnitude more sensitive than UV absorbance measurements.
- **Highly selective.** Separate kits are available for quantitating protein, DNA or RNA (Section 8.3), with minimal interference from common contaminants.
- **Precise.** CVs are generally less than 5% for typical users.

The user-friendly Qubit® fluorometer has been designed to work seamlessly with the Quant-iT™ Assay Kits. The combination of the Quant-iT™ Assay Kits and the Qubit® fluorometer produces a completely integrated quantitation platform. Moreover, because the fluorescent dye in each Quant-iT™ Kit matches common fluorescence excitation and emission filter sets in microplate readers, these assay kits are ideal for high-throughput environments, as well as for small numbers of samples.

Quant-iT™ Protein Assay Kits

The Quant-iT™ Protein Assay Kit (Q33210) simplifies protein quantitation without sacrificing sensitivity.¹⁻³ This protein assay exhibits a detection range between 0.25 and 5 µg protein, and the response curve is sigmoidal (quasi-linear from 0.5 to 4 µg) with little protein-to-protein difference in signal intensity (Figure 9.2.2). Common contaminants, including salts, solvents, reducing agents (dithiothreitol, 2-mercaptoethanol), amino acids, nucleotides and DNA, are well tolerated in this assay; however, it is not compatible with detergents; slight modifications in the procedure are required for other contaminants. Each Quant-iT™ Protein Assay Kit contains:

- Quant-iT™ protein reagent
- Quant-iT™ protein buffer
- A set of eight prediluted bovine serum albumin (BSA) standards between 0 and 500 ng/µL
- Easy-to-follow instructions

Sufficient reagents are provided to perform 1000 assays, based on a 200 µL assay volume in a 96-well microplate format; this assay can also be adapted for use in cuvettes or 384-well microplates. The fluorescence signal exhibits excitation/emission maxima of 470/570 nm and is stable for three hours at room temperature. The Quant-iT™ protein reagent is an improved formulation of Molecular Probes® NanoOrange® reagent, which is described below.

We also offer Quant-iT™ Protein Assay Kits specifically designed for use with the Qubit® fluorometer (100-assay size, Q33211; 500-assay size, Q33212). Similar to the general Quant-iT™ Protein Assay Kit described above, these kits provide:

- Quant-iT™ protein reagent
- Quant-iT™ protein buffer
- Three pre-diluted protein standards
- Easy-to-follow instructions

The assay steps are simple: dilute the reagent using the buffer provided, add the sample (any volume between 1 µL and 20 µL is acceptable) and read the concentration using the Qubit® fluorometer. The assay is performed at room temperature, and the signal is stable for 3 hours. This assay is accurate for initial sample concentrations from 12.5 µg/mL to 5 mg/mL.

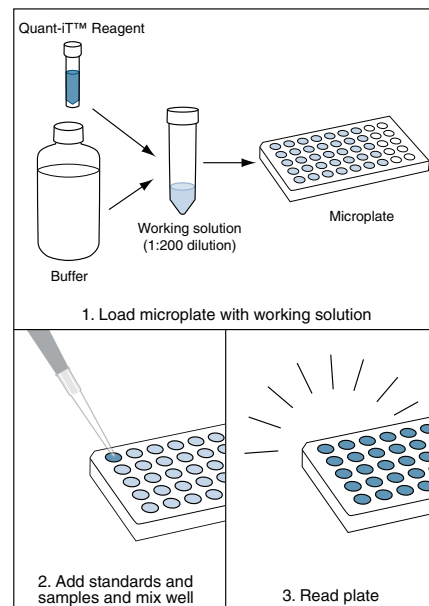

Figure 9.2.1 Microplate assay implementation of DNA, RNA or protein quantitation with the Quant-iT™ Assay Kits.

Figure 9.2.2 Low protein-to-protein variation in the Quant-iT™ protein assay. Solutions of the following proteins were prepared, diluted and assayed with the Quant-iT™ Protein Assay Kit (Q33210): bovine serum albumin (BSA), chicken-egg ovalbumin, chicken-egg lysozyme, bovine-milk β-casein, equine myoglobin, bovine-milk α-casein, porcine pepsin, mouse immunoglobulin G (IgG) and calf-thymus histone. Fluorescence was measured at 485/590 nm and plotted versus the mass of protein sample. Background fluorescence has not been subtracted.

Figure 9.2.3 The Qubit® fluorometer. The Qubit® fluorometer (Q32857) is designed to work seamlessly with the Quant-iT™ assays for DNA, RNA and protein quantitation. It features state-of-the-art optical components, sophisticated data analysis and an intuitive user interface. The result is an easier method to obtain much more accurate and sensitive quantitation than can be obtained with UV absorbance assays, increasing sample performance in downstream applications.

Qubit® Fluorometer

The Qubit® fluorometer (Figure 9.2.3) is designed to work seamlessly with the Quant-iT™ Assay Kits. Together, they form the Qubit™ Quantitation Platform, an efficient combination of sophisticated, accurate, and highly sensitive fluorescence-based quantitation assays for DNA, RNA and protein, along with an extremely user-friendly fluorometer. This powerful pairing offers:

- Selective quantitation—more accurate than UV absorbance readings
- High sensitivity—use as little as 1 μL of sample for quantitation
- Intuitive integrated platform—sophisticated quantitation in 5 minutes or less

In addition to providing quantitation results that are fast, easy and reliable, the Qubit® fluorometer features software that is fully upgradable. The Qubit® fluorometer incorporates sophisticated data analysis algorithms designed to produce accurate measurements and an intuitive user interface for seamless integration with the full range of Quant-iT™ Assay Kits. We offer the Qubit® fluorometer separately (Q32857; USB cable, Q32858; replacement international power cord, Q32859) or bundled in a starter kit that includes four different Quant-iT™ assay kits as well as a supply of 500 Qubit® assay tubes (Q32860); a set of 500 Qubit® assay tubes is also available separately (Q32856).

Quant-iT™ Assay Kits use advanced Molecular Probes® fluorophores that become fluorescent upon binding to DNA, RNA or protein. The selectivity of these interactions ensures more accurate results than can be obtained with UV absorbance readings; Quant-iT™ Assay Kits only report the concentration of the molecule of interest, not sample contaminants. Quant-iT™ Assay Kits are up to 1000 times as sensitive as UV absorbance readings, and as little as 1 μL of sample is all that's needed for accurate, reliable quantitation. We offer Quant-iT™ Assay Kits for a variety of quantitation needs:

- Quant-iT™ dsDNA Broad-Range (BR) and High-Sensitivity (HS) Assay Kits—for sequencing samples, genomic DNA samples and routine cloning experiments (Section 8.3)
- Quant-iT™ RNA Assay Kits—for microarray experiments, real-time PCR samples and northern blots (Section 8.3)
- Quant-iT™ Protein Assay Kits—for analysis of samples destined for western blotting and SDS-PAGE or 2D gel electrophoresis

More information is available at www.invitrogen.com/handbook/qubit.

NanoOrange® Protein Quantitation Kit

The NanoOrange® Protein Quantitation Kit (N6666) provides an ultrasensitive assay for measuring the concentration of proteins in solution.^{2,4} The NanoOrange® Protein Quantitation Kit has several important features:

- **Ease of use.** The NanoOrange® assay protocol is much easier to perform than the Lowry method (Figure 9.2.4). Protein samples are simply added to the diluted NanoOrange® reagent in a lipid-containing medium, and the mixtures are heated at 95°C for 10 minutes. After cooling the mixtures to room temperature, their fluorescence emissions are measured directly. The interaction of the lipid-coated proteins with the NanoOrange® reagent produces a large fluorescence enhancement that can be used to generate a standard curve for protein determination; fluorescence of the reagent in aqueous solutions in the absence of proteins is negligible.
- **Sensitivity and effective range.** The NanoOrange® assay can detect proteins at a final concentration as low as 10 ng/mL when a standard spectrofluorometer or minifluorometer is used. A single protocol is suitable for quantitating protein concentrations between 10 ng/mL and 10 $\mu\text{g/mL}$ —an effective range of three orders of magnitude (Figure 9.2.5).

- **Stability.** The NanoOrange® reagent and its protein complex have high chemical stability. In contrast to the Bradford and BCA assays, readings can be taken for up to six hours after sample preparation with no loss in signal, provided that samples are protected from light.
- **Little protein-to-protein variability** (Figure 9.2.6). The NanoOrange® assay is not only more sensitive, but shows less protein-to-protein variability than Bradford assays.
- **Insensitivity to sample contaminants.** Unlike the Lowry and BCA assays, the NanoOrange® assay is compatible with the presence of reducing agents. Furthermore, the high sensitivity of the assay and stability of the protein-dye complex make it possible to dilute out most potential contaminants, including detergents and salts. Nucleic acids do not interfere with protein quantitation using the NanoOrange® reagent. Although unusually high concentrations of lipids in the sample can interfere with the NanoOrange® assay, this interference can be eliminated by acetone precipitation of the protein, followed by delipidation with diethyl ether.⁵

The NanoOrange® protein quantitation reagent, with an excitation/emission maxima of 470/570 nm when bound to proteins, is suitable for use with a variety of instrumentation. Fluorescence is typically measured using instrument settings or filters that provide excitation/emission at ~485/590 nm, which are commonly available for both spectrofluorometers and microplate readers. A spectrofluorometer—either a standard fluorometer or a minifluorometer—offers the greatest effective range and lowest detection limits for this assay. With fluorescence microplate readers, the NanoOrange® assay is useful over a somewhat narrower range—from 100 ng/mL to 10 µg/mL in final protein concentration.

The NanoOrange® Protein Quantitation Kit (N6666) supplies:

- Concentrated NanoOrange® reagent in dimethylsulfoxide (DMSO)
- Concentrated NanoOrange® diluent
- Bovine serum albumin (BSA) as a protein reference standard
- Detailed protocols for protein quantitation

The amount of dye supplied in this kit is sufficient for ~200 assays using a 2 mL assay volume and a standard fluorometer or minifluorometer, or ~2000 assays using a 200 µL assay volume and a fluorescence microplate reader.

The NanoOrange® reagent is ideal for quantitating protein samples before gel electrophoresis⁵ and western blot analysis.⁶ It has also been used to measure bound versus free protein levels in protein binding assays, and was even able to detect protein trapped in filters during a separation step.⁷ The NanoOrange® reagent is also an optimal reagent for detecting proteins that have been separated by microchip capillary electrophoresis.^{8,9} A high-throughput assay that may be suitable for clinical samples has been developed for quantitating human serum albumin using a fluorescence microplate reader and using capillary electrophoresis laser-induced fluorescence¹⁰ (CE-LIF). Additionally, the NanoOrange® reagent has been shown to be useful in cell-based assays, including an assay designed to measure total protein content of cell cultures¹¹ and a rapid method for demonstrating flagellar movement of bacteria.¹²

Figure 9.2.4 Protein quantitation with the NanoOrange® Protein Quantitation Kit. The NanoOrange® assay (N6666) is simple to perform: after adding diluted dye, the samples are heated to denature the proteins, cooled to room temperature and the fluorescence read in either a microplate reader or a fluorometer.

Figure 9.2.5 Quantitative analysis of bovine serum albumin (BSA) using the NanoOrange® Protein Quantitation Kit (N6666). Fluorescence measurements were carried out on an SLM SPF-500C fluorometer using excitation/emission wavelengths of 485/590 nm. The inset shows an enlargement of the results obtained (0–500 ng protein per mL) and illustrates the detection limit of ~10 ng/mL.

Figure 9.2.6 Quantitative analysis of six different proteins using the NanoOrange® Protein Quantitation Kit (N6666): A) bovine serum albumin (BSA, □), trypsin (●) and carbonic anhydrase (Δ); B) IgG (■), streptavidin (○) and RNase A (▲). The y-axis fluorescence intensity scale is the same in both panels, illustrating the minimal protein-to-protein staining variation of the NanoOrange® assay. Data were collected using a microplate reader with excitation/emission wavelengths set at 485 ± 20 nm/590 ± 35 nm.

Figure 9.2.8 Detection of bovine serum albumin (BSA) using the CBQCA Protein Quantitation Kit (C6667). The primary plot shows detection of BSA from 50 ng to 1000 ng. Inset A shows that the detection range can extend up to 150 µg. Inset B shows that the lower detection limit can extend down to 10 ng. Each point is the average of four determinations.

Figure 9.2.9 Quantitation of proteins in a lipid environment using the CBQCA Protein Quantitation Kit (C6667). The protein concentrations of an LDL preparation and a bovine brain homogenate were first determined by the modified Lowry method using BSA as a standard. Assays were then performed using the CBQCA Protein Quantitation Kit on samples containing from 100 ng to 1000 ng protein in 0.1 M sodium borate buffer, pH 9.3, containing 0.1% Triton X-100. Similar results were obtained without the addition of detergent (data not shown). Fluorescence was measured using a fluorescence microplate reader with excitation at 485 ± 10 nm and emission detection at 530 ± 12.5 nm. Each point is the average of three determinations.

Figure 9.2.10 Comparison of the fluorometric quantitation of bovine serum albumin (BSA) using ATTO-TAG™ CBQCA (which is supplied in the CBQCA Protein Quantitation Kit, C6667), OPA (P2331MP) or fluorescamine (F2332, F20261). BSA samples were derivatized using large molar excesses of the fluorogenic reagents and were analyzed using a fluorescence microplate reader. Excitation/emission wavelengths were 360/460 nm for OPA and fluorescamine and 485/530 nm for ATTO-TAG™ CBQCA. The inset shows an enlargement of the results obtained using CBQCA to assay protein concentrations between 0 and 500 ng/mL.

CBQCA Protein Quantitation Kit

The ATTO-TAG™ CBQCA reagent (A6222) was originally developed as a chromatographic derivatization reagent for amines^{13–15} (Section 1.8), but this reagent is also useful for quantitating proteins by virtue of its rapid and quantitative reaction with their accessible amines. We have developed the CBQCA Protein Quantitation Kit (C6667, Figure 9.2.7, Figure 9.2.8), which employs the ATTO-TAG™ CBQCA reagent for rapid and sensitive protein quantitation in solution^{1,2,16} (Table 9.1). The CBQCA protein quantitation assay functions well in the presence of lipids and detergents,^{16,17} substances that interfere with many other protein determination methods.¹⁶ For example, the CBQCA-based assay can be used directly to determine the protein content of lipoprotein samples or lipid–protein mixtures (Figure 9.2.9). The CBQCA assay has been shown to give faster and more sensitive detection of both free amino acids in human plasma¹⁸ and both low and high molecular weight primary amines in clinical samples from hemodialysis.¹⁹ ATTO-TAG™ CBQCA is more water soluble than either fluorescamine or *o*-phthalaldehyde and much more stable in aqueous solution than fluorescamine. Moreover, ATTO-TAG™ CBQCA provides greater sensitivity for protein quantitation in solution than either fluorescamine or *o*-phthalaldehyde (Figure 9.2.10). As little as 10 ng of BSA can be detected in a 100–200 µL assay volume using a fluorescence microplate reader, and the effective range extends up to 150 µg (Figure 9.2.8). Alternatively, the reaction mixtures can be diluted to 1–2 mL for fluorescence measurement in a standard fluorometer or minifluorometer.

Each CBQCA Protein Quantitation Kit (C6667) contains:

- ATTO-TAG™ CBQCA detection reagent
- Potassium cyanide
- Dimethylsulfoxide (DMSO)
- Bovine serum albumin (BSA) protein reference standard
- Detailed protocols for protein quantitation

The CBQCA Protein Quantitation Kit provides sufficient reagents for 300–800 assays using a standard fluorometer, minifluorometer or fluorescence microplate reader.

EZQ® Protein Quantitation Kit

The EZQ® Protein Quantitation Kit (R33200) provides a fast and easy high-throughput assay for proteins. Because detergents, reducing agents, urea and tracking dyes do not interfere, this fluorescence-based protein quantitation assay is ideal for determining the protein concentration of samples prior to polyacrylamide gel electrophoresis.²⁰ This convenient kit can also provide a quick assessment of protein content during protein purification schemes and fractionation procedures.

The EZQ® assay requires only 1 µL of a sample per spot, and up to 96 samples, including standards, can be assayed in one session. The protein samples are simply spotted onto one of the provided assay papers, fixed with methanol and then stained with the EZQ® protein quantitation reagent. This assay paper is then clamped to the specially designed 96-well microplate

Figure 9.2.7 Protein quantitation with the CBQCA Protein Quantitation Kit. The CBQCA assay (C6667) is simple to perform: after the dye and an activator are added, the sample is incubated for 1 hour and the fluorescence is read in either a microplate reader or a fluorometer.

supersubstructure for quick analysis in a top- or bottom-reading fluorescence microplate reader. For added versatility, the solid-phase assay format and provided 96-well microplate are also compatible with laser scanners equipped with 450, 473 or 488 nm lasers and with UV illuminators in combination with photographic or CCD cameras for image documentation and analysis. Once the samples are spotted, the assay protocol can be completed in about 1 hour. The protein concentration is determined from a standard curve, and the effective range for the assay is generally 0.05–5 mg/mL or 0.05–5 μg per spot (Figure 9.2.11). Protein-to-protein sensitivity differences in the assay are minimal—the observed coefficient of variation is typically ~16% (Figure 9.2.12).

Each EZQ® Protein Quantitation Kit contains:

- EZQ® protein quantitation reagent
- EZQ® 96-well microplate cassette
- Assay paper
- Ovalbumin, for preparing protein standards
- Detailed protocols for protein quantitation using a variety of fluorescence-detection instruments

Sufficient reagent and assay paper are provided for ~2000 protein quantitation assays.

Other Reagents for Protein Quantitation in Solution

Most traditional fluorogenic reagents for general protein quantitation in solution detect accessible primary amines. The sensitivity of assays based on these reagents therefore depends on the number of amines available—a function of both the protein's three-dimensional structure and its amino acid composition. For example, horseradish peroxidase (MW ~40,000 daltons), which has only six lysine residues,²¹ will be detected less efficiently than egg white avidin (MW ~66,000 daltons), which has 36 lysine residues,²² and bovine serum albumin (MW ~66,000 daltons), which has 59 lysine residues.²³ However, the assays are generally rapid and easy to conduct, particularly in minifluorometer and fluorescence microplate reader formats.

Certain dyes that detect primary aliphatic amines, including ATTO-TAG™ CBQCA (A6222), fluorescamine (F2332, F20261) and *o*-phthalaldehyde (OPA, P2331MP), have been the predominant reagents for fluorometric determination of proteins in solution (Table 9.1). These same reagents, and others such as naphthalene-2,3-dicarboxaldehyde^{24,25} (NDA, N1138; Section 1.8), have frequently been used for amino acid analysis of hydrolyzed proteins.

Fluorescamine

Fluorescamine (F2332, F20261) is intrinsically nonfluorescent but reacts in milliseconds with primary aliphatic amines, including peptides and proteins, to yield a fluorescent derivative²⁶ (Figure 9.2.13). This amine-reactive reagent has been shown to be useful for determining protein concentrations of aqueous solutions^{27–29} and for measuring the number of accessible lysine residues in proteins.²³ Protein quantitation with fluorescamine is particularly well suited to a minifluorometer or fluorescence microplate reader.³⁰ Fluorescamine can also be used to detect proteins in gels and to analyze low molecular weight amines by TLC, HPLC and capillary electrophoresis.³¹

Figure 9.2.13 Fluorogenic amine-derivatization reaction of fluorescamine (F2332, F20261).

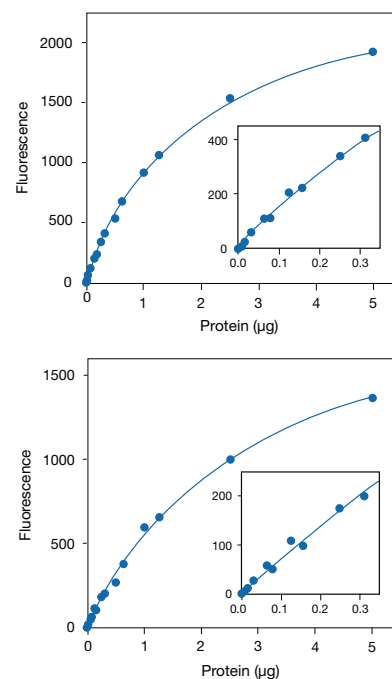

Figure 9.2.11 EZQ® protein quantitation assay of ovalbumin. A dilution series of ovalbumin was prepared, assayed with the EZQ® Protein Quantitation Kit (R33200) and then quantitated using both a 473 nm laser-based scanning instrument (top panel) and a fluorescence microplate reader (bottom panel). The assays were performed over a broad range; the insets show the low range in greater detail. The assays were performed in triplicate, and the mean values, in arbitrary fluorescence units, were plotted after subtracting background values of 86 (upper panel) or 18 (lower panel).

Figure 9.2.12 Protein-to-protein variation in the EZQ® protein quantitation assay. Triplicate 1 μg samples of various proteins were assayed using the EZQ® Protein Quantitation Kit (R33200) and a fluorescence microplate reader. The mean fluorescence values, after correcting for background fluorescence, are expressed relative to that of ovalbumin. The coefficient of variation is ~16%. The protein samples are: A, ovalbumin; B, bovine serum albumin (BSA); C, myoglobin; D, soybean trypsin inhibitor; E, β -casein; F, carbonic anhydrase; G, transferrin; H, mouse IgG; I, lysozyme; and J, histones.

o-Phthaldialdehyde

The combination of *o*-phthaldialdehyde (OPA, P2331MP) and 2-mercaptoethanol provides a rapid and simple method of determining protein concentrations in the range of 0.2 µg/mL to 25 µg/mL³² (Figure 9.2.14). As compared with fluorescamine, OPA is both more soluble and stable in aqueous buffers and its sensitivity for detection of peptides is reported to be 5–10 times better.³³ The OPA assay for lysine content is reasonably reliable over a broad range of proteins.²³ OPA can also be used to detect *increases* in the concentration of free amines that result from protease-catalyzed protein hydrolysis.³⁴

SYPRO® Red and SYPRO® Orange Protein Gel Stains

An assay has been reported that uses the SYPRO® Red protein gel stain (S6653, S6654; Section 9.3) for quantitating total protein

Figure 9.2.14 Fluorogenic amine-derivatization reaction of *o*-phthaldialdehyde (OPA) (P2331MP).

content of bacterial cells by flow cytometry.³⁵ This assay provides an accurate method to measure planktonic bacterial biomass in marine samples. Fluorescence of the SYPRO® Orange protein gel stain (S6650, S6651; Section 9.3) has been used to follow isothermal protein denaturation³⁶ (Note 9.1—Monitoring Protein-Folding Processes with Environment-Sensitive Dyes) and to selectively stain proteins in biofilms prior to two-photon laser-scanning microscopy.³⁷

DATA TABLE 9.2 PROTEIN QUANTITATION IN SOLUTION

Cat. No.	MW	Storage	Soluble	Abs	EC	Em	Solvent	Notes
A6222	305.29	F,D,L	MeOH	465	ND	560	MeOH	1, 2, 3
F2332	278.26	F,D,L	MeCN	380	7800	464	MeCN	4
F20261	278.26	F,D,L	MeCN	380	8400	464	MeCN	4, 5
P2331MP	134.13	L	EtOH	334	5700	455	pH 9	6

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Spectral data are for the reaction product with glycine in the presence of cyanide. Unreacted reagent in MeOH: Abs = 254 nm (EC = 46,000 cm⁻¹M⁻¹), nonfluorescent.
- ND = not determined.
- Solubility in methanol is improved by addition of base (e.g., 1–5% (v/v) 0.2 M KOH).
- Fluorescamine spectra are for the reaction product with butylamine. The fluorescence quantum yield and lifetime of the butylamine adduct in EtOH are 0.23 and 7.5 nanoseconds, respectively. (Arch Biochem Biophys (1974) 163:390) The unreacted reagent is nonfluorescent (Abs = 234 nm, EC = 28,000 cm⁻¹M⁻¹ in MeCN).
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- Spectral data are for the reaction product of P2331MP with alanine and 2-mercaptoethanol. The spectra and stability of the adduct depend on the amine and thiol reactants. (Biochim Biophys Acta (1979) 576:440) Unreacted reagent in H₂O: Abs = 257 nm (EC = 1000 cm⁻¹M⁻¹).

PRODUCT LIST 9.2 PROTEIN QUANTITATION IN SOLUTION

Cat. No.	Product	Quantity
A6222	ATTO-TAG™ CBQCA derivatization reagent (CBQCA; 3-(4-carboxybenzoyl)quinoline-2-carboxaldehyde)	10 mg
C6667	CBQCA Protein Quantitation Kit *300–800 assays*	1 kit
R33200	EZQ® Protein Quantitation Kit *2000 assays*	1 kit
F2332	fluorescamine	100 mg
F20261	fluorescamine *FluoroPure™ grade*	100 mg
N6666	NanoOrange® Protein Quantitation Kit *200–2000 assays*	1 kit
P2331MP	<i>o</i> -phthaldialdehyde (OPA) *high purity*	1 g
Q33211	Quant-iT™ Protein Assay Kit, 100 assays *0.25–5 µg* *for use with the Qubit® fluorometer*	1 kit
Q33212	Quant-iT™ Protein Assay Kit, 500 Assays *0.25–5 µg* *for use with the Qubit® fluorometer*	1 kit
Q33210	Quant-iT™ Protein Assay Kit, 1000 assays *0.25–5 µg*	1 kit
Q32856	Qubit™ assay tubes *set of 500*	1 set
Q32857	Qubit® fluorometer	each
Q32859	Qubit™ fluorometer international power cord *replacement*	each
Q32858	Qubit™ fluorometer USB cable	each
Q32860	Qubit™ Quantitation Starter Kit	1 kit

9.3 Protein Detection on Gels, Blots and Arrays

SYPRO® Protein Gel Stains

The luminescent SYPRO® protein gel stains are revolutionizing the detection of the total-protein profile in polyacrylamide gels. SYPRO® protein gel stains exhibit several important characteristics that together make them far superior to traditional staining methods, including:

- Fast and easy staining protocols
- High sensitivity
- Minimal protein-to-protein variation in staining
- Broad linear quantitation range
- Compatibility with subsequent microanalysis and a variety of instrumentation

Conventional methods for universal profiling of proteins in gels include Coomassie brilliant blue staining¹ and silver staining.² Although Coomassie brilliant blue is an inexpensive reagent, its staining is relatively insensitive and time consuming. Silver staining may be up to 100 times more sensitive than Coomassie brilliant blue staining, but it is relatively expensive and entails several labor-intensive and time-sensitive steps. Silver staining also exhibits a high degree of protein-to-protein variability; staining intensity and color are very dependent on each polypeptide's sequence and degree of glycosylation, and some proteins are detectable only as negatively stained patches. Moreover, silver staining shows very poor linearity with protein concentration (Figure 9.3.1) and poor reproducibility in staining from gel to gel, making it inadequate for comparative studies of protein expression in cells.

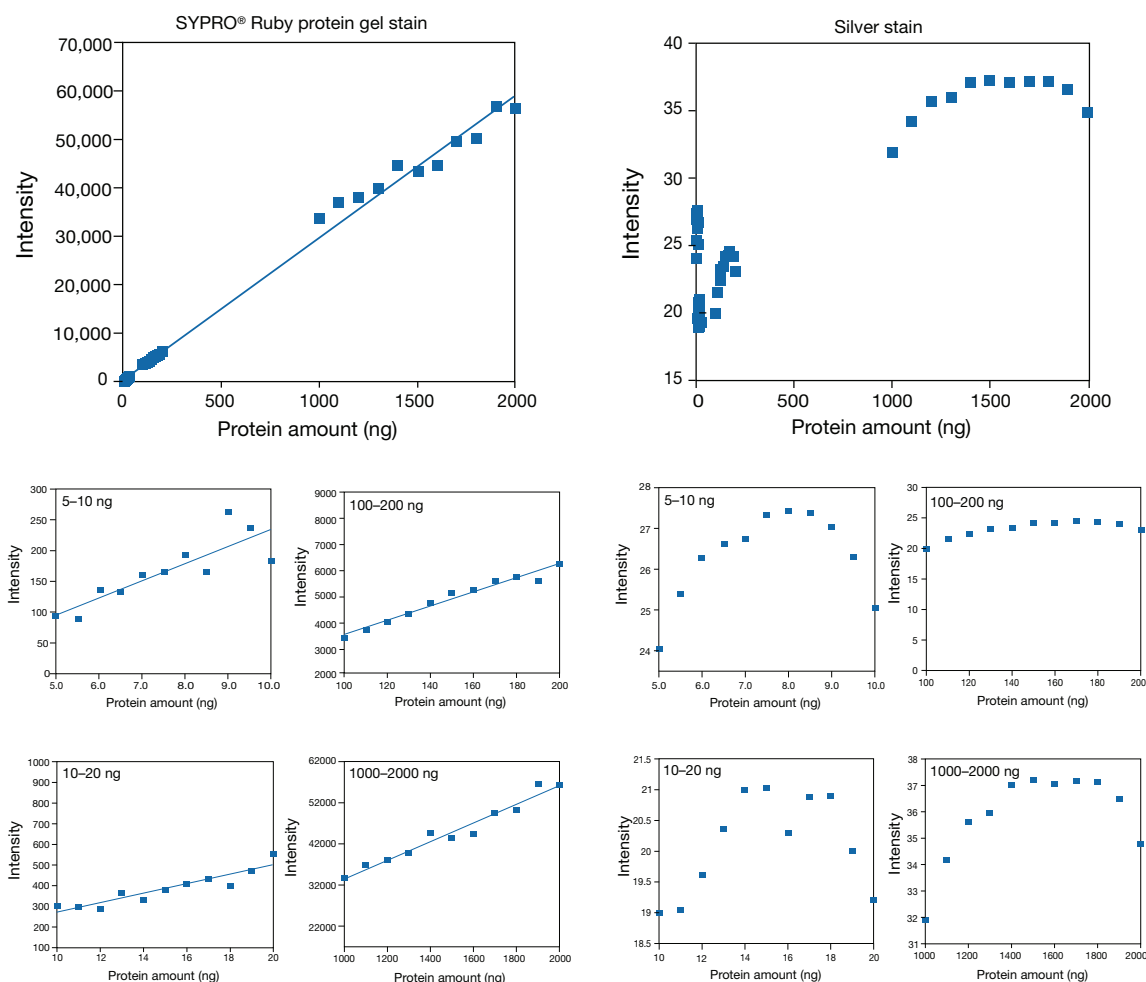

Figure 9.3.1 Quantitation of proteins in gels using SYPRO® Ruby protein gel stain versus silver stain. Dilutions of proteins were electrophoresed on eight different SDS-polyacrylamide gels, two gels for each of four dilution ranges. The gels were stained with either SYPRO® Ruby protein gel stain (S12000, S12001, S21900) or a silver stain. Staining intensities were quantitated using either the Fluor-S MAX Multimager documentation system (Bio-Rad® Laboratories) or the FLA3000G laser scanner (Fuji® Photo Film Co.) and plotted against the protein amount for bovine serum albumin. SYPRO® Ruby protein gel stain shows a linear quantitation range over three orders of magnitude, as well as consistent staining intensities from gel to gel. In contrast, the silver stain shows linear quantitation over only a small range, a very shallow slope and inconsistent staining intensities from gel to gel, even when corrected for background differences.

Many of the drawbacks of these traditional stains can be overcome by using one of the SYPRO® protein gel stains, without sacrificing detection sensitivity.³ We have developed a SYPRO® dye optimized for protein profiling in nearly every type of gel (Table 9.2) or blot application (Table 9.3). The characteristics and applications of the individual SYPRO® protein gel and blot stains for detecting the total-protein profile of a sample are described in this section. Section 9.4 discusses the use of these SYPRO® stains in conjunction with phosphoprotein and glycoprotein detection reagents for multiparameter staining.

SYPRO® Ruby Protein Gel Stain: Ultrasensitive Protein Detection in 1D, 2D and IEF Gels

SYPRO® Ruby protein gel stain (S12000, S12001, S21900) is a ready-to-use protein stain that has sensitivity equal to or exceeding that of the best silver staining techniques, is compatible with Edman sequencing and mass spectrometry⁴ and can be visualized with a simple UV transilluminator or a laser scanner.^{3,5-17} SYPRO® Ruby protein gel stain offers several advantages over conventional staining techniques:

- **High-sensitivity staining.** SYPRO® Ruby protein gel stain provides at least the same subnanogram sensitivity as the best silver staining techniques in 1D, 2D^{11,13} or IEF gels (Figure 9.3.2).

- **Simple staining protocol.** After fixation, the gel is incubated in the staining solution. No stop solutions or destaining steps are required and, unlike silver staining, gels can be left in the dye solution for indefinite periods without overstaining, vastly simplifying the simultaneous processing of multiple gels and making it possible to perform high-throughput staining without investing in robotic staining devices.
- **Accurate peptide and protein detection.** SYPRO® Ruby protein gel stain shows little protein-to-protein variability in staining¹⁸ and detects some proteins that are completely missed by silver staining (Figure 9.3.3), such as heavily glycosylated proteins. Unlike silver staining, SYPRO® Ruby dye does not stain extraneous nucleic acids, lipids or carbohydrates in the sample.¹³
- **Excellent performance in comparative protein expression studies.** SYPRO® Ruby stain shows a greater linear quantitation range than either silver or Coomassie brilliant blue staining—extending over three orders of magnitude—making it possible to accurately compare protein expression levels¹³ (Figure 9.3.1, Figure 9.3.2). Gel-to-gel staining is extremely consistent; same-spot intensity comparisons between identical 2D gels show a correlation coefficient of 0.9.¹² Multiple gels can easily be compared using available software (Figure 9.3.4). Other protein quantitation methods, including running multiple prestained samples on the same gel, generally do not produce results that approach this level of discrimination.¹⁹

Table 9.2 SYPRO® and Coomassie Fluor™ luminescent and fluorescent protein gel stains.

Dye (Cat. No.)	Ex/Em *	Major Applications	Features
SYPRO® Ruby protein gel stain (S12000, S12001, S21900)	280, 450/610	2D gels, IEF gels, 1D SDS-PAGE	<ul style="list-style-type: none"> • High sensitivity (1–2 ng/band; comparable to silver staining) • Linear quantitation range over three orders of magnitude
SYPRO® Orange protein gel stain (S6650, S6651)	300, 470/570	1D SDS-PAGE	<ul style="list-style-type: none"> • Very good sensitivity (4–8 ng/band; higher than Coomassie brilliant blue staining) • Little protein-to-protein variability • Linear quantitation range over three orders of magnitude
SYPRO® Red protein gel stain (S6653, S6654)	300, 550/630	1D SDS-PAGE	<ul style="list-style-type: none"> • Very good sensitivity (4–8 ng/band; higher than Coomassie brilliant blue staining) • Little protein-to-protein variability • Linear quantitation range over three orders of magnitude
SYPRO® Tangerine protein gel stain (S12010)	300, 490/640	1D SDS-PAGE, blotting applications, zymography, electroelution	<ul style="list-style-type: none"> • Very good sensitivity (4–8 ng/band; higher than Coomassie brilliant blue staining) • Little protein-to-protein variability • Linear quantitation range over three orders of magnitude • No fixation required
Coomassie Fluor™ Orange protein gel stain (C33250, C33251)	300, 470/570	1D SDS-PAGE	<ul style="list-style-type: none"> • Premixed and ready-to-use solution • Very good sensitivity (8 ng/band; higher than Coomassie brilliant blue staining) • Little protein-to-protein variability • Linear quantitation range over at least two orders of magnitude

All SYPRO® gel and blot stains are compatible with Edman sequencing and mass spectrometry. *Excitation (Ex) and emission (Em) maxima, in nm. For maximum sensitivity, use excitation sources and optical filters matched to these values.

Table 9.3 Molecular Probes® fluorescent and luminescent protein blot stains.

Dye (Cat. No.)	Ex/Em *	Major Applications	Features
SYPRO® Ruby protein blot stain (S11791)	280, 450/618	Mass spectrometry, microsequencing, counterstain for blot-based detection techniques (nitrocellulose or PVDF membranes)	<ul style="list-style-type: none"> • High sensitivity (1–2 ng/band; comparable to colloidal gold staining) • Reversible
BODIPY® FL-X succinimidyl ester (D6102) †	365, 505/575	Counterstain for blot-based detection techniques (PVDF membranes)	<ul style="list-style-type: none"> • Very good sensitivity (4–8 ng/band) • Permanent, covalent staining for multicolor techniques
BODIPY® TR-X succinimidyl ester (D6116) ‡	300, 590/615	Counterstain for blot-based detection techniques (PVDF membranes)	<ul style="list-style-type: none"> • Very good sensitivity (4–8 ng/band) • Permanent, covalent staining for multicolor techniques

* Excitation (Ex) and emission (Em) maxima, in nm. For maximum sensitivity, use excitation sources and optical filters matched to these values. † Available as a stand-alone reagent (D6102, Section 1.4). ‡ Available as a stand-alone reagent (D6116, Section 1.4).

- Compatibility with microsequencing and mass spectrometry.**⁴ Unlike silver staining techniques, which use glutaraldehyde- or formaldehyde-based fixatives, SYPRO® Ruby dye is a gentle stain that interacts noncovalently with proteins. Thus, high-quality Edman sequencing or mass spectrometry data^{4,12,20,21} (Figure 9.3.5) can be obtained immediately after staining, without modification steps that may compromise sensitivity. Automated in-gel digestion methods have been used in the analysis of femtomole levels of SYPRO® Ruby dye-stained proteins.²²
- Utility for isoelectric focusing (IEF).** SYPRO® Ruby protein gel stain also provides a reliable, high-sensitivity staining method for isoelectric focusing (IEF) gels (Figure 9.3.6) without the problems typically encountered with silver staining, such as ampholyte staining or mirroring effects on the plastic gel backing.
- Minimal hazardous waste.** As compared with silver stains, SYPRO® Ruby protein gel stain generates much less hazardous waste, minimizing the time and expense associated with waste disposal.

Figure 9.3.3 SYPRO® Ruby protein gel stain (S12000, S12001, S21900) shows less protein-to-protein variation than silver staining. Proteins from a cell lysate were run on a 2D gel and stained with SYPRO® Ruby protein gel stain (left) or silver stain (right). The grayscale values of the SYPRO® Ruby dye-stained gel have been inverted for easier comparison with the silver-stained gel.

Figure 9.3.5 Mass spectrum profile of NADH:ubiquinone reductase precursor (75,000-dalton subunit) obtained after 2D gel electrophoresis of bovine heart mitochondria and staining with SYPRO® Ruby protein gel stain (S12000, S12001, S21900). Bovine heart mitochondria were a gift of Roderick Capaldi, University of Oregon.

Figure 9.3.2 Amounts of carbonic anhydrase ranging from 1 ng to 1000 ng were separated on an SDS-polyacrylamide gel and stained with SYPRO® Ruby protein gel stain (S12000, S12001, S21900). The inset shows the excellent linearity in the lower part of the range from 1 ng to 60 ng protein. Staining intensities were quantitated using the Molecular Imager® FX documentation system (Bio-Rad® Laboratories). For comparison, the gray band shows the linear range for the same protein detected with silver staining.

Figure 9.3.4 Comparison of two protein samples run on 2D gels. Proteins from either a normal liver tissue sample or a liver tumor sample were run on two 2D gels and stained with SYPRO® Ruby protein gel stain (S12000, S12001, S21900). Images of the gels were captured using the FLA-3000 scanner (Fuji®). Images from a portion of the two gels were then pseudocolored either pink or green, overlaid and matched spot-for-spot using Z3 software (Compugen). Green spots represent proteins expressed in the liver tumor samples; pink spots represent proteins expressed in the normal liver tissue sample. Black spots represent proteins expressed in both tissues.

Figure 9.3.6 SYPRO® Ruby protein gel stain versus silver stain for IEF gels. Serial dilutions of isoelectric focusing protein standards were electrophoresed on two identical polyacrylamide gels. One gel was stained with SYPRO® Ruby protein gel stain (S12000, S12001, S21900) (left) and the other with silver stain (right). Both stains show a similar limit of sensitivity for all proteins.

Figure 9.3.7 Luminescence excitation (dashed line) and emission (solid line) spectra of the SYPRO® Ruby protein gel stain (S12000, S12001, S21900) and SYPRO® Ruby protein blot stain (S11791).

Figure 9.3.9 Quantitation of proteins in a gel using SYPRO® Orange protein gel stain (S6650, S6651). A protein mixture was serially diluted and electrophoresed on a 15% SDS-polyacrylamide gel and then stained with SYPRO® Orange protein gel stain. The gel was then scanned using a Storm gel and blot analysis system (excitation/emission 488/>520 nm) and analyzed to yield the fluorescence intensities of the stained bands. The fluorescence intensity scale is the same in both panels, illustrating the minimal protein-to-protein staining variation of SYPRO® Orange gel stain. Detection limits are between 2 and 16 ng of protein; the linear detection ranges are approximately 1000-fold. Proteins represented are: A) β -galactosidase (O), lysozyme (■), bovine serum albumin (BSA, □) and phosphorylase B (●); B) myosin (O), soybean trypsin inhibitor (■), ovalbumin (□) and carbonic anhydrase (●).

SYPRO® Ruby protein gel stain is based on an organometallic ruthenium complex, which shows an extremely bright and photostable red-orange luminescence when excited with either UV or blue light (Figure 9.3.7). Stained proteins can be visualized using a UV transilluminator, a blue-light transilluminator or a laser-scanning instrument. Gels can then be documented using Polaroid® 667 black-and-white print film, a CCD camera with an image documentation system or a laser-scanning instrument.¹³ For optimal sensitivity using a UV transilluminator and Polaroid® 667 black-and-white print film, the SYPRO® photographic filter (S6656) is recommended.

SYPRO® Ruby protein gel stain is supplied as 200 mL of a 1X staining solution (S12001), sufficient for staining about four minigels, or 1 L of a 1X staining solution (S12000), sufficient for staining about 20 minigels or two standard 2D gels. Additionally, we offer SYPRO® Ruby protein gel stain in a 5 L box (S21900), sufficient for staining about 100 minigels or 10 standard 2D gels. These boxes are easy to stack and store, and the convenient spigot makes it easy to dispense just the right amount of stain.

SYPRO® Orange and SYPRO® Red Protein Gel Stains: For Routine Detection of Proteins in 1D SDS-Polyacrylamide Gels

SYPRO® Orange (S6650, S6651) and SYPRO® Red (S6653, S6654) protein gel stains provide a fluorescence-based alternative for protein detection in SDS-polyacrylamide gels that is not only faster and more sensitive than Coomassie brilliant blue staining, but can be as sensitive as short-protocol silver staining methods (Figure 9.3.8) at a fraction of the time, effort and cost.^{23–28}

In the presence of excess SDS, nonpolar regions of polypeptides are coated with detergent molecules, forming a micelle-like structure with a nearly constant SDS/protein ratio (1.4 g SDS:1.0 g protein); this constant charge-per-mass ratio is the basis of molecular weight determination by SDS-polyacrylamide gel electrophoresis. SYPRO® Orange and SYPRO® Red dyes bind to the SDS coat that surrounds proteins in SDS-polyacrylamide gels. Thus, the staining observed with these dyes exhibits relatively little protein-to-protein variation and is linearly related to protein mass (Figure 9.3.9). Some important features of SYPRO® Orange and SYPRO® Red protein gel stains include:

- **Ease of use.** Following electrophoresis, the gel is stained for 10–60 minutes and then briefly rinsed—no separate fixation, stop or destaining steps are required. After staining, the gel is immediately ready for photography, or it can be stored, in or out of the staining solution, for days.

Figure 9.3.8 Comparison of the sensitivity achieved with SYPRO® Orange, SYPRO® Red, silver and Coomassie brilliant blue stains. Identical SDS-polyacrylamide gels were stained with A) SYPRO® Orange protein gel stain (S6650, S6651), B) SYPRO® Red protein gel stain (S6653, S6654), C) silver stain and D) Coomassie brilliant blue stain, according to standard protocols. SYPRO® Orange and SYPRO® Red dye-stained gels were photographed using 300 nm transillumination, a SYPRO® photographic filter (S6656) and Polaroid® 667 black-and-white print film. The silver- and Coomassie brilliant blue-stained gels were photographed with transmitted white light and Polaroid® 667 black-and-white print film; no photographic filter was used to photograph these gels.

- **High sensitivity.** SYPRO® Orange and SYPRO® Red protein gel stains routinely provide a sensitivity level of at least 8–16 ng per band in SDS-polyacrylamide minigels when visualized with standard 300 nm transillumination (Figure 9.3.8). Photography using Polaroid® 667 black-and-white print film and a SYPRO® photographic filter (S6656) enhances the detection of staining with SYPRO® Orange or SYPRO® Red dye by several-fold over visible detection because the film integrates the signal throughout the duration of the exposure. Laser scanners also detect nanogram quantities of SYPRO® dye-stained proteins in gels.
- **Broad linear quantitation range.** Protein detection in gels stained with either SYPRO® Orange or SYPRO® Red stain is linear over three orders of magnitude in protein quantity²⁶ (Figure 9.3.9).
- **Uniform protein staining.** Unlike silver staining,²⁹ SYPRO® Orange and SYPRO® Red dyes exhibit relatively low protein-to-protein variability in SDS-polyacrylamide gels²⁷ (Figure 9.3.9) and do not stain nucleic acids, which are sometimes found in protein mixtures from cell or tissue extracts.²⁶ In addition, SYPRO® Orange and SYPRO® Red dyes only weakly stain lipopolysaccharides in bacterial lysates, whereas these biopolymers are strongly detected by some types of silver staining.²⁶ Glycoproteins (such as the IgG variable subunit) and proteins with prosthetic groups (such as bovine cytochrome oxidase) are also efficiently stained with SYPRO® Orange and SYPRO® Red dyes.²⁷
- **Photostability.** Proteins stained with SYPRO® Orange or SYPRO® Red dye are relatively photostable, enabling the researcher to acquire multiple photographic images and to use long film-exposure times (2–8 seconds). Gels that are illuminated for long periods of time may partially photobleach but can be restained with little loss of sensitivity.³⁰
- **Compatibility with many types of instruments.** Although their excitation maxima are in the visible range (Figure 9.3.10), SYPRO® dye-stained gels are readily visualized using standard 300 nm transilluminators.²³ SYPRO® Orange protein gel stain also exhibits good sensitivity when viewed with a blue-light transilluminator, and both SYPRO® Orange and SYPRO® Red protein gel stains are suitable for use with many laser-scanning instruments.²⁷
- **Chemical stability.** SYPRO® Orange and SYPRO® Red gel stains are chemically stable; if protected from light, fluorescence of the stained gel is stable for several days, and staining solutions can be stored for months.
- **Economy.** SYPRO® Orange and SYPRO® Red gel stains are not only less expensive than silver-staining kits but faster and less laborious to use. Additionally, use of SYPRO® Orange or SYPRO® Red dye avoids the costs of purchase and disposal of organic solvents that are required for Coomassie brilliant blue staining.
- **Compatibility with mass spectroscopy.** Unlike silver stains, SYPRO® Orange and SYPRO® Red dyes do not covalently bind to proteins, allowing subsequent analysis of stained proteins by microsequencing or mass spectrometry.^{4,25,31}

SYPRO® Orange and SYPRO® Red stains have very similar staining properties, although we have observed that proteins stained with SYPRO® Orange dye are slightly brighter, whereas gels stained with SYPRO® Red dye tend to have lower background fluorescence. For maximum sensitivity with UV transilluminators, we recommend documenting the signal using Polaroid® 667 black-and-white print film and the SYPRO® photographic filter (S6656). For maximum sensitivity with laser scanners, we recommend matching the appropriate SYPRO® dye with the excitation light source of the instrument. SYPRO® Orange protein gel stain is most suitable for gel scanners that employ argon-ion lasers with output at 488 nm, whereas SYPRO® Red protein gel stain is best matched to laser-scanning instruments that employ Nd:YAG lasers with output at 532 nm. SYPRO® Red protein gel stain has been used as a prestain for protein analysis in an automated ultrathin-layer gel electrophoretic technique.^{32,33} SYPRO® Orange protein gel stain has been used for protein sizing on a microchip³⁴ and for analyzing the kinetics of isothermal protein denaturation (Note 9.1— Monitoring Protein-Folding Processes with Environment-Sensitive Dyes).³⁵

SYPRO® Orange and SYPRO® Red protein gel stains are compatible with SDS or urea/SDS gels. Staining native proteins in gels in the absence of SDS results in more protein-to-protein variation and lower sensitivity than staining SDS-denatured proteins, due to variations in

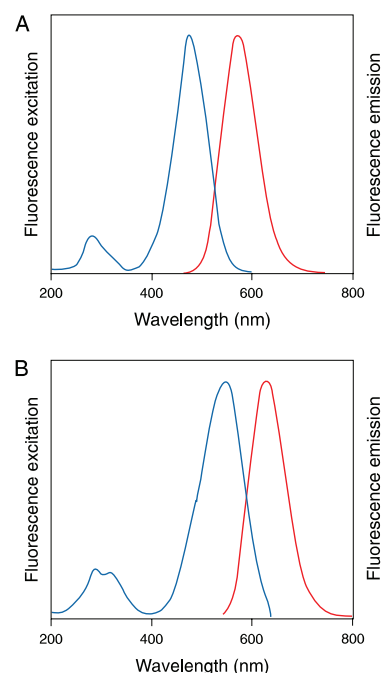

Figure 9.3.10 Fluorescence excitation and emission spectra of A) SYPRO® Orange (S6650, S6651) and B) SYPRO® Red (S6653, S6654) protein gel stains diluted 1:10,000 in water containing 0.05% SDS and 150 µg/mL bovine serum albumin (BSA).

Figure 9.3.11 Analysis of β -glucuronidase activity and total protein content using SYPRO[®] Tangerine protein gel stain and ELF[®] β -D-glucuronidase. Molecular weight standards containing decreasing amounts of *Escherichia coli* β -glucuronidase were run on an SDS-polyacrylamide gel and stained with SYPRO[®] Tangerine protein gel stain (orange, S12010) followed by incubation with the ELF[®] 97 β -D-glucuronidase substrate (green) to detect the activity of β -glucuronidase.

Figure 9.3.12 Linearity of SYPRO[®] Tangerine protein gel stain (S12010). A dilution series of carbonic anhydrase was electrophoresed through a 13% SDS-polyacrylamide gel and stained with SYPRO[®] Tangerine protein gel stain in 7% acetic acid. The fluorescence signal was quantified and plotted versus the protein amount, revealing a sensitivity limit of about 4 ng/band and a linear quantitation range over at least three orders of magnitude.

Figure 9.3.13 Protein molecular weight standards (P6649) separated on a 15% SDS-polyacrylamide gel and stained with SYPRO[®] Orange protein gel stain (S6650, S6651).

hydrophobicity of the target polypeptides. However, sensitivity of SYPRO[®] dye staining in native gels can be improved if gels are soaked in 0.05% SDS solution after electrophoresis but prior to staining. For optimal staining of proteins in 2D gels and IEF gels, we recommend SYPRO[®] Ruby protein gel stain (S12000, S12001, S21900).

Because SYPRO[®] Orange and SYPRO[®] Red dyes do not covalently bind to proteins, stained proteins can be subsequently analyzed by microsequencing or mass spectrometry.^{4,25,31} These dyes, however, are not recommended for staining gels prior to blotting, as there is a significant loss of sensitivity when proteins are stained with SYPRO[®] Orange or SYPRO[®] Red dyes in typical western blotting buffers. To obtain maximum sensitivity when staining proteins in western blotting protocols, we recommend SYPRO[®] Tangerine protein gel stain (S12010) for staining proteins on the gel *before* blotting or SYPRO[®] Ruby protein blot stain (S11791) for staining proteins on nitrocellulose or PVDF membranes *after* blotting.

SYPRO[®] Orange and SYPRO[®] Red protein gel stains are available as 500 μ L stock solutions in dimethylsulfoxide (DMSO), either in a single vial (S6650, S6653) or specially packaged as a set of 10 vials, each containing 50 μ L (S6651, S6654). The reagents are supplied as 5000X concentrates; thus, 500 μ L of either stain yields 2.5 L of staining solution. Photography of proteins in gels, which is essential for obtaining the maximum sensitivity, requires use of the SYPRO[®] photographic filter (S6656).

SYPRO[®] Tangerine Protein Gel Stain: Sensitive Protein Detection without Fixation for Electroelution, Zymography and Classroom Use

SYPRO[®] Tangerine protein gel stain^{3,36} (S12010), which stains proteins in gels without the need for either acids or organic solvents, serves as an alternative to conventional protein stains that fix proteins in the gel.³⁶ Whereas SYPRO[®] Orange and SYPRO[®] Red stains require a staining solution containing acetic acid for maximum performance, staining with SYPRO[®] Tangerine protein gel stain is possible in almost any buffer that contains NaCl. Because proteins are not fixed during the staining procedure, they can be readily eluted from gels, used for zymography (in-gel enzyme activity assays, Figure 9.3.11) or analyzed by mass spectrometry.³⁶ SYPRO[®] Tangerine stain can also be used to stain gels before transferring the proteins to nitrocellulose or PVDF membranes for immunostaining³⁶ (western blotting). Like SYPRO[®] Orange and SYPRO[®] Red protein gel stains, SYPRO[®] Tangerine protein gel stain shows high sensitivity (down to \sim 4 ng/band) and a broad linear quantitation range (Figure 9.3.12). Easy to use, SYPRO[®] Tangerine protein gel stain is also ideal for use in educational settings, especially when used with UV-free blue-light transilluminators.

SYPRO[®] Tangerine stain is compatible with conventional SDS-polyacrylamide gel electrophoresis, but it is not recommended for 2D or IEF gels. Stained proteins can be visualized using a UV transilluminator, a blue-light transilluminator or a laser scanner. Photography of stained gels using Polaroid[®] 667 black-and-white print film requires use of the SYPRO[®] photographic filter (S6656) for optimal sensitivity. SYPRO[®] Tangerine protein gel stain^{3,36} (S12010) is available as 500 μ L of a 5000X concentrate in dimethylsulfoxide (DMSO), an amount sufficient to stain about 100 minigels.

SYPRO[®] Protein Gel Stain Starter Kit

SYPRO[®] Orange, SYPRO[®] Red and SYPRO[®] Tangerine protein gel stains are all available in a SYPRO[®] Protein Gel Stain Starter Kit (S12012) for first-time users. Each kit includes:

- 50 μ L of SYPRO[®] Orange protein gel stain, sufficient for 5–20 minigels
- 50 μ L of SYPRO[®] Red protein gel stain, sufficient for 5–20 minigels
- 50 μ L of SYPRO[®] Tangerine protein gel stain, sufficient for 5–20 minigels
- SYPRO[®] protein gel stain photographic filter
- Detailed protocols

Protein Molecular Weight Standards

We offer a protein mixture for use as molecular weight markers in SDS-polyacrylamide gel electrophoresis (Figure 9.3.13). This broad-range marker mixture (P6649) contains a balanced formulation of 11 polypeptides with molecular weights from 6500 to 205,000 daltons. These protein molecular weight standards give rise to sharp, well-separated bands when the gel is stained with any of our protein gel or blot stains. The mixture provides amounts of marker

proteins sufficient for loading about 200 gel lanes. We also have available PeppermintStick™ phosphoprotein molecular weight standards (P33350) and CandyCane™ glycoprotein molecular weight standards (C21852), which are described in Section 9.4.

Electrophoretic Mobility-Shift (Bandshift) Assay (EMSA) Kit

To make bandshift assays easier, we offer the Electrophoretic Mobility-Shift Assay (EMSA) Kit (E33075), which provides a fast and quantitative fluorescence-based method for detecting both nucleic acid and protein in the same gel³⁷ (Figure 9.3.14). This kit uses two different stains for detection: the fluorescent SYBR® Green EMSA nucleic acid gel stain for RNA or DNA and the luminescent SYPRO® Ruby EMSA protein gel stain for proteins. Because the nucleic acids and proteins are stained in the gel after electrophoresis, there is no need to prelabel the DNA or RNA with a radioisotope, biotin or a fluorescent dye before the binding reaction, and therefore there is no possibility that the label will interfere with protein binding. Staining takes only about 20 minutes for the nucleic acid stain, and about 4 hours for the subsequent protein stain, yielding results much faster than radioisotope labeling (which may require multiple exposure times) or chemiluminescence-based detection (which requires blotting and multiple incubation steps).

This kit also makes it possible to perform ratiometric measurements of nucleic acid and protein in the same band, providing more detailed information on the binding interaction.³⁷ The signals from the two stains are linear over a broad range, allowing accurate determination of the amount of nucleic acid and protein, even in a single band, with detection limits of ~1 ng for nucleic acids and ~20 ng for protein. Both stains can be visualized using a standard 300 nm UV transilluminator, a 254 nm epi-illuminator or a laser scanner (Figure 9.3.14). For optimal sensitivity using a UV transilluminator and Polaroid® 667 black-and-white print film, the SYPRO® photographic filter (S6656) and the SYBR® photographic filter (S7569, Section 8.4) are recommended. Digital images can easily be overlaid for a two-color representation of nucleic acid and protein in the gel.

The EMSA Kit contains sufficient reagents for 10 nondenaturing polyacrylamide minigel assays, including:

- SYBR® Green EMSA nucleic acid gel stain
- SYPRO® Ruby EMSA protein gel stain
- Trichloroacetic acid, for preparing the working solution of SYPRO® Ruby EMSA protein gel stain
- Concentrated EMSA gel-loading solution
- Concentrated binding buffer
- Detailed protocols

SYPRO® Photographic Filter

To achieve optimal sensitivity with the SYPRO® stains, it is essential to photograph the gel or blot because the camera's integrating capability can make bands visible that are not detected by eye. Photographs should be taken using a photographic filter with spectral properties closely matched to those of the fluorescent or luminescent dye used.

When using Polaroid® 667 black-and-white print film and UV illumination, protein gels or blots stained with any of the SYPRO® protein stains (including SYPRO® Ruby, SYPRO® Orange, SYPRO® Red and SYPRO® Tangerine gel stains as well as SYPRO® Ruby protein blot stain) should be photographed through the SYPRO® photographic filter (Figure 9.3.15, Figure 9.3.16), a 75 mm × 75 mm gelatin filter. Note that these gelatin filters are generally not suitable for use with portable or stationary gel-documentation systems or with CCD cameras.

Figure 9.3.14 Titration of *lac* operator DNA with lac repressor protein. Increasing amounts of lac repressor protein were mixed with 40 ng of *lac* operator DNA, incubated for 20 minutes and then separated on a 6% nondenaturing polyacrylamide gel. The gel was stained with SYBR® Green EMSA stain (green) followed by SYPRO® Ruby EMSA stain (red), components of the Electrophoretic Mobility-Shift Assay Kit (E33075). After each staining, the image was documented using an FLA-3000 laser-based scanner (Fuji®) and the digital images pseudocolored and overlaid. Yellow bands indicate areas stained with both stains.

Figure 9.3.15 Molecular Probes® 75 mm × 75 mm gelatin photographic filter for use with Polaroid® black-and-white print film photography.

Figure 9.3.16 Transmission profile of the SYBR® Safe photographic filter (S37100) and the SYPRO® photographic filter (S6656), which are identical.

NOTE 9.1**Monitoring Protein-Folding Processes with Environment-Sensitive Dyes**

1,8-ANS and bis-ANS (A47, B153; Section 13.5) have proven to be sensitive probes for partially folded intermediates in protein-folding pathways. These applications take advantage of the strong fluorescence enhancement exhibited by these amphiphilic dyes when their exposure to water is lowered (Figure 1, Figure 2). Consequently, fluorescence of ANS increases substantially when proteins to which it is bound undergo transitions from unfolded to fully or partially folded states that provide shielding from water. Molten globule intermediates are characterized by particularly high ANS fluorescence intensities due to the exposure of hydrophobic core regions that are inaccessible to the dye in the native structure.¹ Binding of 1,8-ANS and bis-ANS to proteins is noncovalent and involves a combination of electrostatic and hydrophobic modes.^{2–6} Some investigators have noted that the dye-binding event itself may induce protein conformational changes, indicating the advisability of correlating ANS fluorescence measurements with data obtained using other physical techniques.^{5,7–9} In particular, high-resolution structural analysis of an ANS–protein complex by X-ray crystallography has demonstrated the occurrence of local rearrangements of the protein structure to accommodate the dye.¹⁰

The general mechanism of protein-folding detection by ANS has been developed as the basis of fluorescence thermal shift (a.k.a. differential scanning fluorometry) assays for high-throughput analysis of protein stability.^{11–14} The assay readout is a profile of protein–dye complex fluorescence intensity as a function of temperature. Profiles are obtained and compared for multiple samples in which environmental or structural factors influencing protein stability are systematically varied. Thermocycler instruments designed for real-time PCR monitoring provide a readily adaptable instrument platform for these measurements.^{12,13,15} Most high-throughput fluorescence thermal shift assays use SYPRO® Orange dye (S6650, S6651; Section 9.3) instead of ANS. Other environment-sensitive dyes with demonstrated utility include SYPRO® Red dye (S6653, S6654; Section 9.3), Dapoxyl® sulfonic acid (D12800, Section 13.5), Nile Red (N1142, Section 13.5) and CPM (D346, Section 2.3). Within the broad context of protein stability optimization, fluorescence thermal shift assays have many applications including:

- Analysis of ligand binding to proteins of unknown function¹⁶
- Identification of protein–protein interaction inhibitors¹⁷
- Analysis of protein stabilization by peptide aptamers¹⁸ and amino acid ligands¹⁹
- Characterization of engineered protein variants²⁰
- Optimization of protein crystallization conditions^{21,22}
- Enhancement of recombinant protein quality and yield²³

Figure 1 Fluorescence emission spectra of equal concentrations of 1,8-ANS (A47) in ethanol:water mixtures. The labels adjacent to each curve indicate the percentage of ethanol in the solvent mixture.

Figure 2 Fluorescence enhancement of 1,8-ANS (1-anilino-naphthalene-8-sulfonic acid, A47) upon binding to protein. The image shows aqueous solutions of 1,8-ANS excited by ultraviolet light. Addition of protein (bovine serum albumin) to the solution in the cuvette on the left results in intense blue fluorescence. In comparison, the fluorescence of uncomplexed free dye in the cuvette on the right is negligible.

Coomassie Fluor™ Orange Protein Gel Stain

Coomassie Fluor™ Orange protein gel stain (C33250, C33251) provides a fast, simple and sensitive method for staining of proteins in SDS-polyacrylamide electrophoretic gels. Gels do not need to be washed before staining with the Coomassie Fluor™ Orange dye or destained after staining. After electrophoresis, the gel is simply stained, rinsed and photographed on a standard UV transilluminator. Our premixed and ready-to-use Coomassie Fluor™ Orange protein gel stain offers the following advantages over conventional colorimetric stains:

- **High sensitivity.** Coomassie Fluor™ Orange protein gel stain detects as little as 8 ng of protein per minigel band (Figure 9.3.17). This sensitivity matches the best colloidal Coomassie stains and exceeds standard Coomassie brilliant blue stains.
- **Broad linear range of detection.** The fluorescence intensity of Coomassie Fluor™ Orange dye-stained bands is linear with protein quantity over at least two orders of magnitude, permitting accurate quantitation.
- **Rapid staining.** Staining is complete in less than an hour, and there is no risk of overstaining the gel.
- **Compatibility with standard laboratory equipment.** Stained proteins can be visualized using a standard 300 nm UV transilluminator or a laser scanner (Figure 9.3.18). For optimal sensitivity using a UV transilluminator and Polaroid® 667 black-and-white print film, the SYPRO® photographic filter (S6656) is recommended.
- **Low protein-to-protein variability.** Because Coomassie Fluor™ Orange dye interacts with the SDS coat around proteins in the gel, it gives more consistent staining between different types of proteins, as compared with Coomassie brilliant blue staining, and it never exhibits negative staining. Coomassie Fluor™ Orange dye also stains glycoproteins.
- **High selectivity for proteins.** Coomassie Fluor™ Orange protein gel stain detects a variety of proteins down to ~6500 daltons without staining nucleic acid or lipopolysaccharide contaminants that are sometimes found in protein preparations derived from cell or tissue extracts.

Coomassie Fluor™ Orange protein gel stain is not recommended for staining proteins in 2D, IEF or non-denaturing gels; for these applications we recommend our SYPRO® Ruby protein gel stain (S12000, S12001, S21900).

Rhinohide™ Polyacrylamide Gel Strengthener

Rhinohide™ polyacrylamide gel strengthener improves upon classic polyacrylamide gel technology by making gels much stronger, providing easier handling and much greater resistance to tearing without adverse side effects (Figure 9.3.19). Rhinohide™ polyacrylamide gel strengthener is highly recommended for low-percentage gels, large-format gels and gels subject to multiple staining and handling steps, and it is compatible with fluorescent protein stains as well as silver and Coomassie stains.

SDS-polyacrylamide gels supplemented with Rhinohide™ polyacrylamide gel strengthener exhibit resolution capabilities comparable to traditional SDS-polyacrylamide gels, with clear, focused bands and without the undesirable side effects common with other gel strengtheners. For example, film-backed gels and polyester fabric-reinforced gels interfere with blotting techniques and can negatively affect protein staining. Alternatively, strengthening gels by the addition of pre-formed polymers causes turbidity and can produce serious spot-morphology artifacts, such as the distortion of high molecular weight bands or doubling of protein spots in the molecular weight dimension of 2D gels.¹⁸ Rhinohide™ polyacrylamide gel strengthener produces gels with excellent transparency, providing exceptional image viewing and scanning of fluorescently stained gels with minimal background staining. We offer a concentrated form of the Rhinohide™ polyacrylamide gel strengthener (R33400) for adding to existing stock solutions of acrylamide/bis-acrylamide (37.5:1). Because pre-stained proteins, such as pre-stained molecular weight markers, will not migrate correctly in acrylamide gels containing the Rhinohide™ polyacrylamide gel strengthener, we recommend using only unstained proteins as markers.

Figure 9.3.17 Protein molecular weight standards (in nanograms) were separated on a 12% SDS-polyacrylamide gel and then stained with Coomassie Fluor™ Orange protein gel stain (C33250, C33251). The colors have been digitally reversed.

Figure 9.3.18 Fluorescence excitation and emission spectra of the Coomassie Fluor™ Orange protein gel stain (C33250, C33251) in a solution of 150 µg/mL bovine serum albumin (BSA) with 0.05% SDS.

Figure 9.3.19 Demonstration of the strength and durability of gels made with the Rhinohide™ polyacrylamide gel strengthener (R33400).

SYPRO® Ruby Protein Blot Stain

To characterize specific proteins in complex mixtures, proteins are frequently separated by electrophoresis, then blotted onto nitrocellulose or PVDF (poly(vinylidene difluoride)) membranes (blots) for immunostaining³⁸ (western blotting), glycoprotein staining, sequencing or mass spectrometry. Total-protein stains provide valuable information about the protein samples on blots, making it possible to assess the efficiency of protein transfer to the blot, detect contaminating proteins in the sample and compare the sample with molecular weight standards. For blots of 2D gels, staining of the entire protein profile makes it easier to localize a protein to a particular spot in the complex protein pattern. The superior properties of our fluorescent and luminescent protein stains, compared with conventional colorimetric stains, make it possible to quickly and easily obtain this information without running duplicate gels. Our luminescent and

Figure 9.3.20 Protein detection with SYPRO® Ruby protein blot stain (S11791). Samples of protein molecular weight standards containing a twofold dilution series of α -tubulin, starting with 1 μ g of tubulin in the left-most lane, were run on an SDS-polyacrylamide gel, blotted onto a PVDF membrane and stained with SYPRO® Ruby protein blot stain.

fluorescent protein staining technology can also be combined with fluorescent reagents for glycoprotein and phosphoprotein detection, which are described in detail in Section 9.4, to create multiparameter staining for multiplex analyses.

SYPRO® Ruby protein blot stain^{3,16,39,40} (Table 9.3) is designed to provide fast and highly sensitive detection of proteins blotted onto membranes, making it easy to assess the efficiency of protein transfer to the blot and to determine if lanes are loaded equally⁴¹ (Figure 9.3.20). Because the stain does not covalently alter the proteins, it can be used to locate proteins on blots before sequencing or mass spectrometry.^{4,39} It can also be used before chromogenic, fluorogenic or chemiluminescent immunostaining procedures to locate molecular weight markers and visualize the total-protein profile in the sample.³⁹ Furthermore, the stain does not interfere with subsequent identification techniques, minimizing the need to run duplicate gels, vastly simplifying the comparison of total protein and target protein on western blots, and allowing precise localization of the target protein relative to other proteins on electroblots of 2D gels. SYPRO® Ruby protein blot stain is also compatible with our Pro-Q® Emerald glycoprotein blot stains for glycoproteins⁴² (Section 9.4). The superior properties of SYPRO® Ruby protein blot stain, as compared with conventional protein blot stains, make it possible to routinely stain blots for total protein before continuing with specific protein detection techniques. SYPRO® Ruby protein blot stain^{3,10,16,39,40} (S11791) combines the following superior staining characteristics:

- **High sensitivity.** SYPRO® Ruby protein blot stain can detect as little as 0.25–1 ng protein/mm² (~2–8 ng/band) blotted onto PVDF or nitrocellulose membranes after only 15 minutes of staining³⁹ (Figure 9.3.20). This sensitivity on blots is far better than that of colorimetric stains, such as Ponceau S, amido black or Coomassie brilliant blue, and rivals the best colloidal gold blot-staining techniques (Figure 9.3.21).

Figure 9.3.21 Comparison of commonly used stains for proteins on blots. Twofold serial dilutions of protein molecular weight standards ranging from 2000 to 1 ng/band were run on six identical SDS-polyacrylamide gels and blotted to PVDF membrane. The membranes were then stained with A) Ponceau S stain, B) Coomassie brilliant blue stain, C) colloidal silver stain, D) amido black stain, E) colloidal gold stain or F) SYPRO® Ruby protein blot stain (S11791).

- **Rapid total-protein staining procedure.** The SYPRO® Ruby protein blot-staining protocol takes less than an hour—including fixation and wash steps—and maximum sensitivity is achieved after only 15 minutes of dye staining, even for some peptides as small as seven amino acids. In contrast, gold or silver staining procedures may require overnight incubations to achieve maximum sensitivity and usually include extensive wash procedures that must be carefully timed.
- **Compatibility with western blot protocols.** Staining the total-protein profile on the blot minimizes guesswork about transfer efficiency and removes the need to run two gels for comparison of total and target protein.⁴¹ SYPRO® Ruby protein blot stain is gentle and, unlike colorimetric or colloidal gold blot stains, does not interfere with subsequent colorimetric or chemiluminescent immunodetection of proteins on western blots.³⁹
- **Compatibility with standard microsequencing and mass spectrometry protocols.** Whereas colloidal gold, Coomassie brilliant blue and amido black staining can interfere with post-staining analysis,⁴³ SYPRO® Ruby protein blot stain binds noncovalently to proteins and is thus fully compatible with Edman sequencing or mass spectrometry.^{4,39}

SYPRO® Ruby protein blot stain is based on an organometallic ruthenium complex. Because the ruthenium complex has dual-excitation maxima (Figure 9.3.7), the dye exhibits luminescence upon excitation with either UV or visible light. This property makes it possible to visualize the luminescence with many types of instruments, including UV epi-illumination sources, UV or blue-light transilluminators and a variety of laser-scanning instruments, including those with excitation light at 450 nm, 473 nm, 488 nm or 532 nm. Also, SYPRO® Ruby dye-stained proteins can be indirectly excited by the chemiluminescence of the high-energy intermediate produced in the reaction of bis-(2,4,6-trichlorophenyl) oxalate (TCPO) with H₂O₂.⁴⁴ The red luminescence of the ruthenium complex has a peak at ~618 nm that is well separated from these excitation peaks, minimizing the amount of background signal seen from the excitation source. The staining signal can be documented using Polaroid® 667 black-and-white print film and a SYPRO® photographic filter (S6656; Figure 9.3.15), using a CCD-based imaging system equipped with a 600 nm bandpass or 490 nm longpass filter, or by using the appropriate filter set and software in a laser scanner. SYPRO® Ruby protein blot stain has exceptional photostability, allowing long exposure times for maximum sensitivity.

SYPRO® Ruby protein blot stain (S11791) is supplied as a 1X staining solution, which is sufficient for staining ~1600 cm² of blotting membrane, and is accompanied by a detailed protocol for its use.

Protein Detection on Microarrays

SYPRO® Ruby Protein Blot Stain for Reversible Protein Detection on Microarrays

We have found that SYPRO® Ruby protein blot stain (S11791) performs particularly well when staining proteins on PVDF microarrays for quality control and normalization purposes.⁴⁵ SYPRO® Ruby protein blot stain shows good sensitivity on protein microarrays (Figure 9.3.22) and should be very useful for staining proteins before exposing the microarray to the sample. The stain washes off PVDF membranes very easily under conditions used with typical western blot blocking buffers.

Reactive Fluorescent Dyes for Permanent Protein Detection on Microarrays

The BODIPY® reactive dyes described in Section 1.4 label amine groups (predominantly lysine residues) on proteins. As compared to the reversible SYPRO® blot stains described above, the amine-reactive BODIPY® FL-X succinimidyl ester (D6102) shows even greater sensitivity for microarray staining (Figure 9.3.22), making it useful for quality control testing or as an internal normalization standard. Both BODIPY® FL-X succinimidyl ester and the red-fluorescent BODIPY® TR-X succinimidyl ester (D6116) are particularly effective general stains for proteins on PVDF membranes^{10,46} (Table 9.3).

This unique method of staining total protein on blots with the reactive BODIPY® dyes has an approximately 30-fold linear dynamic range (Figure 9.3.23), although the absolute intensity between proteins may vary somewhat with the nature of the protein. Reactive BODIPY® dye-based staining is designed to be rapid, simple and highly sensitive, permitting detection of as little as 4 ng of a protein per band in about an hour. Because the reactive dyes form a

Figure 9.3.22 Protein detection on microarrays using BODIPY® FL-X SE or SYPRO® Ruby protein blot stain. Bovine serum albumin was arrayed onto a PVDF membrane using a Packard BioScience PiezoTip dispenser. The array contains 72 spots with 12 dilutions of the dye, in replicates of 6, ranging from 666–0.325 pg per spot. The proteins were stained with either BODIPY® FL-X SE (D6102, left) in sodium borate buffer, pH 9.5, or with SYPRO® Ruby protein blot stain (S11791, right). Arrays were imaged on a ScanArray® 5000XL microarray analysis system (Packard BioScience) and pseudocolored such that the different colors indicate different signal intensities. The sensitivity limit was 1.3–2.6 pg of protein in a 175 µm spot for the BODIPY® FL-X SE detection technique and 104 pg of protein per 175 µm spot for the SYPRO® Ruby protein blot stain technique.

Figure 9.3.23 Linear dynamic range of detection for BODIPY® FL-X succinimidyl ester, used as a blot stain. A two-fold dilution series of molecular weight markers (P6649) was loaded onto a gel, electrophoresed and electroblotted to a PVDF membrane. The proteins on the blot were then stained with BODIPY® FL-X succinimidyl ester (D6102). The fluorescence intensity for one of the proteins (carbonic anhydrase) was measured and plotted against the amount of protein loaded in the lane. The result shows an approximately linear dynamic range from 4 ng to 125 ng.

Figure 9.3.24 Dual labeling of proteins on a western blot. Proteins from a rat fibroblast lysate were separated by 2D gel electrophoresis and blotted onto a PVDF membrane. The proteins are acidic to basic (left to right) and high to low molecular weight (top to bottom). After electrophoresis, the blot was stained with BODIPY[®] FL-X succinimidyl ester (green, D6102) to detect total protein. The blot was then incubated with an anti- α -tubulin antibody (A11126), followed by the alkaline phosphatase conjugate of goat anti-mouse IgG antibody (G21060). Finally, the blot was stained with DDAO phosphate (red, D6487), which produces a red-fluorescent product in the presence of alkaline phosphatase. The fluorescent signals were visualized using UV epi-illumination. The signals were documented separately using appropriate photographic filters (A, B), and the resulting images overlaid (C).

covalent bond with the protein, the staining is permanent and lasts through any subsequent blot manipulations. The covalent modification appears to minimally interfere with subsequent immunostaining, as we have successfully performed two-color labeling with reactive BODIPY[®] dyes and either fluorogenic immunostains or glycoprotein stains and visualized both stains simultaneously (Figure 9.3.24). Simultaneous dual labeling of a sample simplifies localization of a specific protein with respect to other proteins in the sample, particularly on electroblots of 2D gels, pairs of which are difficult to align. Note that because reaction of the dye covalently modifies the protein at random locations, staining by the amine-reactive BODIPY[®] dyes may complicate or preclude subsequent analysis by mass spectrometry or microsequencing.

Protein Detection in Capillary Electrophoresis

Capillary electrophoresis (CE) is an exceptionally powerful tool for the resolution of biomolecules.^{47,48} Fluorescent detection of proteins that are separated by capillary electrophoresis can occur either during the run—the more common procedure—or subsequent to the separation on isolated fractions. When detected during the electrophoretic separation, the protein is either derivatized with a fluorescent reagent prior to the separation or labeled with a fluorescent dye that is incorporated into the running medium. In general, the same reagents may be useful for fluorometric detection of peptides and proteins that are separated by high-performance liquid chromatography (HPLC). In addition to the total-protein staining techniques described below, many selective staining techniques, such as the use of BODIPY[®] FL GTP- γ -S (G22183, Section 17.3) to detect GTP-binding proteins,⁴⁹ can be applied to proteins separated by capillary electrophoresis.

Use of SYPRO[®] Dyes for Capillary Electrophoresis

SDS-capillary gel electrophoresis (SDS-CGE) separates proteins based on principles similar to those of standard slab-gel electrophoresis, but with the advantages of faster times, higher resolution and greater sensitivity. The use of online detection by laser-induced fluorescence (LIF) increases the sensitivity several orders of magnitude over UV detection, eliminates the time spent staining and photographing the gel and allows for the possibility of automated sample processing. SDS-CGE analyzed by LIF is widely used for the separation and identification of DNA fragments and has increased the efficiency of genomics, DNA typing and forensics laboratories.^{47,48} SDS-CGE promises to be just as useful for proteomics laboratories and other laboratories that require characterization of a large number of protein samples.

For SDS-CGE of protein samples, the amine groups of lysine residues and the N-terminus of the proteins are typically derivatized with a fluorescent or fluorogenic dye such as the ATTO-TAG[™] CBQCA^{50,51} (A2333, A6222) or ATTO-TAG[™] FQ⁵²⁻⁵⁵ (A2334, A10192) reagents before separation in the capillary. The derivatized proteins are then coated with SDS and travel through the capillary gel towards the positive electrode based on their size, with smaller proteins traveling faster. The derivatized proteins are detected by fluorescence emitted as they pass a laser that excites the fluorophores.

One disadvantage of this labeling technique is that the proteins generally contain multiple amine groups, each of which can react with the derivatization reagent. Typically, only a few of the amine groups on each protein molecule react, and the result is an enormous number of different derivatives, creating broad peaks that may be difficult to correlate with the original protein's structure or abundance.⁵⁵ In addition, variations between runs make it difficult to reproducibly estimate molecular weights. In contrast, use of SYPRO[®] Red protein gel stain (S6653, S6654) to prestain SDS-coated proteins allows more accurate determination of molecular weights because the proteins are relatively uniformly coated with SDS and the dye. Staining the SDS-coated proteins with SYPRO[®] Red protein gel stain leads to molecular weight determinations similar in accuracy to those achieved with polyacrylamide slab gels, with a limit of detection estimated to exceed the detection limit of silver staining in slab gels.⁵⁶ The NanoOrange[®] reagent (N6666, Section 9.2) is also reported to be an effective reagent for detecting proteins that have been separated by microchip capillary electrophoresis.⁵⁷⁻⁵⁹

Protein Derivatization Reagents

Several of the same reagents that were described in Section 9.2 for protein quantitation in solution are also useful for peptide and protein derivatization, either prior to or following separation by capillary electrophoresis. However, chemical derivatization prior to separation is likely to change the electronic charge and always changes the mass of the protein. Furthermore, incomplete derivatization of amines or thiols on the protein can lead to a pure protein resolving into multiple species in the electrophoretogram.

In an improved procedure for fluorescent analysis of peptides by capillary electrophoresis, Zhou and colleagues⁶⁰ modified all α - and ϵ -amino groups of the peptide with phenyl isothiocyanate. Following one cycle of Edman degradation, the single free α -amino group was modified with fluorescent reagents to give a homogeneous, dye-labeled peptide.

The preferred reagents for derivatizing amine residues in proteins either prior to or following electrophoretic separation are those that are essentially nonfluorescent until reacted with the protein. These include:

- ATTO-TAG™ CBQCA, which is available in the ATTO-TAG™ CBQCA Amine-Derivatization Kit (A2333) and as a stand-alone reagent (A6222). ATTO-TAG™ CBQCA reacts with primary amines to form highly fluorescent isoindoles^{50,61–69} and has been extensively used for the derivatization of amino acids,^{51,61,70–72} peptides^{63,73–76} and carbohydrates^{62,64,67,77–81} prior to capillary electrophoretic separation. ATTO-TAG™ CBQCA has been used to derivatize a fusion protein expressed in the bacterium *Escherichia coli* before purification by capillary zone electrophoresis. After purification, the fluorescent isoindole can be removed by acid treatment to allow sequencing of the purified protein.⁵⁰
- ATTO-TAG™ FQ (3-(2-furoyl)quinoline-2-carboxaldehyde), which is available in our ATTO-TAG™ FQ Amine-Derivatization Kit (A2334) and as a stand-alone reagent (A10192). ATTO-TAG™ FQ has been used as a protein detection reagent in capillary electrophoresis.^{82–85} It has been reported that ATTO-TAG™ FQ can detect as little as 200 attomoles of a protein by capillary electrophoresis.⁸⁴ Excitation of amine derivatives of ATTO-TAG™ FQ by the 488 nm spectral line of the argon-ion laser is more efficient than that of ATTO-TAG™ CBQCA derivatives. A report⁸⁵ describes the solid-phase derivatization of dilute peptide solutions (10^{-8} M) that have been immobilized on Immobilon® CD membranes. This technique permits the quantitative derivatization and analysis by capillary electrophoresis of only a few picomoles of the analyte.
- Fluorescamine (F2332, F20261), a nonfluorescent reagent that rapidly reacts with amines to give a fluorescent product. Fluorescamine has been used for solution quantitation of proteins and peptides (Section 9.2). It is also useful as a peptide and protein detection reagent for capillary electrophoresis.^{76,86,87} Use of fluorescamine to derivatize a standard protein of known molecular weight together with use of the ATTO-TAG™ FQ reagent to derivatize the sample protein allows the sample to be run simultaneously with the standard, improving the accuracy of molecular weight determination.⁸³ Chiral separation of fluorescamine-labeled amino acids has been optimized using capillary electrophoresis in the presence of hydroxypropyl- β -cyclodextran, a method designed for use in extraterrestrial exploration on Mars.⁸⁸
- Dialdehydes OPA and NDA (P2331MP, N1138), which react with amines in the presence of a nucleophile to give fluorescent products. These inexpensive reagents have been used for capillary electrophoresis of peptides and proteins.^{89–96}

Chapter 1 describes a variety of other amine-reactive reagents that have been used or may be useful for peptide and protein detection in capillary electrophoresis, including dansyl chloride⁹⁷ (D21), NBD chloride (C20260), NBD fluoride (F486), FITC^{60,98} (F143), Pacific Blue™ succinimidyl ester (P10163)⁹⁹ and other common reagents described in Section 1.8.

Derivatization reagents that react with thiols or other functional groups have also been used for protein detection in capillary electrophoresis. Thiol-reactive reagents that are essentially nonfluorescent until conjugated to thiols, such as the coumarin maleimides CPM and DACM (D346, D10251), monobromobimane (M1378, M20381) and *N*-(1-pyrene)maleimide (P28), should work well in this application and are described in Section 2.3. Although intrinsically fluorescent, BODIPY® iodoacetamides and maleimides (Section 2.2) have also been used to detect thiol-containing proteins in SDS gels and by reverse-phase HPLC,¹⁰⁰ and 5-iodoacetamidofluorescein (I30451, Section 2.2) has been used to label proteins for analysis by capillary electrophoresis.¹⁰¹

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Spectral data are for the reaction product with glycine in the presence of cyanide. Unreacted reagent in MeOH: Abs = 254 nm (EC = 46,000 cm⁻¹M⁻¹), nonfluorescent.
- ND = not determined.
- Solubility in methanol is improved by addition of base (e.g., 1–5% (v/v) 0.2 M KOH).
- Data represent the reactive dye component of this labeling kit.
- Spectral data are for the reaction product with glycine in the presence of cyanide. Unreacted reagent in MeOH: Abs = 282 nm (EC = 21,000 cm⁻¹M⁻¹), nonfluorescent.
- Fluorescamine spectra are for the reaction product with butylamine. The fluorescence quantum yield and lifetime of the butylamine adduct in EtOH are 0.23 and 7.5 nanoseconds, respectively. (Arch Biochem Biophys (1974) 163:390) The unreacted reagent is nonfluorescent (Abs = 234 nm, EC = 28,000 cm⁻¹M⁻¹ in MeCN).
- This product is specified to equal or exceed 98% analytical purity by HPLC.
- Spectral data are for the reaction product with glycine in the presence of cyanide, measured in pH 7.0 buffer/MeCN (40:60). (Anal Chem (1987) 59:1102) Unreacted reagent in MeOH: Abs = 279 nm (EC = 5500 cm⁻¹M⁻¹), Em = 330 nm.
- Spectral data are for the reaction product of P2331MP with alanine and 2-mercaptoethanol. The spectra and stability of the adduct depend on the amine and thiol reactants. (Biochim Biophys Acta (1979) 576:440) Unreacted reagent in H₂O: Abs = 257 nm (EC = 1000 cm⁻¹M⁻¹).
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- The active ingredient of this product is an organic dye with MW <1000. The exact MW and extinction coefficient values for this dye are proprietary.
- Abs and Em values are for the dye complexed with bovine serum albumin (H₂O/BSA).
- This product is supplied as a ready-made aqueous staining solution.
- The active ingredient of this product is an organometallic complex with MW <1500. The exact MW value and extinction coefficient of the complex are proprietary.
- SYPRO® Ruby protein gel stain also has an absorption peak at 278 nm with about 4-fold higher EC than the 462 nm peak.

PRODUCT LIST 9.3 PROTEIN DETECTION ON GELS, BLOTS AND ARRAYS

Cat. No.	Product	Quantity
A2333	ATTO-TAG™ CBQCA Amine-Derivatization Kit	1 kit
A6222	ATTO-TAG™ CBQCA derivatization reagent (CBQCA; 3-(4-carboxybenzoyl)quinoline-2-carboxaldehyde)	10 mg
A2334	ATTO-TAG™ FQ Amine-Derivatization Kit	1 kit
A10192	ATTO-TAG™ FQ derivatization reagent (FQ; 3-(2-furoyl)quinoline-2-carboxaldehyde)	10 mg
C33250	Coomassie Fluor™ Orange protein gel stain *ready-to-use solution*	1 L
C33251	Coomassie Fluor™ Orange protein gel stain *ready-to-use solution* *bulk packaging*	5 L
D6102	6-((4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-propionyl)amino)hexanoic acid, succinimidyl ester (BODIPY® FL-X, SE)	5 mg
D6116	6-(((4-(4,4-difluoro-5-(2-thienyl)-4-bora-3a,4a-diaza-s-indacene-3-yl)phenoxy)acetyl)amino)hexanoic acid, succinimidyl ester (BODIPY® TR-X, SE)	5 mg
E33075	Electrophoretic Mobility-Shift Assay (EMSA) Kit *with SYBR® Green and SYPRO® Ruby EMSA stains* *10 minigel assays*	1 kit
F2332	fluorescamine	100 mg
F20261	fluorescamine *FluoroPure™ grade*	100 mg
N1138	naphthalene-2,3-dicarboxaldehyde (NDA)	100 mg
P2331MP	o-phthaldialdehyde (OPA) *high purity*	1 g
P6649	protein molecular weight standards *broad range* *200 gel lanes*	400 µL
R33400	Rhinohide™ polyacrylamide gel strengthener concentrate *sufficient additive for 1 L of 30% acrylamide/bis-acrylamide (37.5:1)*	200 mL
S6650	SYPRO® Orange protein gel stain *5000X concentrate in DMSO*	500 µL
S6651	SYPRO® Orange protein gel stain *5000X concentrate in DMSO* *special packaging*	10 x 50 µL
S6656	SYPRO® photographic filter	each
S12012	SYPRO® Protein Gel Stain Starter Kit	1 kit
S6653	SYPRO® Red protein gel stain *5000X concentrate in DMSO*	500 µL
S6654	SYPRO® Red protein gel stain *5000X concentrate in DMSO* *special packaging*	10 x 50 µL
S11791	SYPRO® Ruby protein blot stain *10–40 blots*	200 mL
S12001	SYPRO® Ruby protein gel stain	200 mL
S12000	SYPRO® Ruby protein gel stain	1 L
S21900	SYPRO® Ruby protein gel stain *bulk packaging*	5 L
S12010	SYPRO® Tangerine protein gel stain *5000X concentrate in DMSO*	500 µL

9.4 Detecting Protein Modifications

Click-iT® Reagents for Detecting Protein Synthesis and Modifications

Click-iT® labeling technology employs a bioorthogonal reactive chemistry for the *in situ* labeling of specific molecular populations, such as proteins that have been newly synthesized or post-translationally modified in some experimental time window of interest. The Click-iT® labeling reaction is based on a copper-catalyzed azide–alkyne cycloaddition^{1,2} and derives its high degree of specificity from the fact that the azide and alkyne reaction partners have no endogenous representation in biological molecules, cells, tissues or model organisms.^{3–5}

Application of this reaction to *in situ* labeling of cells is a two-step process. First, one reaction partner—either an azide or alkyne linked to a "building block" such as an amino acid, monosaccharide, fatty acid, nucleotide or nucleoside—is biosynthetically incorporated. Subsequently, the other reaction partner—the complementary alkyne or azide linked to a fluorescent dye, biotin or other detection reagent—is "clicked" into place in the presence of catalytic copper (I), providing a detection moiety (Figure 9.4.1). One reaction partner must be an azide derivative and the other an alkyne derivative, but either functional moiety can serve as the biosynthetically incorporated molecule or the detection molecule⁶ (e.g., L-azidohomoalanine (AHA) + Alexa Fluor® 488 alkyne is the inverse of the reaction scheme shown in Figure 9.4.1A).

The small size of alkyne and azide tags allows the biosynthetic building blocks to which they are attached to be processed by enzymes, such as aminoacyl tRNA synthetases and nucleotide polymerases, that have poor tolerance for substrates with larger modifications such as fluorescent organic dyes.⁷ Furthermore, the 1,2,3-triazole linkage between

the azide and alkyne reaction partners (Figure 9.4.1) is extremely stable. It is not susceptible to hydrolysis, oxidation or reduction, and it survives ionization in mass spectrometry (MS) analysis. Click-iT® labeling technology and the details of the click reaction are discussed in Section 3.1. For a complete list of azide and alkyne derivatives compatible with Click-iT® labeling technology, see Table 3.1. Here we highlight the azide and alkyne derivatives that can be used for labeling newly synthesized proteins and detecting post-translational protein modifications.

Azide- and Alkyne-Modified Amino Acids

The Click-iT® AHA (L-azidohomoalanine, C10102) and Click-iT® HPG (L-homopropargylglycine, C10186; Figure 9.4.1) reagents are methionine surrogates that provide nonradioactive alternatives to ³⁵S-methionine for pulse-chase detection of protein synthesis and degradation.^{8–11} These amino acid analogs are fed to cultured cells and incorporated into proteins during active protein synthesis. The enzymatically incorporated Click-iT® AHA or Click-iT® HPG is then detected with a fluorescent alkyne or fluorescent azide, respectively, using a Cu(I)-catalyzed click reaction. These Click-iT® reagents provide detection sensitivity comparable to that obtained using the radioactive ³⁵S-methionine method and are compatible with downstream LC-MS/MS and MALDI MS analysis, as well as with total-protein, glycoprotein and phosphoprotein gel stains for differential analyses of newly synthesized protein together with post-translational modifications.

Click-iT® AHA is also available in the Click-iT® AHA Alexa Fluor® 488 Protein Synthesis HCS Assay Kit (C10289), which provides Alexa Fluor® 488 alkyne for detection. Click-iT® AHA has proven to be a successful substitute for methionine in many cell types, including COS-7,

Figure 9.4.1 Click-iT® copper-catalyzed azide–alkyne cycloaddition chemistry applied to detection of **A**) proteins and **B**) carbohydrates. The reaction partners are **A**) L-homopropargylglycine (HPG) and Alexa Fluor® 488 alkyne and **B**) *N*-azidoacetylgalactosamine and Alexa Fluor® 488 alkyne. In both cases, the left-hand partner is a metabolic precursor that can be incorporated into proteins via *de novo* synthesis or post-translational modification pathways.

3T3-L1, HeLa, HEK 293 and Jurkat cells. Note that cells should be labeled in methionine-free media, as methionine is the preferred substrate for methionyl tRNA transferase, and supplemented media (i.e., methionine-free DMEM) should be used in place of HBSS to achieve greater Click-iT® AHA incorporation at lower concentrations.

Azide- and Alkyne-Modified Monosaccharides

The Click-iT® metabolic glycoprotein labeling reagents provide biosynthetic precursors for detecting and characterizing post-translational glycosylation of proteins.^{12–15} Four azide- or alkyne-modified monosaccharides are available for metabolic incorporation into a specific subclass of protein glycan structures:

- Click-iT® GalNAz metabolic glycoprotein labeling reagent (tetraacetylated *N*-azidoacetylglucosamine, C33365; Figure 9.4.1), for labeling *O*-linked glycoproteins
- Click-iT® ManNAz metabolic glycoprotein labeling reagent (tetraacetylated *N*-azidoacetylmannosamine, C33366; Figure 9.4.2), for labeling sialic acid–modified glycoproteins
- Click-iT® GlcNAz metabolic glycoprotein labeling reagent (tetraacetylated *N*-azidoacetylglucosamine, C33367; Figure 9.4.3), for labeling *O*-linked *N*-acetylglucosamine (*O*-GlcNAc)–modified glycoproteins
- Click-iT® fucose alkyne (tetraacetylfucose alkyne, C10264; Figure 9.4.4), for labeling fucosylated proteins

Cultured cells are simply incubated with the modified sugars for 2–3 days or until cells reach the appropriate density. The acetyl groups improve cell permeability of the modified sugars and are removed by nonspecific intracellular esterases (Figure 9.4.2). The resulting azide- or alkyne-modified sugar is then metabolically incorporated through the permissive nature of the oligosaccharide biosynthesis pathway, yielding functionalized glycoproteins that can be chemoselectively coupled to complementary alkyne- or azide-functionalized fluorophores and biotinylation reagents for detection or affinity capture. We offer three Click-iT® Protein Analysis Detection Kits (C33370, C33371, C33372) described below for the detection of azide-functionalized glycoproteins in 1D or 2D electrophoresis gels or western blots. These labeled glycoproteins are compatible with total-protein, glycoprotein and phosphoprotein gel stains and provide a detection sensitivity of a few hundred femtomoles, allowing an in-depth analysis of low-abundance glycoproteins as well as glycoproteins with a small degree of glycosylation.

Glycoproteins labeled with the Click-iT® labeling and detection reagents are also compatible with downstream LC-MS/MS and MALDI-MS analyses for further identification and characterization. For added convenience, we offer an *O*-GlcNAc peptide LC/MS standard (C33374) from the transcription factor CREB for LC-MS/MS and MALDI-MS analyses of the *O*-GlcNAc posttranslational modification. This peptide is also available together with its phosphorylated counterpart for use as LC/MS standards (C33373) in differential mass spectrometry–based studies of the corresponding modifications, as well as for characterizing differential β -elimination/addition conditions.

Figure 9.4.2 Metabolic incorporation of tetraacetylated azido sugars.

Figure 9.4.3 Click-iT® GlcNAz metabolic glycoprotein labeling reagent (tetraacetylated *N*-azidoacetylglucosamine for labeling *O*-linked *N*-acetylglucosamine (*O*-GlcNAc)–modified glycoproteins; C33367).

Figure 9.4.4 Click-iT® fucose alkyne (tetraacetylfucose alkyne) (C10264).

Click-iT® O-GlcNAc Enzymatic Labeling System

We also offer the the Click-iT® O-GlcNAc Enzymatic Labeling System for *in vitro* enzyme-mediated *N*-azidoacetylgalactosamine labeling of O-GlcNAc–modified glycoproteins^{16,17} (C33368). Proteins are enzymatically labeled using the permissive mutant β -1,4-galactosyltransferase (Gal-T1, Y289L), which transfers azido-modified galactose (GalNAz) from UDP-GalNAz to O-GlcNAc residues on the target proteins. Target proteins can then be detected using an alkyne-derivatized fluorophore or one of the Click-iT® Protein Analysis Detection Kits described below. Using the Click-iT® O-GlcNAc Enzymatic Labeling System in conjunction with the Click-iT® Tetramethylrhodamine (TAMRA) Protein Analysis Detection Kit, we have detected as little as 1 picomole of α -crystallin, a protein which is only 2–10% O-GlcNAc modified.

Each Click-iT® O-GlcNAc Enzymatic Labeling System provides:

- UDP-GalNAz
- Gal-T1 (Y289L)
- Click-iT® O-GlcNAc enzymatic labeling buffer
- MnCl₂
- α -crystallin, for use as a positive control
- Detailed labeling protocols

Azide-Modified Isoprenoids and Fatty Acids

We offer several azide-modified isoprenoids and fatty acids, including:

- Click-iT® farnesyl alcohol, azide (C10248), for identifying farnesylated proteins
- Click-iT® geranylgeranyl alcohol, azide (C10249), for identifying geranylgeranylated proteins
- Click-iT® palmitic acid, azide (15-azidopentadecanoic acid, C10265), for identifying protein fatty acylation
- Click-iT® myristic acid, azide (12-azidododecanoic acid, C10268), for identifying protein fatty acylation

These azide-functionalized isoprenoids and fatty acids enable detection of post-translational lipidation of proteins by in-gel fluorescence scanning, fluorescence microscopy and flow cytometry.^{18–20}

Azide- and Alkyne-Derivatized Dyes and Biotinylation Reagents

We offer a rich selection of azide- and alkyne-derivatized fluorescent dyes for coupling to complementary azide- and alkyne-functionalized biomolecules (Table 3.1, Section 3.1), including:

- Alexa Fluor® 488 azide (A10266, Figure 9.4.1) and alkyne (A10267, Figure 9.4.1)
- Alexa Fluor® 555 azide (A20012) and alkyne (A20013)
- Alexa Fluor® 594 azide (A10270) and alkyne (A10275)
- Alexa Fluor® 647 azide (A10277) and alkyne (A10278)
- Oregon Green® 488 azide (O10180) and alkyne (O10181)
- Tetramethylrhodamine (TAMRA) azide (T10182) and alkyne (T10183)
- Biotin azide (B10184) and alkyne (B10185)

Antibodies to Oregon Green® 488, tetramethylrhodamine and Alexa Fluor® 488 dyes (Section 7.4) and Tyramide Signal Amplification (TSA™) Kits (Section 6.2) are available to provide signal amplification if necessary.²¹ The biotin azide and alkyne reagents facilitate western blotting applications and streptavidin enrichment in combination with our streptavidin and CaptAvidin™ agarose affinity matrices^{14,22,23} (S951, C21386; Section 7.6).

Click-iT® Protein Analysis Detection Kits

In addition to azide- and alkyne-derivatized dyes and biotinylation reagents, we offer three Click-iT® Protein Analysis Detection Kits (C33370, C33371, C33372) that provide labeled alkynes for the detection of azide-labeled biomolecules. These Click-iT® Protein Analysis Detection Kits provide sufficient reagents for 10 labeling reactions based on the provided protocol and include:

- TAMRA alkyne (in C33370), Dapoxyl® alkyne (in C33371) or biotin alkyne (in C33372)
- Click-iT® reaction buffer
- CuSO₄
- Click-iT® reaction buffer additives
- Detailed labeling protocols

Click-iT® Reaction Buffers

For added convenience, we offer Click-iT® Reaction Buffer Kits for protein or cell samples labeled with an azide- or alkyne-tagged biomolecule. The Click-iT® Cell Reaction Buffer Kit (C10269) includes sufficient reagents to perform 50 reactions based on a 0.5 mL reaction volume for subsequent analyses by flow cytometry, fluorescence microscopy or high-content screening (HCS). The Click-iT® Protein Reaction Buffer Kit (C10276) includes everything required for click coupling to functionalized proteins for subsequent standard protein biochemical analyses (e.g., western blots or mass spectrometry).

Pro-Q® Diamond Phosphoprotein Stain for Gels and Blots

We have developed a suite of compatible methodologies for the differential staining of specific proteins (phosphoproteins, glycoproteins or membrane proteins) and the total-protein profile in two or more visually distinguishable colors, producing a more complete picture of the proteome. This set of protein stains not only offer the capacity for the simultaneous detection of multiple protein targets in a single sample, but also provides a combination of high sensitivity and simplicity that can streamline protocols in 1D and 2D polyacrylamide gels or on blots.

The Pro-Q® Diamond phosphoprotein gel stain, Pro-Q® Emerald glycoprotein gel stains and SYPRO® Ruby protein gel stain—which we have optimized to complement each other in selectivity, sensitivity and staining protocols—can be used in serial detection of phosphoproteins, glycoproteins and total proteins on a single protein sample separated by 1D or 2D gel electrophoresis (Figure 9.4.5). Our Rhinohide™ polyacrylamide gel strengthener (R33400, Section 9.3) greatly improves the strength of any polyacrylamide gel, making it

easy to perform these multiple staining procedures without special gel handling. After each staining step, an image of the gel is collected. Once collected, the three images can be overlaid in any combination for analysis of phosphorylation, glycosylation and total-protein expression. Because all three stains are used on the same gel, unambiguous spot matching of phosphoproteins and glycoproteins is made simple by direct comparison with the total-protein profile provided by the SYPRO® Ruby protein gel stain. This simultaneous measurement of several variables allows for perfect spatial registration of signals and increases the amount of data that can be collected in a single experiment, leading to more controlled experiments, more accurate data comparisons and fewer ambiguities.

Pro-Q® Diamond Phosphoprotein Gel Stain and Destain

Pro-Q® Diamond phosphoprotein gel stain^{24–27} is a breakthrough technology that provides a simple, direct method for selectively staining O-linked phosphoproteins in polyacrylamide gels (Figure 9.4.6). It is ideal for the identification of kinase targets in signal transduction pathways and for phosphoproteomic studies. This proprietary fluorescent stain allows direct, in-gel detection of phosphate groups attached to tyrosine, serine or threonine residues. The Pro-Q® Diamond phosphoprotein gel stain can be used with standard SDS-polyacrylamide

Figure 9.4.6 Selectivity of the Pro-Q® Diamond phosphoprotein gel stain (P33300, P33301, P33302) for phosphoproteins. A polyacrylamide gel containing various proteins was stained with A) Pro-Q® Diamond phosphoprotein gel stain, followed by B) SYPRO® Ruby protein gel stain. This gel shows a nonphosphorylated protein, lysozyme (lanes 3 and 4), as well as several phosphoproteins, α -casein (lanes 1 and 2), ovalbumin (lanes 5 and 6) and pepsin (lanes 7 and 8), before (even lanes) and after (odd lanes) treatment with phosphatases. Loss of Pro-Q® Diamond staining indicates loss of all phosphates from pepsin, partial loss of phosphates from α -casein and ovalbumin and no change in the nonphosphorylated protein lysozyme.

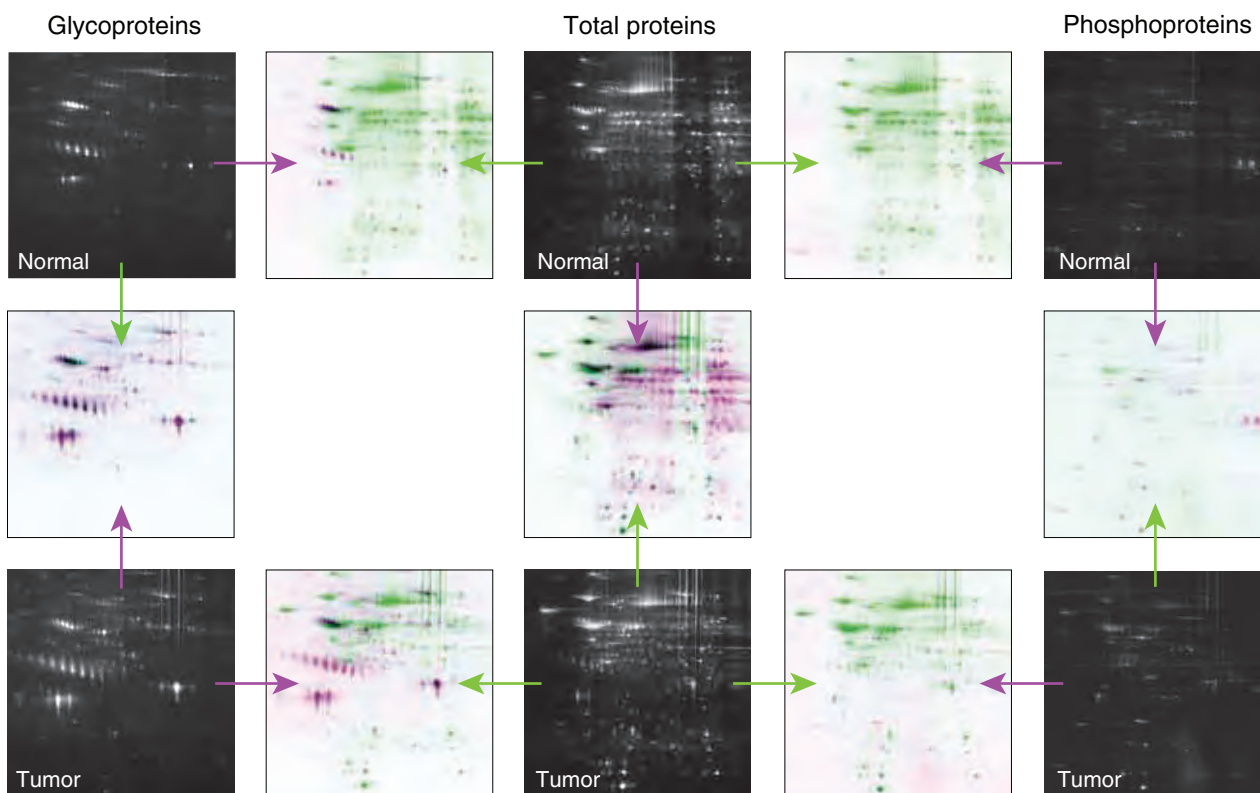

Figure 9.4.5 An overview of the Multiplexed Proteomics® approach. Images collected after each staining step can be overlaid in any combination for analysis of protein expression, phosphorylation and glycosylation between samples.

Figure 9.4.7 Visualization of total protein and phosphoproteins in a 2D gel. Proteins from a Jurkat T-cell lymphoma line cell lysate were separated by 2D gel electrophoresis and stained with Pro-Q® Diamond phosphoprotein gel stain (P33300, P33301, P33302, blue) followed by SYPRO® Ruby protein gel stain (S12000, S12001, S21900, red). After each dye staining, the gel was imaged on an FLA-3000 scanner (Fuji®). The digital images were acquired using Z3 software (Compugen), and the resulting composite image was digitally pseudocolored and overlaid.

Figure 9.4.9 Fluorescence excitation and emission spectra of the Pro-Q® Diamond phosphoprotein gel stain (P33300, P33301, P33302).

gels (Figure 9.4.6) or with 2D gels (Figure 9.4.7)—blotting is not required and there is no need for radioisotopes, phosphoprotein-specific antibodies or western blot detection reagents. The simple and reliable staining protocol delivers results in as little as 4 to 5 hours. The stain is also compatible with mass spectrometry, allowing analysis of the phosphorylation state of entire proteomes. The Pro-Q® Diamond phosphoprotein gel stain provides:

- **Simple in-gel detection.** Proteins containing phosphate groups attached to tyrosine, serine or threonine residues can be detected directly in either 1D or 2D polyacrylamide gels after the gel is fixed, stained and destained; no antibodies are required and no blotting is necessary.
- **Selectivity without radioactivity.** The Pro-Q® Diamond phosphoprotein gel stain is a fluorescent stain that selectively detects phosphoproteins; radioisotopes are not used and therefore no radioactive waste is generated.
- **Sensitivity.** The Pro-Q® Diamond phosphoprotein gel stain allows the detection of as little as 1–16 ng of phosphoprotein per band, depending on the phosphorylation level of the protein.

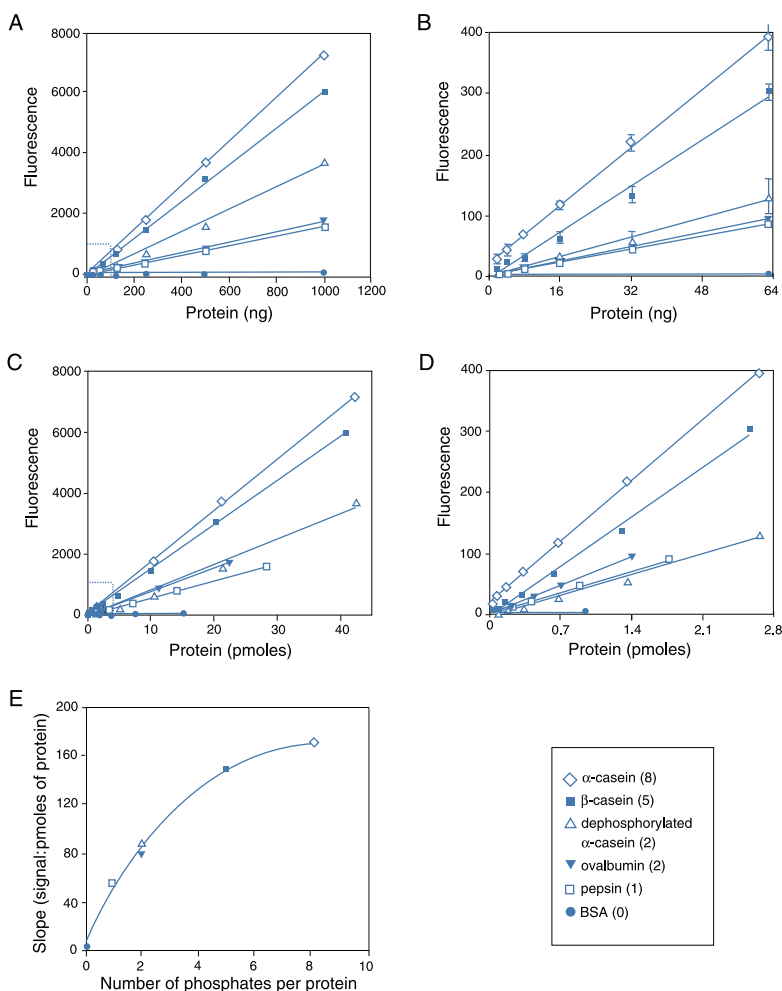

Figure 9.4.8 Sensitivity and linear range of Pro-Q® Diamond phosphoprotein gel stain (P33300, P33301, P33302). Six different proteins were serially diluted and run on separate SDS-polyacrylamide gels, which were then stained with Pro-Q® Diamond phosphoprotein gel stain. The images were documented on a fluorescence imager, and the fluorescence emission from each band was quantitated. The number of known phosphate groups on each protein is indicated in the figure legend. A) Fluorescence emission of the band, plotted as a function of protein amount, in nanograms. B) Magnification of data points in the highlighted box in panel A. C) The fluorescence emission of the band, plotted as a function of picomoles of protein. D) Magnification of the data points in the highlighted box in panel C. E) The slope of the line for each protein in panel C, plotted against the known number of phosphates per protein.

- **Quantitation.** The Pro-Q® Diamond signal for individual phosphoproteins is linear over three orders of magnitude and correlates with the number of phosphate groups (Figure 9.4.8).
- **Compatibility.** Pro-Q® Diamond gel stain (excitation/emission maxima ~555/580 nm; Figure 9.4.9) is compatible with a visible-light-scanning instrument, a visible-light transilluminator or (with reduced sensitivity) a 300 nm transilluminator, as well as with mass spectrometry analysis.
- **Multiplexing capability.** Pro-Q® Diamond gel stain can be used with SYPRO® Ruby protein gel stain (Figure 9.4.6) and Pro-Q® Emerald glycoprotein gel stain on the same gel for multiparameter staining.

The Pro-Q® Diamond phosphoprotein gel stain (Table 9.4) is supplied ready-to-use in three different sizes: a 200 mL size (P33301) suitable for staining approximately four minigels; a 1 L size (P33300) suitable for staining approximately 20 minigels or two large-format gels, e.g., 2D gels; and a 5 L bulk-packaging size (P33302). In addition, we offer Pro-Q® Diamond Phosphoprotein Gel Staining Kits (MPP33300, MPP33301, MPP33302) that include both the Pro-Q® Diamond gel stain and the PeppermintStick™ phosphoprotein molecular weight standards. All products are accompanied by a simple and reliable staining and destaining protocol that delivers results in as little as four to five hours. For convenient destaining, we also offer the Pro-Q® Diamond phosphoprotein gel destaining solution as a ready-to-use solution in either a 1 L (P33310) or 5 L (P33311) size.

Multiplexed Proteomics® Kits for Phosphoprotein and Total-Protein Gel Staining

When used together, the Pro-Q® Diamond phosphoprotein gel stain and the SYPRO® Ruby protein gel stain (S12000, S12001, S21900; Section 9.3) make a powerful combination for proteome analysis. The SYPRO® Ruby dye is a total-protein stain that, like the Pro-Q® Diamond gel stain, is quantitative over three orders of magnitude. Determining the ratio of the Pro-Q® Diamond dye to SYPRO® Ruby dye signal intensities for each band or spot thus provides a measure of the phosphorylation level normalized to the total amount of protein. Using both stains in combination makes it possible to distinguish a low amount of a highly phosphorylated protein from a higher amount of a less phosphorylated protein. To make

this staining more convenient and economical, we offer the Multiplexed Proteomics® Kit #2 with 200 mL of the Pro-Q® Diamond phosphoprotein gel stain and 200 mL of the SYPRO® Ruby protein gel stain (M33306), the Multiplexed Proteomics® Kit #1 with 1 L of each stain (M33305) and the Multiplexed Proteomics® Phosphoprotein Gel Stain Kits (MPM33305, MPM33306), which include the Pro-Q® Diamond phosphoprotein gel stain, SYPRO® Ruby protein gel stain and PeppermintStick™ phosphoprotein molecular weight standards; Table 9.4 summarizes all of our Pro-Q® Diamond gel stain reagents and kits.

Pro-Q® Diamond Phosphoprotein Blot Stain Kit

The Pro-Q® Diamond Phosphoprotein Blot Stain Kit (P33356) provides a simple and quick method for directly detecting phosphoproteins on poly(vinylidene difluoride) (PVDF) or nitrocellulose membranes without the use of radioactivity or antibodies. As with the gel stain, the Pro-Q® Diamond phosphoprotein blot stain detects phosphoserine-, phosphothreonine- and phosphotyrosine-containing proteins, independent of the sequence context of the phosphorylated amino acid residue. Thus, the native phosphorylation levels of proteins from a variety of sources, including tissue specimens and body fluids, can be analyzed. Protein samples are separated by 1D or 2D gel electrophoresis, electroblotted to the membrane, stained and destained using a protocol similar to that typically performed with amido black or Ponceau S staining of total-protein profiles on membranes. After staining, gels are simply imaged using any of a variety of laser scanners, xenon-arc lamp-based scanners or CCD-based imaging devices employing UV transilluminators; the excitation/emission maxima of the Pro-Q® Diamond phosphoprotein blot stain are ~555/580 nm (Figure 9.4.9). The limits of detection for the stain on PVDF membrane blots are typically 8–16 ng of phosphoprotein, with a linear dynamic range of approximately 15-fold. The sensitivity of the Pro-Q® Diamond phosphoprotein blot stain is decreased when using nitrocellulose blots. Each Pro-Q® Diamond Phosphoprotein Blot Stain Kit provides sufficient reagents for staining ~20 minigel electroblots, including:

- Pro-Q® Diamond phosphoprotein blot stain reagent
- Pro-Q® Diamond blot stain buffer
- Detailed protocols for staining and photographing the blot

Table 9.4 Pro-Q® Diamond gel stain reagents and kits.

Product	Cat. No.	Includes		
		Pro-Q® Diamond Phosphoprotein Gel Stain	SYPRO® Ruby Protein Gel Stain	Phosphoprotein MW Standard
Pro-Q® Diamond phosphoprotein gel stain	P33300	1 L		~20 minigels or two large-format gels (e.g., 2D gels)
Pro-Q® Diamond phosphoprotein gel stain	P33301	200 mL		~4 minigels
Pro-Q® Diamond phosphoprotein gel stain	P33302	5 L		~100 minigels or 10 large-format gels
Multiplexed Proteomics® Phosphoprotein Gel Stain Kit #1	M33305	1 L	1 L	~20 minigels or two large-format gels
Multiplexed Proteomics® Phosphoprotein Gel Stain Kit #2	M33306	200 mL	200 mL	~4 minigels
Pro-Q® Diamond Phosphoprotein Gel Staining Kit	MPP33300	1 L		40 µL ~20 minigels or two large-format gels
Pro-Q® Diamond Phosphoprotein Gel Staining Kit	MPP33301	200 mL		40 µL ~4 minigels
Pro-Q® Diamond Phosphoprotein Gel Staining Kit	MPP33302	5 L		40 µL ~100 minigels or 10 large-format gels
Multiplexed Proteomics® Phosphoprotein Gel Stain Kit	MPM33305	1 L	1 L	40 µL ~20 minigels or two large-format gels
Multiplexed Proteomics® Phosphoprotein Gel Stain Kit	MPM33306	200 mL	200 mL	40 µL ~4 minigels

The Pro-Q® Diamond phosphoprotein blot stain binds noncovalently to phosphoproteins and is thus fully compatible with matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) and Edman sequencing. Furthermore, the Pro-Q® Diamond phosphoprotein blot stain is compatible with the standard colorimetric, fluorometric and chemiluminescent detection techniques employed in immunoblotting. This phosphoprotein blot stain may be used in conjunction with the SYPRO® Ruby protein blot stain, a total-protein stain that is quantitative over two orders of magnitude on blots. Using the SYPRO® and Pro-Q® Diamond blot stains in combination makes it possible to distinguish a low amount of a highly phosphorylated protein from a higher amount of a less phosphorylated protein.

PeppermintStick™ Phosphoprotein Molecular Weight Standards

PeppermintStick™ phosphoprotein molecular weight standards are a mixture of phosphorylated and nonphosphorylated proteins with molecular weights from 14,400 to 116,250 daltons. Separation by polyacrylamide gel electrophoresis resolves this mixture into two phosphorylated and four nonphosphorylated protein bands (Figure 9.4.10). These standards serve both as molecular weight markers and as positive and negative controls for our Pro-Q® Diamond phosphoprotein gel stain and other methods that detect phosphorylated proteins. We offer two different unit sizes of the PeppermintStick™ phosphoprotein molecular weight standards: a 40 µL unit size sufficient for 20–40 gel lanes (P27167) and a 400 µL unit size sufficient for 200–400 gel lanes (P33350).

Phosphopeptide Standard Mixture

Formulated especially for MALDI-MS, the phosphopeptide standard mixture (P33357) contains equimolar amounts of three unphosphorylated and four phosphorylated peptides, ranging in mass between 1047 and 2192 and representing phosphoserine (pS), phosphothreonine (pT) and phosphotyrosine (pY) monophosphopeptides, as well as a peptide containing both pT and pY. This mixture is ideal for

Figure 9.4.10 PeppermintStick™ phosphoprotein molecular weight standards (P33350, P27167) separated on a 13% SDS polyacrylamide gel. The markers contain (from largest to smallest) β -galactosidase, bovine serum albumin (BSA), ovalbumin, β -casein, avidin and lysozyme. Ovalbumin and β -casein are phosphorylated. The gel was stained with Pro-Q® Diamond phosphoprotein gel stain (blue) followed by SYPRO® Ruby protein gel stain (red). The digital images were pseudocolored.

use as an internal or external control for LC/MS, MALDI analysis or β -elimination reactions.

Pro-Q® Diamond Phosphoprotein Enrichment Kits

The Pro-Q® Diamond Phosphoprotein Enrichment Kit (P33358) enables efficient, nonradioactive isolation of phosphoproteins from complex cellular extracts. This kit provides resin, reagents and columns designed to isolate phosphoproteins from 0.5–1.0 mg of total cellular protein per column. The column bed volume can be easily scaled up or down depending on the amount of available starting material. The phosphoprotein-binding properties of the resin allow efficient capture of both native and denatured proteins. Therefore, cell or tissue samples can be denatured in lysis buffers and stored in the freezer prior to the phosphoprotein enrichment procedure. Each Pro-Q® Diamond Phosphoprotein Enrichment Kit contains:

- Phosphoprotein Enrichment Module
- Resin (50% v/v slurry)
- Disposable 2 mL columns, 10 columns
- Lysis buffer
- Wash buffer
- Elution buffer
- Vivaspin® filtration concentrators with 10 kDa cut-off polyethersulfone membrane, 10 concentrators
- Protease Inhibitor and Endonuclease Module
- Protease inhibitor
- Endonuclease

Protocols for both undenatured and denatured lysates are provided, and these procedures can be completed in approximately three hours. For added convenience, the Pro-Q® Diamond Phosphoprotein Enrichment and Detection Kit (P33359) provides all the reagents in the Pro-Q® Diamond Phosphoprotein Enrichment Kit, as well as Pro-Q® Diamond phosphoprotein gel stain and PeppermintStick™ phosphoprotein molecular weight markers for detecting phosphoproteins on SDS-polyacrylamide gels.

Pro-Q® Diamond Phosphoprotein/Phosphopeptide Microarray Stain Kit

The Pro-Q® Diamond Phosphoprotein/Phosphopeptide Microarray Stain Kit (P33706) provides a method for selective staining of phosphoproteins or phosphopeptides on microarrays, without the use of antibodies or radioactivity. This kit permits direct detection of phosphate groups attached to tyrosine, serine or threonine residues in a microarray environment and has been optimized for microarrays with acrylamide gel surfaces. Each Pro-Q® Diamond Phosphoprotein/Phosphopeptide Microarray Stain Kit provides:

- Pro-Q® Diamond phosphoprotein/phosphopeptide microarray stain
- Pro-Q® Diamond microarray destain solution
- Microarray staining gasket with seal tabs, 10 chambers
- Slide holder tube, 20 tubes
- Detailed protocols

The Pro-Q® Diamond Phosphoprotein/Phosphopeptide Microarray Stain Kit is useful for identifying kinase targets in signal transduction pathways and for phosphoproteomics studies.

Pro-Q® Diamond LC Phosphopeptide Detection Kit

The Pro-Q® Diamond LC Phosphopeptide Detection Kit (P33203) is designed to provide sensitive and selective fluorescence-based detection of phosphorylated peptides during liquid chromatography separations. The Pro-Q® Diamond LC phosphopeptide detection reagent interacts selectively with phosphoserine-, phosphothreonine- and phosphotyrosine-containing peptides to form highly fluorescent dye-phosphopeptide complexes that elute from an HPLC column with altered retention times, allowing identification and purification of phosphopeptides prior to analysis by mass spectrometry. This kit is ideal for isolating phosphopeptides from chromatographic fractions or from complex peptide mixtures such as the tryptic digest of a phosphoprotein. The Pro-Q® Diamond LC Phosphopeptide Detection Kit provides:

- Pro-Q® Diamond LC phosphopeptide detection reagent
- Concentrated activation buffer
- Positive control phosphopeptide RII
- Kemptide, a negative control peptide
- Detailed protocols

Sufficient reagents are provided for 20 HPLC separations; a single separation will selectively detect 20 picomoles or less of a monophosphorylated peptide using a standard microbore C₁₈ HPLC column.

Other Reagents for Phosphoproteomics

The Antibody Beacon™ Tyrosine Kinase Assay Kit (A35725), described in detail in Section 10.3, provides a simple yet robust solution assay for real-time monitoring of tyrosine kinase activity and the effectiveness of potential inhibitors and modulators. The key to this tyrosine kinase assay is a small-molecule tracer ligand labeled with our bright green-fluorescent Oregon Green® 488 dye. When an anti-phosphotyrosine antibody binds this tracer ligand to form the Antibody Beacon™ detection complex, the fluorescence of the Oregon Green® 488 dye is efficiently quenched. In the presence of a phosphotyrosine-containing peptide, however, this Antibody Beacon™ detection complex is rapidly disrupted, releasing the tracer ligand and relieving its antibody-induced quenching. Upon its displacement by a phosphotyrosine residue, the Oregon Green® 488 dye-labeled tracer ligand exhibits an approximately 4-fold enhancement in its fluorescence, enabling the detection of as little as 50 nM phosphotyrosine-containing peptide with excellent signal-to-background discrimination.

Pro-Q® Glycoprotein Stain Kits for Gels and Blots

Glycoproteins play important roles as cell-surface markers, as well as in cell adhesion, immune recognition and inflammation reactions.²⁸ To facilitate research on glycoproteins, we offer the Pro-Q® Glycoprotein

Stain Kits for Gels and for Blots, which provide extraordinary sensitivity, linearity and ease of use for selective detection of glycoproteins.

Pro-Q® Emerald Glycoprotein Stain Kits for Gels and for Blots

Pro-Q® Emerald 300 and Pro-Q® Emerald 488 Glycoprotein Stain Kits (Table 9.5) provide advanced reagents for detecting glycoproteins in gels and on blots.²⁹ The Pro-Q® Emerald glycoprotein stains react with periodate-oxidized carbohydrate groups, creating a bright green-fluorescent signal on glycoproteins (Figure 9.4.11). The staining procedure requires only three steps: fixation, oxidation and staining—no reduction step is required. Depending on the nature and degree of glycosylation, the Pro-Q® Emerald 300 stain allows the detection of as little as 1 ng of a glycoprotein per band in gels (4 ng/band with the Pro-Q® Emerald 488 stain), making these stains about 50 times more sensitive than the standard periodic acid–Schiff base method using acidic fuchsin dye. Blot staining is not quite as sensitive (2–18 ng of a glycoprotein per band can be detected) and is more time consuming, but provides an opportunity to combine glycoprotein staining with immunostaining or other blot-based detection techniques. The Pro-Q® Emerald 300 stain is best visualized using 300 nm UV illumination, whereas the Pro-Q® Emerald 488 stain is best visualized using visible light with wavelengths near its 510 nm excitation maximum. The Pro-Q® Emerald dye is also used as the detection reagent in our Pro-Q® Emerald 300 Lipopolysaccharide Gel Stain Kit (P20495), which is described in Section 13.3.

Figure 9.4.11 Detecting glycoproteins with Pro-Q® Emerald glycoprotein detection reagents. Oxidation with periodic acid converts *cis*-glycols to dialdehydes, which can then react with the hydrazide-based Pro-Q® Emerald reagents to form a covalent bond.

Table 9.5 Pro-Q® Emerald glycoprotein stain kits for gels and for blots.w

Product	Glycoprotein Stain	Kit Type	Cat. No.
Pro-Q® Emerald 300 Glycoprotein Stain Kits	Pro-Q® Emerald 300 stain, Ex/Em = 280/530 nm	Gel Stain Kit (includes SYPRO® Ruby protein gel stain*)	P21855
		Gel and Blot Stain Kit (does not include a total-protein stain)	P21857
Pro-Q® Emerald 488 Glycoprotein Stain Kit	Pro-Q® Emerald 488 stain, Ex/Em = 510/520 nm	Gel and Blot Stain Kit (does not include a total-protein stain)	P21875

* See Section 9.3 for a description of the SYPRO® Ruby protein gel stain.

Figure 9.4.13 Mobility-shift gel assay using deglycosylating enzymes, stained with the SYPRO® Ruby protein gel stain (top; S12000, S12001, S21900) and Pro-Q® Emerald 300 glycoprotein stain (bottom). The glycoproteins α 1-acidic glycoprotein, fetuin and horseradish peroxidase (HRP) are shown before (lanes 2, 4 and 6, respectively) and after (lanes 3, 5 and 7, respectively) glycosidase treatment. Glycosidase treatment resulted in a mobility shift and loss of green-fluorescent Pro-Q® Emerald 300 staining for α 1-acidic glycoprotein and fetuin, indicating that the carbohydrate groups had been cleaved off. HRP, which contains an α -(1,3)-fucosylated asparagine GlcNac-linkage that is resistant to many glycosidases, showed neither a mobility shift nor a loss of green-fluorescent Pro-Q® Emerald 300 staining. Thus, use of the Pro-Q® Emerald 300 Glycoprotein Stain Kits (P21855, P21857, M33307) identifies glycoproteins that are not susceptible to the glycosidases used in the assay, providing important structural information about the glycoprotein's carbohydrate moiety.

The Pro-Q® Emerald glycoprotein stains can be combined with general protein stains for dichromatic detection of glycoproteins and total proteins in gels²⁹ and on blots, making it much easier to identify the location of the glycoproteins in the total-protein profile (Figure 9.4.12, Figure 9.4.13, Figure 9.4.14, Figure 9.4.15). The SYPRO® Ruby protein gel and blot stains (described in Section 9.3) provide the same sensitivity as silver staining (gels) or colloidal gold staining (blots) but, unlike these chromogenic techniques, do not require formaldehyde or glutaraldehyde, which can produce false-positive responses when glycoproteins are stained. These total-protein stains make it possible to visualize the entire protein complement of a sample and to thus identify contaminating proteins, to compare stained proteins to molecular weight standards and to provide a control for protease contamination in glycosidase mobility-shift experiments. The SYPRO® Ruby protein blot stain is additionally useful for assessing the efficiency of protein transfer to a blot (Figure 9.4.14), which is especially important when working with glycoproteins, because they often transfer poorly to blotting membranes. Proteins labeled with the SYPRO® Ruby total-protein stains exhibit red-orange fluorescence when excited with either a 300 nm UV light source or a laser scanner with a 473, 488 or 532 nm laser light source.

The Pro-Q® Emerald Glycoprotein Stain Kits also include our CandyCane™ molecular weight standards, a mixture of glycosylated and nonglycosylated proteins that, when separated by electrophoresis, provide alternating positive and negative controls (Figure 9.4.16). The CandyCane™ molecular weight standards are also available separately (C21852). In addition, we offer a Pro-Q®

Figure 9.4.12 Multiplexed analysis of normal liver cells (left) and liver tumor cells (right). Gels are stained for total protein and glycoproteins using SYPRO® Ruby protein gel stain (S12000, S12001, S21900) and a Pro-Q® Emerald glycoprotein stain (P21855, P21857, P21875), respectively. Individual gel images can then be digitally overlaid, matched and analyzed for changes in protein expression and glycosylation.

Emerald 300 Glycoprotein Gel Stain Kit (P21855) that includes our SYPRO® Ruby protein gel stain for detecting total proteins. The Pro-Q® Emerald Glycoprotein Stain Kits for gels and blots (P21855, P21857, P21875) contain sufficient materials to stain approximately ten 8 cm × 10 cm gels or blots, including:

- Pro-Q® Emerald 300 glycoprotein stain (in Kits P21855 and P21857) or Pro-Q® Emerald 488 glycoprotein stain (in Kit P21875)
- Pro-Q® Emerald 300 staining buffer (in Kits P21855 and P21857) or Pro-Q® Emerald 488 staining buffer (in Kit P21875)
- Oxidizing reagent (periodic acid)
- SYPRO® Ruby protein gel stain (in Kit P21855 only)
- CandyCane™ glycoprotein molecular weight standards
- Detailed protocols

Multiplexed Proteomics® Kit for Glycoprotein and Total-Protein Gel Staining

When used together, the Pro-Q® Emerald 300 glycoprotein gel stain and the SYPRO® Ruby protein gel stain (S12000, S12001, S21900; Section 9.3) make a powerful combination for proteome analysis (Figure 9.4.12). Determining the ratio of the Pro-Q® Emerald dye to SYPRO® Ruby dye signal intensities for each band or spot provides a measure of the glycosylation level normalized to the total amount of protein. Using both stains in combination makes it possible to distinguish a lightly glycosylated, high-abundance protein from a heavily glycosylated, low-abundance protein. To make this staining more convenient and economical, we offer the Multiplexed Proteomics® Glycoprotein Gel Stain Kit with 1 L of our Pro-Q® Emerald 300 glycoprotein gel stain and 1 L of our SYPRO® Ruby protein gel stain (M33307).

CandyCane™ Glycoprotein Molecular Weight Standards

CandyCane™ glycoprotein molecular weight standards (C21852) contain a mixture of glycosylated and nonglycosylated proteins with molecular weights from 14,000 to 180,000 daltons. When separated by polyacrylamide gel electrophoresis, the standards appear as alternating bands corresponding to glycosylated and nonglycosylated proteins (Figure 9.4.16). Thus, these standards serve both as molecular weight markers and as positive and negative controls for methods that detect glycosylated proteins, such as those provided in our Pro-Q® Emerald Glycoprotein Stain Kits.

Other Specialized Techniques for Detecting Specific Proteins on Gels and Blots

Detecting Calcium-Binding Proteins

The luminescent lanthanide terbium, which is available as its chloride salt (Tb^{3+} from $TbCl_3$, T1247), selectively stains calcium-binding proteins in SDS-polyacrylamide gels.³⁰ With some modifications to the staining protocol, these lanthanides can also be used to detect all protein bands.³⁰ Terbium chloride has also been used as a rapid negative stain for proteins in SDS-polyacrylamide gels, in which the background is green fluorescent and the proteins are unstained.³¹

Detecting Penicillin-Binding Proteins

BOCILLIN™ FL penicillin and BOCILLIN™ 650/665 penicillin (B13233, B13234) are green- and infrared-fluorescent penicillin analogs, respectively, that bind selectively and with high affinity to

Figure 9.4.14 Staining glycoproteins and the total protein profile on blots using the Pro-Q® Emerald 300 Glycoprotein Gel and Blot Stain Kit (P21857). A 2-fold dilution series of the CandyCane™ glycoprotein molecular weight standards (C21852) was run on an SDS-polyacrylamide gel and blotted onto a PVDF membrane. The blot was first stained with the SYPRO® Ruby protein blot stain (S11791) to detect the total protein profile (left). After documentation of the signal, the blot was stained with the Pro-Q® Emerald 300 glycoprotein stain (right) provided in the Pro-Q® Emerald 300 Glycoprotein Gel and Blot Stain Kit.

Figure 9.4.15 2D gel stained with the SYPRO® Ruby protein gel stain and the Pro-Q® Emerald 300 reagent. Combined Cohn fractions II and III from cow plasma, containing primarily β - and γ -globulins, were run on a 2D gel and stained first with the Pro-Q® Emerald 300 reagent (P21855, P21857; left) and then with the SYPRO® Ruby protein gel stain (S12000, S12001, S21900, and in P21855; right).

Figure 9.4.16 Glycosylated and nonglycosylated proteins in the CandyCane™ glycoprotein molecular weight standards (C21852). The standards were electrophoresed through two identical 13% polyacrylamide gels. Both lanes contain ~0.5 μ g of protein in each band. The left lane was stained with our SYPRO® Ruby protein gel stain (S12000, S12001, S21900) to detect all eight marker proteins. The right lane was stained using the reagents in the Pro-Q® Emerald 300 Glycoprotein Gel Stain Kit (P21855).

penicillin-binding proteins present on the cytoplasmic membranes of eubacteria.^{32,33} When electrophoresed under nonreducing conditions, the dye-labeled penicillin-binding proteins are easily visible in the gel with sensitivity in the low nanogram range³⁴ (Figure 9.4.17). BOCILLIN™ FL penicillin, synthesized from penicillin V and the BODIPY® FL dye (spectrally similar to fluorescein), has been used to determine the penicillin-binding protein profiles of *Escherichia coli*, *Pseudomonas aeruginosa* and *Streptococcus pneumoniae*, and these binding profiles are found to be similar to those reported by researchers using radioactively labeled penicillin V.³² Fluorescently labeled penicillin has also been used for direct labeling and rapid detection of whole *E. coli* and *Bacillus licheniformis*³⁵ and of *Enterobacter pneumoniae*.³⁶

Figure 9.4.17 Detection of penicillin-binding proteins (PBPs) from *Escherichia coli* and *Pseudomonas aeruginosa*. The membrane fractions from *E. coli* and *P. aeruginosa* were prepared as previously described and labeled with BOCILLIN™ 650/665 penicillin (B13234). The labeled membranes were separated on an SDS-polyacrylamide gel, stained with SYPRO® Ruby and visualized using a Typhoon imager. The location of PBPs from *E. coli* are labeled to the left of the gels. Lanes 1, 3, and 5 are *E. coli* membrane preparations; lanes 2, 4, and 6 are *P. aeruginosa* membrane preparations; lanes 1 and 2 are overlays of images obtained from total protein (green) and PBP (red) scans; lanes 3 and 4 are total protein visualized with the SYPRO® Ruby protein gel stain; lanes 5 and 6 are PBPs as detected by BOCILLIN™ 650/665. Image used with permission from Wiley VCH publishers.

Figure 9.4.18 Binding of the nonfluorescent FIAsh-EDT₂ ligand to a recombinantly expressed tetracysteine sequence yields a highly fluorescent complex.

The β-lactam sensor-transducer (BlaR), an integral membrane protein from *Staphylococcus aureus*, covalently and stoichiometrically reacts with β-lactam antibiotics, including BOCILLIN™ FL penicillin, by acylation of its active-site serine residue.³⁷

Detecting TC-Tagged Fusion Proteins with TC-FIAsh™ and TC-ReAsH™ Reagents

TC-FIAsh™ and TC-ReAsH™ detection technology, based on the tetracysteine tag first described by Griffin, Adams and Tsien in 1998,^{38,39} takes advantage of the high-affinity interaction of a biarsenical ligand (FIAsh-EDT₂ or ReAsH-EDT₂) with the thiols in a tetracysteine (TC) expression tag fused to the protein of interest. The FIAsh-EDT₂ ligand is essentially fluorescein that has been modified to contain two arsenic atoms at a set distance from each other, whereas the ReAsH-EDT₂ ligand is a similarly modified resorufin. Virtually nonfluorescent in the ethanedithiol (EDT)-bound state, these reagents become highly fluorescent when bound to the thiol-containing tetracysteine tag Cys-Cys-Xxx-Yyy-Cys-Cys, where Xxx-Yyy is typically Pro-Gly⁴⁰ (Figure 9.4.18). Modified tags with additional flanking sequences produce higher affinity binding of the biarsenical ligand, resulting in improved signal-to-background characteristics.^{41,42}

Transduction of the host cell line with an expression construct comprising the protein of interest fused to a tetracysteine tag is followed by addition FIAsh-EDT₂ reagent (Figure 9.4.18) or ReAsH-EDT₂ reagent, generating green or red fluorescence, respectively, upon binding the tetracysteine motif. For detection of tetracysteine-tagged proteins expressed in cells, we offer the TC-FIAsh™ II and TC-ReAsH™ II In-Cell Tetracysteine Tag Detection Kits (T34561, T34562, T34563), which are described in Section 2.2.

As an alternative to in-cell detection, we offer the TC-FIAsh™ Expression Analysis Detection Kits (A10067, A10068) for detecting tetracysteine-tagged proteins in polyacrylamide gels (Figure 9.4.19). These kits provide:

- FIAsh loading buffer
- Orange total-protein stain (in A10067) or Red total-protein stain (in A10068)
- Dimethylsulfoxide (DMSO)
- BenchMark™ Protein Ladder
- Detailed protocols

Sufficient reagents are provided for ten 17-well minigels, based on a 12 μL reaction volume. When bound to TC-tagged protein, FIAsh dye exhibits excitation/emission maxima of 505/530 nm. The Orange and Red total-protein gel stains supplied in these detection kits exhibit emission maxima of 585/620 nm and 650/660 nm, respectively.

Figure 9.4.19 Protein gel staining using TC-FIAsh™ Expression Analysis Detection Kit (A10068). A) Tetracysteine-tagged proteins are labeled with FIAsh-EDT₂ reagent and fluoresce green. B) Total proteins are labeled with the Red total-protein stain provided in the kit and fluoresce red. C) An overlay of the two images reveals relative amounts of protein.

Detecting Oligohistidine Fusion Proteins

The oligohistidine domain is a Ni²⁺-binding peptide sequence comprising a string of four to six histidine residues. When the DNA sequence corresponding to the oligohistidine domain is fused in frame with a gene of interest, the resulting recombinant protein can be easily purified using a nickel-chelating resin.^{43,44}

Developed by QIAGEN, the Penta-His mouse IgG₁ monoclonal antibody (P21315) provides a sensitive method for specific detection of fusion proteins that have an oligohistidine domain comprising five or six consecutive histidine residues. The antibody does not recognize tetrahistidine domains or domains in which the histidine string is interrupted by another amino acid. The Penta-His antibody binds to the oligohistidine domain regardless of the surrounding amino acid context and even when the group is partially hidden, although subtle differences in the amino acid context may change the sensitivity limit for a particular fusion protein. The antibody is ideal for detecting oligohistidine fusion proteins on western blots (Figure 9.4.20). The Penta-His antibody is also useful for immunoprecipitation, ELISA assays and immunohistochemistry.

Anti-Dinitrophenyl Antibody for Measuring Protein Carbonyls

Oxidative injury can be monitored by following the formation of protein-derived aldehydes and ketones. Traditionally, protein-derived aldehydes and ketones have been quantitated using a colorimetric assay based on their reaction with 2,4-dinitrophenylhydrazine to yield protein-bound dinitrophenyl (DNP) moieties. A much more sensitive ELISA method has been developed that detects the protein-bound DNP using unlabeled or biotin-labeled anti-DNP antibodies⁴⁵ (A6430, A6435; Section 7.4). The bound anti-DNP antibody is subsequently detected with horseradish peroxidase-conjugated secondary detection reagents (Section 7.2). Our Alexa Fluor[®] 488 and fluorescein conjugates of the anti-DNP antibody (A11097, A6423; Section 7.2) can also be applied to this detection scheme.⁴⁶ Our polyclonal antibody to nitrotyrosine (A21285, Section 7.4) can be used similarly to separate and detect proteins of cell extracts that have been naturally nitrated by nitric oxide (Section 18.3, Figure 9.4.21).

Detecting Glutathiolation with BioGEE

Biotinylated glutathione ethyl ester (BioGEE, G36000; Figure 9.4.22) is a cell-permeant, biotinylated glutathione analog for detecting glutathiolation. Under conditions of oxidative stress, cells may transiently incorporate glutathione into proteins. Stressed cells incubated with BioGEE will also incorporate this biotinylated glutathione derivative into proteins, facilitating the identification of oxidation-sensitive proteins.^{47,48} Once these cells are fixed and permeabilized, glutathiolation levels can be detected with a fluorescent streptavidin conjugate (Section 7.6, Table 7.9) using either flow cytometry or fluorescence microscopy. Proteins glutathiolated with BioGEE can be captured using streptavidin or CaptAvidin[™] agarose (S951, C21386; Section 7.6) and analyzed by mass spectrometry or by western blotting methods.^{49,50}

Glutathione Agarose and Anti-Glutathione S-Transferase Antibody for GST Fusion Protein Identification and Purification

In protein fusion techniques, the coding sequence of one protein is fused in-frame with another so that the expressed hybrid protein possesses desirable properties of both parent proteins. One common partner in these engineered products is glutathione S-transferase (GST),

Figure 9.4.22 Glutathione ethyl ester, biotin amide (BioGEE, G36000).

Figure 9.4.20 Detection of an oligohistidine fusion protein with the Penta-His mouse monoclonal antibody. Two-fold serial dilutions of an *Escherichia coli* lysate containing overexpressed oligomycin sensitivity-conferring protein (OSCP) fused with a hexahistidine domain were run on an SDS-polyacrylamide gel and blotted onto a PVDF membrane. The blot was stained with the SYPRO[®] Ruby protein blot stain (S11791) to detect the entire protein profile (top). After imaging, the blot was incubated with Penta-His mouse IgG₁ monoclonal antibody (P21315), followed by immunodetection using an alkaline phosphatase conjugate of goat anti-mouse antibody in conjunction with DDAO phosphate (bottom).

Figure 9.4.21 Specificity of our rabbit anti-nitrotyrosine antibody (A21285) to nitrated proteins. Equal amounts of avidin (A887, lane 1) and CaptAvidin[™] biotin-binding protein (C21385, lane 2) were run on an SDS-polyacrylamide gel (4–20%) and blotted onto a PVDF membrane. CaptAvidin[™] biotin-binding protein, a derivative of avidin, has nitrated tyrosine residues in the biotin-binding site. Nitrated proteins were identified with the anti-nitrotyrosine antibody in combination with an alkaline phosphatase conjugate of goat anti-rabbit IgG antibody (G21079) and the red-fluorescent substrate, DDAO phosphate (D6487).

Figure 9.4.23 Coomassie brilliant blue-stained SDS-polyacrylamide gel, demonstrating the purification of a glutathione *S*-transferase (GST) fusion protein using glutathione agarose (G2879). Lane 1 contains crude supernatant from an *Escherichia coli* lysate and lane 2 contains the affinity-purified GST fusion protein.

a protein with natural binding specificity that can be exploited to facilitate its purification.⁵¹ Because the GST portion of the fusion protein retains its affinity and selectivity for glutathione, the fusion protein can be conveniently purified from the cell lysate in a single step by affinity chromatography on glutathione agarose^{51–57} (Figure 9.4.23). For purification of GST fusion proteins, we offer glutathione linked via the sulfur atom to crosslinked beaded agarose (10 mL of sedimented bead suspension, G2879). Each milliliter of gel can bind approximately 5–6 mg of bovine-liver GST. Adding excess free glutathione liberates the GST fragment from the matrix, which can then be regenerated by washing with a high-salt buffer.

We also offer a highly purified rabbit polyclonal anti-GST antibody (A5800) that can be used to purify GST fusion proteins by immunoprecipitation.⁵⁸ This highly specific antibody, which was generated against a 260–amino acid N-terminal fragment of the *Schistosoma japonica* enzyme expressed in *Escherichia coli*, is also useful for detecting GST fusion proteins on western blots and for detecting GST distribution in cells. The intensely green-fluorescent Alexa Fluor® 488 conjugate of anti-glutathione *S*-transferase (A11131) is also available for direct detection of GST fusion proteins.

Following purification, the fusion protein can serve as an immunogen for antibody production^{59,60} or its properties can be compared with those of the native polypeptide to provide insights on the normal function of the polypeptide of interest. Such methods have been used to investigate biological properties of many proteins. Examples include cleavage of the capsid assembly protein ICP35 by the herpes simplex virus type 1 protease,⁶¹ the role of the Rho GTP-binding protein in *lbc* oncogene function⁶² and the association of v-Src with cortactin in Rous sarcoma virus–transformed cells.⁶³ In fact, the Ca²⁺-binding properties of a protein kinase C–GST fusion protein were examined while the GST fusion protein was still bound to the glutathione agarose.⁶⁴ Likewise, interactions of a DNA-binding protein–GST fusion protein have been assessed using an affinity column consisting of the fusion protein bound to glutathione agarose.⁵² Alternatively, the GST fusion expression vector can be engineered to encode a recognition sequence for a site-specific protease, such as thrombin or factor Xa, between the GST structural gene and gene of interest.^{65–68} Once the fusion protein is bound to the affinity matrix, the site-specific enzyme can be added to release the protein.

Streptavidin Acrylamide and Reactive Acrylamide Derivatives

Streptavidin acrylamide (S21379), which is prepared from the succinimidyl ester of 6-((acryloyl)amino)hexanoic acid (acryloyl-X, SE, A20770), may be useful for the preparation of biosensors.⁶⁹ A similar streptavidin acrylamide has been shown to copolymerize with acrylamide on a polymeric surface to create a uniform monolayer of the immobilized protein. The streptavidin can then bind biotinylated ligands, including biotinylated hybridization probes, enzymes, antibodies and drugs.

Like streptavidin and CaptAvidin™ biotin-binding protein, other amine-containing biomolecules can be crosslinked to acrylamides using acryloyl-X, SE. Acryloyl-X, SE reacts with amines of proteins, amine-modified nucleic acids and other biomolecules to yield acrylamides that can be copolymerized into polyacrylamide matrices or on surfaces, such as in microarrays and in biosensors. We prepare both streptavidin and CaptAvidin™ biotin-binding protein conjugated to 4% beaded crosslinked agarose (S951, C21386; Section 7.6)—matrices that can be used to isolate biotinylated peptides, proteins, hybridization probes, haptens and other molecules.

PRODUCT LIST 9.4 DETECTING PROTEIN MODIFICATIONS

Cat. No.	Product	Quantity
A20770	6-((acryloyl)amino)hexanoic acid, succinimidyl ester (acryloyl-X, SE)	5 mg
A5800	anti-glutathione S-transferase, rabbit IgG fraction *3 mg/mL*	0.5 mL
A11131	anti-glutathione S-transferase, rabbit IgG fraction, Alexa Fluor® 488 conjugate *2 mg/mL*	0.5 mL
B13234	BOCILLIN™ 650/665 penicillin, sodium salt	1 mg
B13233	BOCILLIN™ FL penicillin, sodium salt	1 mg
C21852	CandyCane™ glycoprotein molecular weight standards *200 gel lanes*	400 µL
C10102	Click-iT® AHA (L-azidohomoalanine) *for nascent protein synthesis*	5 mg
C10289	Click-iT® AHA Alexa Fluor® 488 Protein Synthesis HCS Assay *2-plate size*	1 kit
C33372	Click-iT® Biotin Protein Analysis Detection Kit *10 reactions*	1 kit
C10269	Click-iT® Cell Reaction Buffer Kit	1 kit
C33371	Click-iT® Dapoxyl® Protein Analysis Detection Kit *for UV excitation* *10 reactions*	1 kit
C10248	Click-iT® farnesyl alcohol, azide *mixed isomers*	1 mg
C10264	Click-iT® fucose alkyne (tetraacetylucose alkyne)	5 mg
C33365	Click-iT® GalNAz metabolic glycoprotein labeling reagent (tetraacetylated N-azidoacetylglactosamine) *for O-linked glycoproteins* *5.2 mg*	each
C10249	Click-iT® geranylgeranyl alcohol, azide *mixed isomers*	1 mg
C33368	Click-iT® O-GlcNAc Enzymatic Labeling System *for O-linked GlcNAc glycoproteins* *10 labelings*	1 kit
C33373	Click-iT® O-GlcNAc peptide and phosphopeptide LC/MS standards *5 nmol each*	1 set
C33374	Click-iT® O-GlcNAc peptide LC/MS standard (H-Thr-Ala-Pro-Thr-(O-GlcNAc)Ser-Thr-Ile-Ala-Pro-Gly-OH) *Theoretical Mass (M+H): 1118.50*	5 nmol
C33367	Click-iT® GlcNAz metabolic glycoprotein labeling reagent (tetraacetylated N-azidoacetylglucosamine) *for O-GlcNAc-modified proteins* *5.2 mg*	each
C10186	Click-iT® HPG (L-homopropargylglycine) *for nascent protein synthesis*	5 mg
C33366	Click-iT® ManNAz metabolic glycoprotein labeling reagent (tetraacetylated N-azidoacetyl-d-mannosamine) *for sialic acid glycoproteins* *5.2 mg*	each
C10268	Click-iT® myristic acid, azide (12-azidododecanoic acid)	1 mg
C10265	Click-iT® palmitic acid, azide (15-azidopentadecanoic acid)	1 mg
C10276	Click-iT® Protein Reaction Buffer Kit	1 kit
C33370	Click-iT® Tetramethylrhodamine (TAMRA) Protein Analysis Detection Kit *UV/532 nm excitation* *10 reactions*	1 kit
G2879	glutathione agarose, linked through sulfur *sedimented bead suspension*	10 mL
G36000	glutathione ethyl ester, biotin amide (BioGEE) *glutathionol detection reagent* *special packaging*	10 x 100 µg
M33307	Multiplexed Proteomics® Glycoprotein Gel Stain Kit *with 1 L each of Pro-Q® Emerald 300 and SYPRO® Ruby (S12000) gel stains*	1 kit
MPM33305	Multiplexed Proteomics® Phosphoprotein Gel Stain Kit *includes MPP33300 and S12000*	1 kit
MPM33306	Multiplexed Proteomics® Phosphoprotein Gel Stain Kit *includes MPP33301 and S12001*	1 kit
M33305	Multiplexed Proteomics® Phosphoprotein Gel Stain Kit #1 *with 1 L each of Pro-Q® Diamond (P33300) and SYPRO® Ruby (S12000) gel stains*	1 set
M33306	Multiplexed Proteomics® Phosphoprotein Gel Stain Kit #2 *with 200 mL each of Pro-Q® Diamond (P33301) and SYPRO® Ruby (S12001) gel stains*	1 set
P21315	Penta-His mouse IgG1, monoclonal antibody (anti-pentahistidine) *BSA free*	100 µg
P27167	PeppermintStick™ phosphoprotein molecular weight standards	40 µL
P33350	PeppermintStick™ phosphoprotein molecular weight standards *200 gel lanes*	400 µL
P33357	phosphopeptide standard mixture *400 pmol of each peptide*	2800 pmol
P33203	Pro-Q® Diamond LC Phosphopeptide Detection Kit	1 kit
P33356	Pro-Q® Diamond Phosphoprotein Blot Stain Kit *20 minigel blots*	1 kit
P33359	Pro-Q® Diamond Phosphoprotein Enrichment and Detection Kit	1 kit
P33358	Pro-Q® Diamond Phosphoprotein Enrichment Kit	1 kit
P33310	Pro-Q® Diamond phosphoprotein gel destaining solution	1 L
P33311	Pro-Q® Diamond phosphoprotein gel destaining solution *bulk packaging*	5 L
P33301	Pro-Q® Diamond phosphoprotein gel stain	200 mL
P33300	Pro-Q® Diamond phosphoprotein gel stain	1 L
P33302	Pro-Q® Diamond phosphoprotein gel stain *bulk packaging*	5 L
MPP33301	Pro-Q® Diamond Phosphoprotein Gel Staining Kit *includes 200 mL stain and 40 µL standard*	1 kit
MPP33300	Pro-Q® Diamond Phosphoprotein Gel Staining Kit *includes 1 L stain and 40 µL standard*	1 kit
MPP33302	Pro-Q® Diamond Phosphoprotein Gel Staining Kit *includes 5 L stain and 400 µL standard*	1 kit
P33706	Pro-Q® Diamond Phosphoprotein/Phosphopeptide Microarray Stain Kit	1 kit
P21857	Pro-Q® Emerald 300 Glycoprotein Gel and Blot Stain Kit *10 minigels or minigel blots*	1 kit
P21855	Pro-Q® Emerald 300 Glycoprotein Gel Stain Kit *with SYPRO® Ruby protein gel stain* *10 minigels*	1 kit
P21875	Pro-Q® Emerald 488 Glycoprotein Gel and Blot Stain Kit *10 minigels or minigel blots*	1 kit
S21379	streptavidin acrylamide	1 mg
A10067	TC-FlAsH™ Expression Analysis Detection Kit - Orange *fluorescent in-gel detection of TC-tagged and total protein*	1 kit
A10068	TC-FlAsH™ Expression Analysis Detection Kit - Red *fluorescent in-gel detection of TC-tagged and total protein*	1 kit
T1247	terbium(III) chloride, hexahydrate	1 g

9.5 Peptide Analysis, Sequencing and Synthesis

This section describes Molecular Probes® reagents used in the synthesis of fluorophore- or hapten-labeled peptides and fluorogenic protease substrates, as well as in peptide and protein sequencing. Some of our fluorescent probes and research chemicals have also been used for N-terminal amino acid analysis and peptide sequencing, as well as for protein fragment modification prior to Edman sequencing.

N-Terminal Amino Acid Analysis

Except when it is already blocked by formylation, acetylation, pyroglutamic acid formation or other chemistry, the N-terminal amino acid of proteins can be labeled with a variety of fluorescent and chromophoric reagents from Chapter 1. However, only those functional groups that survive complete protein hydrolysis, such as sulfonamides, are useful for N-terminal amino acid analysis. Dansyl chloride (D21) is the most commonly employed reagent for such analyses.¹

Nonacylated N-terminal serine and threonine residues of proteins can be periodate-oxidized to aldehydes²⁻⁴ (Figure 9.5.1) that can then be modified by a variety of hydrazine and hydroxylamine derivatives listed in Section 3.3. Only peptides and proteins that contain these two terminal amino acids become fluorescent, although oxidation of the carbohydrate portion of glycoproteins to aldehydes may cause interference in this analysis.

N-Acetylated or N-formylated proteins have been detected by transfer of the acyl group to dansyl hydrazine (D100) and subsequent chromatographic separation of the fluorescent product.^{5,6} The sensitivity of this method can likely be improved by the use of other fluorescent hydrazine and hydroxylamine derivatives described in Section 3.3.

Peptide Sequencing

The dominant chemistry for sequencing peptides employs the non-fluorescent reagent phenyl isothiocyanate, which forms phenylthiohydantoin (PTH) in the sequencing reaction. As analogs of phenyl isothiocyanate, fluorescein-5-isothiocyanate (FITC; F143, F1906, F1907; Section 1.5) and other fluorescent isothiocyanates yield peptide conjugates that are also susceptible to Edman degradation via their thiohydantoin. Thus, these fluorescent reagents are potentially useful for ultrasensitive amino acid sequencing.⁷⁻¹⁰

Figure 9.5.1 Sodium periodate oxidation of an N-terminal serine residue to an aldehyde, with the release of formaldehyde. The aldehyde thus formed from the protein can be subsequently modified with a variety of hydrazine, hydroxylamine or amine derivatives.

Peptide Synthesis

Peptides specifically labeled with fluorescent dyes, haptens, photoactive groups or radioisotopes are important both as probes for receptors and as substrates for enzymes (Section 10.4). Labeled peptides can be prepared by modifying isolated peptides or by incorporating the label during solid-phase synthesis. We offer several fluorescent neuro-peptides, most of which are described in Section 16.2.

Labeling Peptides in Solution

Appropriately substituted synthetic peptides can be labeled in solution by almost any of the reactive probes described in Chapters 1–5 (Labeling Small Peptides with Amine-Reactive Dyes in Organic Solvents—Note 9.2). Many peptides contain multiple residues that can be modified, potentially leading to complex mixtures of products, some of which may be biologically inactive. Modification of a peptide's thiol group by one of the thiol-reactive reagents described in Chapter 2 is usually easy, selective and very efficient. If the peptide is synthetic, or can be modified by site-directed mutagenesis, incorporation of a cysteine residue at the desired site of labeling is recommended. The N-terminal α -amine of peptides, which has a lower pK_a than the ϵ -amino group of lysine residues, can sometimes be labeled in the presence of other amines if the pH is kept near neutral. Conversion of tyrosine residues to *o*-aminotyrosines (Section 3.2) can be used to provide selective sites for peptide modification, unless the tyrosine residues are essential for the biological activity of the peptide.

Solid-Phase Synthesis of Labeled Peptides

If specific labeling of peptides in solution is problematic, it may be more convenient to conjugate the fluorophore to the N-terminus of a resin-bound peptide *before* removal of other protecting groups and release of the labeled peptide from the resin. About five equivalents of an amine-reactive fluorophore are usually used per amine of the immobilized peptide. The fluorescein, Alexa Fluor®, Oregon Green®, Rhodamine Green™, tetramethylrhodamine, Rhodamine Red™, Texas Red®, coumarin and NBD fluorophores, as well as the QSY®, dabcyI and dabsyl chromophores and the biotin hapten, are all expected to be reasonably stable to hydrogen fluoride (HF) as well as to most other acids.¹¹⁻¹⁶ These fluorophores, chromophores and biotin are also expected to be stable to reagents used for deprotection of peptides synthesized using Fmoc chemistry.¹⁷ In contrast, the BODIPY® fluorophore may be unstable to the conditions used to remove some protecting groups.

We prepare unique reagents for use in the automated synthesis of peptides that are specifically labeled with fluorophores, chromophores and haptens. These precursors permit the incorporation of a specific label at a specific site in the peptide's sequence. The α -Fmoc derivative of ϵ -dabcyI-L-lysine (D6216) can be used to incorporate the dabcyI chromophore at selected sites in the peptide sequence. The dabcyI chromophore, which has broad visible absorption (Figure 9.5.2), has been extensively used as a quenching group in the automated synthesis of HIV protease and renin (H2930, R2931; Section 10.4) and other fluorogenic

peptidase substrates.^{18–21} The dabcyI group can also be incorporated at the N-terminus by using dabcyI succinimidyl ester^{16,22} (D2245). The aminonaphthalene derivative EDANS (A91) has been the most common fluorophore for pairing with the dabcyI quencher in fluorescence resonance energy transfer (FRET) experiments because its fluorescence emission spectrum overlaps the absorption spectrum of dabcyI (Figure 9.5.2) (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). This fluorophore is conveniently introduced during automated synthesis of peptides by using γ -EDANS- α -Fmoc-L-glutamic acid (F11831). The tetramethylrhodamine fluorophore can be incorporated during automated Fmoc synthesis of peptides using our single-isomer α -(Fmoc)- ϵ -TMR-L-lysine building block (F11830).

QSY[®] dyes (Section 1.6, Section 1.8) have broad visible to near-infrared absorption (Figure 9.5.3). These dyes, which are essentially nonfluorescent, are particularly useful as energy acceptors from blue-, green-, orange- or red-fluorescent donor dyes (Note 1.2). The QSY[®] 7, QSY[®] 9, QSY[®] 21 and QSY[®] 35 chromophores can be conjugated to amines via their succinimidyl esters (Q10193, Q20131, Q20132, Q20133). The QSY[®] 7 and QSY[®] 35 chromophores can also be conjugated to peptide thiols or thiol-modified oligonucleotides via its maleimide²³ (Q10257) or iodoacetamide (Q20348); additionally, peptide amides can be prepared from QSY[®] 7 amine (Q10464). We have also prepared α -(Fmoc)- ϵ -QSY[®] 7-L-lysine and α -(Fmoc)- β -QSY[®] 35-L-alanine (Q21930, Q21931), which can be used in the automated synthesis of QSY[®] 7 quencher- or QSY[®] 35 quencher-containing peptides.

NOTE 9.2

Labeling Small Peptides with Amine-Reactive Dyes in Organic Solvents

Most of the product literature associated with our amine-reactive dyes provides protocols for labeling proteins, typically IgG antibodies in aqueous buffers. The following protocol is a starting point for labeling peptides in organic solvents. Please note that the reaction conditions, including concentrations of the reactants and the reaction times, may require optimization. Furthermore, many peptides are not soluble in a 100% organic solution. It is very important to test the solubility of the peptide in dimethylsulfoxide (DMSO) or dimethylformamide (DMF) before attempting this procedure.

1. Dissolve the peptide to be labeled in DMSO or DMF at 0.1–1 mM.
2. Add 100 mM triethylamine to the reaction solution. This will ensure that the amines to be derivatized are deprotonated.
3. Add the amine-reactive dye to the reaction solution. The reactive dye should be in a 1:1 to 3:1 molar ratio to the peptide.
4. React at room temperature or at 4°C for at least 4 hours with continuous stirring, protected from light. The reaction can proceed overnight. Thin-layer chromatography may be useful for monitoring the reaction's progress.
5. Purify the conjugate by an appropriate method, such as HPLC-based separation.

Figure 9.5.2 Spectral overlap between EDANS fluorescence and dabcyI absorption, which is required for efficient quenching of EDANS fluorescence by resonance energy transfer to the nonfluorescent dabcyI chromophore. Spectra are normalized to the same intensities.

Figure 9.5.3 Normalized absorption spectra of the QSY[®] 35 (blue), QSY[®] 7 (red) and QSY[®] 21 (orange) dyes. The QSY[®] 7 and QSY[®] 9 dyes have essentially identical spectra.

Notes

- D21 butylamine derivative has Abs = 337 nm (EC = 5300 cm⁻¹M⁻¹), Em = 492 nm in CHCl₃. Em and QY are highly solvent dependent: Em = 496 nm (QY = 0.45) in dioxane, 536 nm (QY = 0.28) in MeOH and 557 nm (QY = 0.03) in H₂O. (Biochemistry (1967) 6:3408) EC typically decreases upon conjugation to proteins (EC = 3400 cm⁻¹M⁻¹ at 340 nm). (Biochemistry (1986) 25:513) Fluorescence lifetimes (τ) of protein conjugates are typically 12–20 nanoseconds. (Arch Biochem Biophys (1969) 133:263, Arch Biochem Biophys (1968) 128:163)
- Do NOT dissolve in DMSO.
- D2245 is nonfluorescent both before and after reaction with amines. Reaction product with butylamine has Abs = 428 nm (EC = 32,000 cm⁻¹M⁻¹) in MeOH.
- This sulfonated succinimidyl ester derivative is water soluble and may be dissolved in buffer at ~pH 8 for reaction with amines. Long-term storage in water is NOT recommended due to hydrolysis.
- Iodoacetamides in solution undergo rapid photodecomposition to unreactive products. Minimize exposure to light prior to reaction.

PRODUCT LIST 9.5 PEPTIDE ANALYSIS, SEQUENCING AND SYNTHESIS

Cat. No.	Product	Quantity
A91	5-((2-aminoethyl)amino)naphthalene-1-sulfonic acid, sodium salt (EDANS)	1 g

10.1 Introduction to Enzyme Substrates and Their Reference Standards

We offer a large assortment of fluorogenic and chromogenic enzyme substrates, which are described in the following sections. We prepare substrates for detecting very low levels of enzymatic activity in fixed cells, tissues, cell extracts and purified preparations, as well as substrates for enzyme-linked immunosorbent assays (ELISAs). Our RediPlate™ product line includes enzyme substrates predispensed in 96-well plates for high-throughput applications, along with the appropriate reference standards and other reaction components. We have also developed effective methods for detecting some enzymes in live cells.

In this section, we describe the characteristics of our enzyme substrates and the fluorophores and chromophores from which they are derived, focusing primarily on the suitability of these substrates for different types of enzyme assays. The fluorophores that are available as reference standards—including a NIST-traceable fluorescein standard (F36915)—can be found in the data table and product list associated with this section. Substrates for specific enzymes are described in subsequent sections of this chapter.

Substrates Yielding Soluble Fluorescent Products

Solution assays designed to quantitate enzymatic activity in cell extracts or other biological fluids typically employ substrates that yield highly fluorescent or intensely absorbing water-soluble products. ELISAs also rely on these substrates for indirect quantitation of analytes.¹⁻³ An ideal fluorogenic substrate for fluorescence-based solution assays yields a highly fluorescent, water-soluble product with optical properties significantly different from those of the substrate. If the fluorescence spectra of the substrate and product overlap significantly, analysis will likely require a separation step, especially when using excess substrate to obtain pseudo-first-order kinetics. Fortunately, many substrates have low intrinsic fluorescence or are metabolized to products that have longer-wavelength excitation or emission spectra (Figure 10.1.1). These fluorescent products can typically be quantitated in the presence of the unreacted substrate using a fluorometer or a fluorescence microplate reader. Microplate readers facilitate high-throughput analysis and require relatively small assay volumes, which usually reduces reagent costs. Moreover, the front-face optics in many microplate readers allows researchers to use more concentrated solutions, which may both improve the linearity of the kinetics and reduce inner-filter effects.

When the spectral characteristics of the substrate and its metabolic product are similar, techniques such as thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC), capillary electrophoresis, solvent extraction or ion exchange can be used to separate the product from unconsumed substrate prior to analysis. For example, our FAST CAT® Chloramphenicol Acetyltransferase Assay Kits (F2900, F6616, F6617; Section 10.6) utilize chromatography to separate the intrinsically fluorescent substrates from their fluorescent products.

Substrates Derived from Water-Soluble Coumarins

Hydroxy- and amino-substituted coumarins have been the most widely used fluorophores for preparing fluorogenic substrates. Phosphate, ester and ether derivatives of 7-hydroxy-4-methylcoumarin (β -methylumbelliferone, H189), typified by 4-methylumbelliferyl phosphate (MUP, M6491; Section 10.3), are only weakly fluorescent in the optimal configuration for 7-hydroxy-4-methylcoumarin detection (excitation/emission = 360/460 nm, Figure 10.1.2). Thus, enzymatic cleavage of the phosphate, ester or ether results in an increase in fluorescence under these conditions. Because the fluorescence of 7-hydroxycoumarin dyes is pH dependent, this detection configuration is only optimal when the phenolate anion form is the predominant species (i.e., at pH >8 for 7-hydroxy-4-methylcoumarin). At lower pH values, the excitation wavelength must be switched to about 320 nm, which is optimal for the protonated phenol form. 6,8-Difluoro-7-hydroxy-4-methylcoumarin (DiFMU, D6566; Figure 10.1.2, Figure 10.1.3) has a much lower

Figure 10.1.1 Normalized emission spectra of 1) 7-hydroxy-4-methylcoumarin (H189) and 6,8-difluoro-7-hydroxy-4-methylcoumarin (DiFMU, D6566), 2) fluorescein (F1300, F36915), 3) resorufin (R363) and 4) DDAO (H6482) in aqueous solution at pH 9. These fluorophores correspond to the hydrolysis, oxidation or reduction products of several of our fluorogenic enzyme substrates.

Figure 10.1.2 Absorption and fluorescence emission spectra of 7-hydroxy-4-methylcoumarin (H189) in pH 9.0 buffer. The spectra of 6,8-difluoro-7-hydroxy-4-methylcoumarin (D6566) are essentially identical.

Figure 10.1.3 6,8-Difluoro-7-hydroxy-4-methylcoumarin (DiFMU, D6566).

Figure 10.1.4 Comparison of the pH-dependent fluorescence changes produced by attachment of electron-withdrawing fluorine atoms to a hydroxycoumarin. 7-Hydroxy-4-methylcoumarin-3-acetic acid (O, H1428) and 6,8-difluoro-7-hydroxy-4-methylcoumarin (●, D6566) demonstrate the decrease of the pK_a from ~7.4 to ~6.2. Fluorescence intensities were measured for equal concentrations of the two dyes using equal excitation/emission at 360/450 nm.

Figure 10.1.5 Absorption and fluorescence emission spectra of 7-amino-4-methylcoumarin in pH 7.0 buffer.

Figure 10.1.6 Absorption and fluorescence emission spectra of rhodamine 110 in pH 7.0 buffer.

Figure 10.1.8 Normalized absorption and fluorescence emission spectra of DDAO, which is formed by alkaline phosphatase-mediated hydrolysis of DDAO phosphate (D6487).

phenol/phenolate⁴ pK_a (Figure 10.1.4), allowing measurements to be made over a broader pH range without adjusting the excitation/emission wavelength settings to accommodate the pH-dependent spectral shift of the 7-hydroxycoumarin fluorophore. Furthermore, the electron-withdrawing effect of the fluorine substituents manifested in the lower pK_a also facilitates cleavage of the phosphate, ester or ether substituent, resulting in accelerated enzyme kinetics. Consequently, the phosphate ester of 6,8-difluoro-7-hydroxy-4-methylcoumarin (DiFMUP, D6567, D22065, E12020; Section 10.3) is one of the most sensitive fluorogenic substrates for continuous high-throughput assay of alkaline phosphatase and its bioconjugates.

Aromatic amines, including the commonly used 7-amino-4-methylcoumarin (AMC, A191; Figure 10.1.5), are partially protonated at low pH (less than ~5) but fully deprotonated at physiological pH. Thus, their fluorescence spectra are not subject to variability due to pH-dependent protonation/deprotonation when assayed near or above physiological pH. AMC is widely used to prepare peptidase substrates in which the amide has shorter-wavelength absorption and emission spectra than the amine hydrolysis product.

Substrates Derived from Water-Soluble Green to Yellow Fluorophores

As compared with coumarin-based substrates, substrates derived from fluoresceins, rhodamines and resorufins often provide significantly greater sensitivity in fluorescence-based enzyme assays. In addition, most of these longer-wavelength dyes have extinction coefficients that are 5 to 25 times that of coumarins, nitrophenols or nitroanilines, making them additionally useful as sensitive chromogenic substrates.

Hydrolytic substrates based on the derivatives of fluorescein (fluorescein reference standard, F1300; fluorescein NIST-traceable standard, F36915) or rhodamine 110 (R110, R6479; Figure 10.1.6) usually incorporate two moieties, each of which serves as a substrate for the enzyme. Consequently, they are cleaved first to the monosubstituted analog and then to the free fluorophore. Because the monosubstituted analog often absorbs and emits light at the same wavelengths as the ultimate hydrolysis product, this initial hydrolysis complicates the interpretation of hydrolysis kinetics.⁵ When highly purified, however, the disubstituted fluorescein- and rhodamine 110-based substrates have virtually no visible-wavelength absorbance or background fluorescence, making them extremely sensitive detection reagents. For example, researchers have reported that the activity of as few as 1.6 molecules of β -galactosidase can be detected with fluorescein di- β -D-galactopyranoside (FDG) and capillary electrophoresis.⁶ Fluorogenic substrates based on either the AMC and R110 fluorophore are used in our EnzChek® Caspase Assay Kits (Section 10.4, Section 15.5) to detect apoptotic cells.

Chemical reduction of fluorescein- and rhodamine-based dyes yields colorless and nonfluorescent dihydrofluoresceins and dihydrorhodamines. Although extremely useful for detection of reactive oxygen species (ROS) in phagocytic and other cells (Section 18.2), these dyes tend to be insufficiently stable for solution assays.

Substrates Derived from Water-Soluble Red Fluorophores

Long-wavelength fluorophores are often preferred because background absorbance and autofluorescence are generally lower when longer excitation wavelengths are used. Substrates derived from the red-fluorescent resorufin (R363, Figure 10.1.7) and the dimethylacridinone derivative 7-hydroxy-9H-(1,3-dichloro-9,9-dimethylacridin-2-one) (DDAO, H6482; Figure 10.1.8; Figure 10.1.9) contain only a single hydrolysis-sensitive moiety, thereby avoiding the biphasic kinetics of both fluorescein- and rhodamine-based substrates.⁷

Resorufin is used to prepare several substrates for glycosidases, hydrolytic enzymes and dealkylases. In most cases, the relatively low pK_a of resorufin (~6.0) permits continuous measurement of enzymatic activity. Thiols such as DTT or 2-mercaptoethanol should be avoided in

Figure 10.1.7 Resorufin, sodium salt (R363).

Figure 10.1.9 7-Hydroxy-9H-(1,3-dichloro-9,9-dimethylacridin-2-one; DDAO, H6482).

assays utilizing resorufin-based substrates. Our Amplex® Red peroxidase substrate (A12222, A22177; Section 10.5) is a chemically reduced, colorless form of resorufin that is oxidized to resorufin by horseradish peroxidase (HRP) in combination with hydrogen peroxide. Resorufin is also the product of enzyme-catalyzed reduction of resazurin (R12204; Section 10.6, Section 15.2)—also known as alamarBlue® dye. Our Amplex® UltraRed reagent (A36006, Section 10.5) improves upon the performance of the Amplex® Red reagent, offering brighter fluorescence and enhanced sensitivity on a per-mole basis in peroxidase or peroxidase-coupled enzyme assays.

Substrates derived from DDAO, a red He-Ne laser-excitabile fluorophore, generally exhibit good water solubility, low K_M and high turnover rates. In addition, the difference between the excitation maximum of the DDAO-based substrates and that of the phenolic DDAO product is greater than 150 nm (Figure 10.1.8), which allows the two species to be easily distinguished.

Substrates for Live-Cell Enzyme Assays

We have developed a number of innovative strategies for investigating enzymatic activity in live cells.^{8,9} For example, we offer a diverse set of probes that can passively enter the cell; once inside, they are processed by intracellular enzymes to generate products with improved cellular retention (Section 14.2). We also offer kits and reagents for detecting the expression of several common reporter genes in cells and cell extracts. These include substrates for β -galactosidase and β -glucuronidase (Section 10.2), secreted alkaline phosphatase (SEAP, Section 10.3), chloramphenicol acetyltransferase (CAT) and luciferase (Section 10.6). Some of our EnzChek® and DQ™ Kits (Section 10.4) are useful for study of the uptake and metabolism of proteins during phagocytosis (Section 16.1). Substrates for specific proteases are also useful for the detection of apoptosis (Section 15.5).

Thiol-Reactive Fluorogenic Substrates

We prepare a number of enzyme substrates for live-cell assays that incorporate a mildly thiol-reactive chloromethyl moiety. Once inside the cell, this chloromethyl group undergoes what is believed to be a glutathione S-transferase-mediated reaction to produce a membrane-impermeant, glutathione-fluorescent dye adduct, although our experiments suggest that they may also react with other intracellular components. Regardless of the mechanism, many cell types loaded with these chloromethylated substrates are both fluorescent and viable for at least 24 hours after loading and often through several cell divisions. Furthermore, unlike the free dye, the peptide-fluorescent dye adducts contain amino groups and can therefore be covalently linked to surrounding biomolecules by fixation with formaldehyde or glutaraldehyde. This property permits long-term storage of the labeled cells or tissue and, in cases where the anti-dye antibody is available (Section 7.4), amplification of the conjugate by standard

Figure 10.1.10 CellTracker™ Blue CMAC (7-amino-4-chloromethylcoumarin, C2110).

Figure 10.1.11 CellTracker™ Blue CMF₂HC (4-chloromethyl-6,8-difluoro-7-hydroxycoumarin, C12881).

immunochemical techniques, including tyramide signal amplification (TSA, Section 6.2). Chloromethyl analogs of fluorogenic substrates for glycosidases (for example, in the DetectaGene™ Green CMFDG Kit, (D2920); Section 10.2) and peptidases are available. Our CellTracker™ Blue CMAC and CellTracker™ Blue CMF₂HC dyes (C2110, Figure 10.1.10; C12881, Figure 10.1.11) are precursors to peptidase and glycosidase substrates, respectively, and are also used for long-term cell tracing (Section 14.2).

Lipophilic Fluorophores

Lipophilic analogs of fluorescein and resorufin exhibit many of the same properties as the water-soluble fluorophores, including relatively high extinction coefficients and good quantum yields. In most cases, however, substrates based on these lipophilic analogs load more readily into cells, permitting use of much lower substrate concentrations in the loading medium, and their fluorescent products are better retained after cleavage than their water-soluble counterparts. Lipophilic substrates and their products probably also distribute differently in cells and likely associate with lipid regions of the cell. When passive cell loading or enhanced dye retention are critical parameters of the experiment, we recommend using our lipophilic substrates for glycosidases (such as our ImaGene Green™ and ImaGene Red™ products, Section 10.2). Like resazurin (R12204, Section 15.2), dodecylresazurin—the substrate in our LIVE/DEAD® Cell Viability Assay Kit, Vybrant® Cell Metabolic Assay Kit and Metabolic Activity/Annexin V/Dead Cell Apoptosis Kit (L34951, V23110, V35114; Section 15.3, Section 15.5)—is reduced to dodecylresorufin by metabolically active cells; however, this lipophilic substrate is more useful than resazurin for microplate assays of all metabolic activity and permits single-cell analysis of cell metabolism by flow cytometry and cell counting. Dodecylresorufin is also the hydrolysis product of the β -galactosidase substrate used in our ImaGene Red™ C₁₂RG *lacZ* Gene Expression Kit (I2906, Section 10.2).

Substrates Yielding Insoluble Fluorescent or Chromophoric Products

Alkaline phosphatase, β -galactosidase and horseradish peroxidase (HRP) conjugates are widely used as secondary detection reagents for immunohistochemical analysis and *in situ* hybridization, as well as for protein and nucleic acid detection by Southern, northern and western blots. In order to precisely localize enzymatic activity in a tissue, cell, gel or blot, the substrate must yield a product that immediately precipitates or reacts at the site of enzymatic activity. In addition, various methods such as chromatography, isoelectric focusing and gel electrophoresis are commonly employed to separate enzymes preceding their detection. A review by Weder and Kaiser discusses the use of a wide variety of fluorogenic substrates for the detection of electrophoretically separated hydrolases.¹⁰

Figure 10.1.12 ELF* 97 alcohol (E6578).

Figure 10.1.13 Photostability comparison for ELF* 97 alcohol- and fluorescein-labeled tubulin preparations. Tubulin in acetone-fixed CRE BAG 2 mouse fibroblasts was labeled with an anti- β -tubulin monoclonal antibody and then detected using biotin-XX goat anti-mouse IgG antibody (B2763) in conjunction with either our ELF* 97 Cytological Labeling Kit (E6603, ■) or fluorescein streptavidin (S869, ●). Alternatively, anti-tubulin labeling was detected directly using fluorescein goat anti-mouse IgG antibody (F2761, ○). The photostability of labeling produced by the three methods was compared by continuously illuminating stained samples on a fluorescence microscope using Omega* Optical longpass optical filter sets. Images were acquired every 5 seconds using a Star 1 CCD camera (Photometrics*); the average fluorescence intensity in the field of view was calculated with Image-1 software (Universal Imaging Corp.) and expressed as a fraction of the initial intensity. Three data sets, representing different fields of view, were averaged for each conjugate to obtain the plotted time courses.

Figure 10.1.14 The normalized fluorescence excitation and emission spectra of the ELF* 97 alcohol precipitate (E6578), which is generated by enzymatic cleavage of the soluble ELF* 97 phosphatase substrate (E6588, E6589).

Substrates Yielding Insoluble Fluorescent Products

In addition to the commonly used chromogenic substrates, including BCIP, NBT and X-gal, we have developed a fluorogenic ELF* 97 phosphatase substrate that fluoresces only weakly in the blue range. Upon enzymatic cleavage, however, this substrate forms the intensely yellow-green-fluorescent ELF* 97 alcohol (E6578, Figure 10.1.12), which precipitates immediately at the site of enzymatic activity. The fluorescent ELF* alcohol precipitate is exceptionally photostable (Figure 10.1.13) and has a high Stokes shift (Figure 10.1.14). We offer several ELF* Kits based on the ELF* 97 phosphatase substrate; see Section 6.3 for a complete discussion of ELF* technology.

Tyramide signal amplification (TSA) technology utilizes fluorescent or biotin-labeled tyramide substrates that are activated by HRP to phenoxyl radicals. These phenoxy radicals are then trapped by reaction with nearby tyrosine residues, resulting in localized tyramide deposition. We offer a wide assortment of TSA* Kits based on this detection technology; see Section 6.2 for a complete discussion of TSA technology.

Substrates Yielding Insoluble Chromophoric Products

A number of chromogenic substrates for hydrolytic enzymes are derived from indolyl chromophores. These initially form a colorless—and sometimes blue-fluorescent—3-hydroxyindole ("indoxyl"), which spontaneously, or through mediation of an oxidizing agent such as nitro blue tetrazolium (NBT, N6495; Section 10.3) or potassium ferricyanide,¹¹ is converted to an intensely colored indigo dye that typically precipitates from the medium (Figure 10.1.15). Halogenated indolyl derivatives, including 5-bromo-4-chloro-3-indolyl β -D-galactopyranoside (X-Gal, B1690; Section 10.2) and 5-bromo-4-chloro-3-indolyl phosphate (BCIP, N6547) are generally preferred because they produce finer precipitates that are less likely to diffuse from the site of formation, making them especially useful for detecting enzymatic activity in cells, tissues, gels and blots.

Substrates Based on Excited-State Energy Transfer

The principle of excited-state energy transfer can also be used to generate fluorogenic substrates (Fluorescence Resonance Energy Transfer (FRET)—Note 1.2). For example, the EDANS fluorophore in our HIV protease and renin substrates is effectively quenched by a nearby dabcyI acceptor chromophore (Figure 10.1.16). This chromophore has been carefully chosen for maximal overlap of its absorbance with the fluorophore's fluorescence, thus ensuring that the fluorescence is quenched through excited-state energy transfer. Proteolytic cleavage of the substrate results in spatial separation of the fluorophore and the acceptor chromophore, thereby restoring the fluorophore's fluorescence.^{12–15}

Many of the dyes described in Chapter 1 have been used to form energy-transfer pairs, some of which can be introduced during automated synthesis of peptides using modified amino acids described in Section 9.5. Table 1.10 (Section 1.6) lists our nonfluorescent quenching dyes and their spectral properties.

The protease substrates in three of our EnzChek* Protease Assay Kits (Section 10.4) are heavily labeled casein conjugates; the close proximity of dye molecules results in self-quenching. Hydrolysis of the protein to smaller fragments is accompanied by a dramatic increase in fluorescence, which forms the basis of a simple and sensitive continuous assay for a variety of proteases. In addition, we offer a phospholipase A substrate (bis-BODIPY* FL C₁₁-PC, B7701; Section 17.4) that contains a BODIPY* FL fluorophore on each phospholipid acyl chain. Proximity of the BODIPY* FL fluorophores on adjacent phospholipid acyl chains causes fluorescence self-quenching that is relieved only when the fluorophores are separated by phospholipase A-mediated cleavage. PED6, a phospholipid with a green-fluorescent BODIPY* fatty acid on the lipid portion of the molecule and a 2,4-dinitrophenyl quencher on the polar head group (PED6, D23739; Section 17.4) is useful as a specific phospholipase-A₂ substrate.¹⁶

Fluorescent Derivatization Reagents for Discontinuous Enzyme Assays

The mechanism of some enzymes makes it difficult to obtain a continuous optical change during reaction with an enzyme substrate. However, a discontinuous assay can often be developed by derivatizing the reaction products with one of the reagents described in Chapter 1, Chapter 2 and Chapter 3, usually followed by a separation step in order to generate a product-specific fluorescent signal.

For example, fluorescamine or *o*-phthaldialdehyde (OPA) (F2332, F20261, P2331MP; Section 1.8) can detect the rate of *any* peptidase reaction by measuring the increase in the concentration of free amines in solution.^{17,18} The activity of enzymes that produce free coenzyme A from its esters can be detected using thiol-reactive reagents such as 5,5'-dithiobis-(2-nitrobenzoic acid) (DTNB, D8451; Section 5.2) or 7-fluorobenz-2-oxa-1,3-diazole-4-sulfonamide¹⁹ (ABD-F, F6053; Section 2.2). The products of enzymes that metabolize low molecular weight substrates can frequently be detected by chromatographic or electrophoretic analysis. HPLC or capillary zone electrophoresis can also be used to enhance the sensitivity of reactions that yield fluorescent products.²⁰

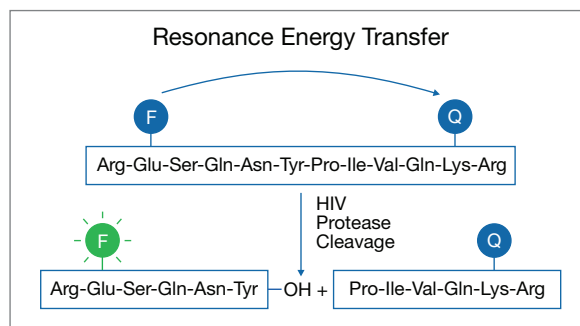

Figure 10.1.16 Principle of the fluorogenic response to protease cleavage exhibited by HIV protease substrate 1 (H2930). Quenching of the EDANS fluorophore (F) by distance-dependent resonance energy transfer to the dabcyI quencher (Q) is eliminated upon cleavage of the intervening peptide linker.

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- A191 in aqueous solution (pH 7.0): Abs = 342 nm (EC = 16,000 cm⁻¹M⁻¹), Em = 441 nm.
- C2110 in MeOH: Abs = 364 nm (EC = 16,000 cm⁻¹M⁻¹), Em = 454 nm.
- Spectra of hydroxycoumarins are pH dependent. Below the pK_a, Abs shifts to shorter wavelengths (325–340 nm) and fluorescence intensity decreases. Approximate pK_a values are 7.8 (H189, C2111), 7.5 (H185) and 4.9 (D6566, C12881).
- The fluorescence quantum yield of DiFMU (D6566) is 0.89 measured in 0.1 M phosphate buffer, pH 10. (Bioorg Med Chem Lett (1998) 8:3107)
- ND = not determined.
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- ELF® 97 alcohol is insoluble in water. Spectral maxima listed are for an aqueous suspension; for this reason, the value of EC cannot be determined.
- Absorption and fluorescence of fluorescein derivatives are pH dependent. Extinction coefficients and fluorescence quantum yields decrease markedly at pH <7.
- F36915 consists of a fluorescein solution in 100 mM sodium borate buffer pH 9.5. The concentration of fluorescein is set spectrophotometrically to be equivalent to that of NIST Standard Reference Material (SRM®) 1932.
- The fluorescence quantum yield of resorufin in pH 9.5 buffer is 0.74 and the fluorescence lifetime (τ) is 2.9 nanoseconds. (Photochem Photobiol (2002) 76:385)
- Absorption and fluorescence of resorufin are pH dependent. Below the pK_a (~6.0), Abs shifts to ~480 nm and both EC and the fluorescence quantum yield are markedly lower.
- Resorufin is unstable in the presence of thiols such as dithiothreitol (DTT) and 2-mercaptoethanol. (Bioorg Chem (1998) 26:63)
- R6479 in aqueous solution (pH 7.0): Abs = 496 nm (EC = 83,000 cm⁻¹M⁻¹), Em = 520 nm.

PRODUCT LIST 10.1 INTRODUCTION TO ENZYME SUBSTRATES AND THEIR REFERENCE STANDARDS

Cat. No.	Product	Quantity
A191	7-amino-4-methylcoumarin *reference standard*	100 mg
C2110	CellTracker™ Blue CMAC (7-amino-4-chloromethylcoumarin)	5 mg
C12881	CellTracker™ Blue CMF ₂ HC (4-chloromethyl-6,8-difluoro-7-hydroxycoumarin)	5 mg
C183	3-cyano-7-hydroxycoumarin	100 mg
D6566	6,8-difluoro-7-hydroxy-4-methylcoumarin (DiFMU) *reference standard*	10 mg
E6578	ELF® 97 alcohol *1 mM solution in DMSO*	1 mL
F36915	fluorescein *NIST-traceable standard* *nominal concentration 50 μM* *special packaging*	5 x 1 mL
F1300	fluorescein *reference standard*	1 g
H6482	7-hydroxy-9H-(1,3-dichloro-9,9-dimethylacridin-2-one) (DDAO) *reference standard*	10 mg
H189	7-hydroxy-4-methylcoumarin *reference standard*	1 g
R363	resorufin, sodium salt *reference standard*	100 mg
R6479	rhodamine 110 (R110) *reference standard*	25 mg

10.2 Detecting Glycosidases

Glycosidase enzymes exhibit very high selectivity for hydrolysis of their preferred sugars. For example, β -galactosidase rapidly hydrolyzes β -D-galactopyranosides but usually does not hydrolyze either the anomeric α -D-galactopyranosides or the isomeric β -D-glucopyranosides. Endogenous glycosidase activity is frequently used to characterize strains of microorganisms^{1–3} and to selectively label organelles of mammalian cells;^{4–6} defects in glycosidase activity are characteristic of several diseases.^{7–9}

In addition, glycosidases are important reporter gene markers. Specifically, *lacZ*, which encodes β -galactosidase, is extensively used as a reporter gene in animals and yeast, whereas the β -glucuronidase (GUS) gene is a popular reporter gene in plants.^{10–14} Glycosidase substrates are also used in conjunction with glycosidase-conjugated secondary detection reagents in immunohistochemical techniques and enzyme-linked immunosorbent assays¹⁵ (ELISAs). Molecular Probes® fluorogenic and chromogenic glycosidase substrates are listed in Table 10.1.

Fluorogenic β -Galactosidase Substrates

Fluorescein Digalactoside

Probably the most sensitive fluorogenic substrate for detecting β -galactosidase is fluorescein di- β -D-galactopyranoside¹⁶ (FDG, F1179; Figure 10.2.1). Nonfluorescent FDG is sequentially hydrolyzed by β -galactosidase, first to fluorescein monogalactoside (FMG) and then to highly fluorescent fluorescein (F1300, F36915; Section 10.1). Enzyme-mediated hydrolysis of FDG can be followed by the increase in either absorbance or fluorescence. Although the turnover rates of FDG and its analogs are considerably slower than that of the common spectrophotometric galactosidase substrate, *o*-nitrophenyl β -D-galactopyranoside (ONPG),^{17,18} the absorbance of fluorescein is about

Figure 10.2.1 Sternomastoid muscle fibers of a living mouse that have been transfected with YOYO®-1 dye-stained DNA (red) containing the *lacZ* reporter gene and then stained with the β -galactosidase substrate fluorescein di- β -D-galactopyranoside (FDG, F1179). DNA stained with YOYO®-1 (Y3601) prior to implantation could still be localized 5 days after application. Fluorescence signals were visualized *in situ* by epifluorescence microscopy with a low-light level SIT camera and a computer imaging system. Image contributed by Peter van Mier, Washington University School of Medicine.

5-fold greater than that of *o*-nitrophenol. Moreover, fluorescence-based measurements can be several orders of magnitude more sensitive than absorption-based measurements. Fluorescence-based assays employing FDG are also reported to be 100- to 1000-fold more sensitive than radioisotope-based ELISAs.¹⁹

In addition to its use in ELISAs, the FDG substrate has proven very effective for identifying *lacZ*-positive cells with fluorescence microscopy^{20–23} and flow cytometry.^{24–29} FDG has been employed to identify cells infected with recombinant herpesvirus,³⁰ to detect unique patterns of β -galactosidase expression in live transgenic zebrafish embryos²⁰ and to monitor β -galactosidase expression in bacteria.^{21,31,32} The purity of FDG and its analogs is very important because a reagent with extremely low fluorescence background is essential for most applications. Our stringent quality control helps ensure that the fluorescent contamination of FDG is less than 50 ppm.

The FluoReporter® *lacZ* Flow Cytometry Kit (F1930) provides materials and protocols for quantitating β -galactosidase activity with FDG in single cells using flow cytometry.

The FluoReporter® *lacZ* Flow Cytometry Kit contains:

- FDG
- Phenylethyl β -D-thiogalactopyranoside (PETG; also available separately as a solid, P1692), a broad-spectrum β -galactosidase inhibitor for stopping the reaction³³
- Chloroquine diphosphate for inhibiting hydrolysis of the substrate in acidic organelles by endogenous galactosidase enzymes
- Propidium iodide for detecting dead cells
- Detailed protocol

Each kit provides sufficient reagents for 50 flow cytometry assays. This assay enables researchers to detect heterogeneous expression patterns and to sort and clone individual cells expressing known quantities of β -galactosidase. Practical reviews on using FDG for flow cytometric analysis and sorting of *lacZ*-positive cells are available.^{34,35}

The fluorescent hydrolysis product of FDG is fluorescein (F1300, F36915; Section 10.1), which rapidly leaks from cells under physiological conditions, making the use of FDG problematic for prolonged studies. Our DetectaGene™ Green, ImaGene Green™ and ImaGene Red™ substrates (described below) have been specifically designed to improve retention of the fluorescent hydrolysis products in cells.

Resorufin Galactoside

Unlike FDG, resorufin β -D-galactopyranoside (R1159) requires only a single-step hydrolysis reaction to attain full fluorescence.³⁶ This substrate is especially useful for sensitive enzyme measurements in ELISAs.^{15,37} The relatively low pK_a (~6.0) of its hydrolysis product, resorufin (R363, Section 10.1), permits its use for continuous measurement of enzymatic activity at physiological pH. Resorufin galactoside has also been used to quantitate β -galactosidase activity in single yeast cells by flow cytometry³⁸ and to detect immobilized β -galactosidase activity in bioreactors.^{39,40}

Figure 10.2.2 Absorption spectra of 1) DDAO galactoside (D6488) and 2) DDAO (H6482) at equal concentrations in pH 9 aqueous buffer. These spectra show the large spectral shift accompanying enzymatic cleavage of DDAO-based substrates.

DDAO Galactoside

Although substrates based on DDAO (7-hydroxy-9*H*-(1,3-dichloro-9,9-dimethylacridin-2-one)) are intrinsically fluorescent (excitation/emission ~460/610 nm), β -galactosidase-catalyzed hydrolysis of DDAO galactoside (D6488) liberates the DDAO fluorophore, which absorbs and emits light at much longer wavelengths (excitation/emission ~645/660 nm) (Figure 10.2.2). Not only can DDAO (H6482, Section 10.1) be excited without interference from the unhydrolyzed substrate, but its fluorescence emission is detected at wavelengths that are well beyond the autofluorescence exhibited by most biological samples. The relatively low pK_a of DDAO (~5.5) permits continuous monitoring of β -galactosidase activity at physiological pH.

Methylumbelliferyl Galactoside

The fluorogenic β -galactosidase substrate β -methylumbelliferyl β -D-galactopyranoside (MUG, M1489MP) is commonly used to detect β -galactosidase activity in cell extracts,^{41–43} lysosomes⁴⁴ and human blood serum.⁴⁵ However, the hydrolysis product, 7-hydroxy-4-methylcoumarin (β -methylumbelliferone, H189; Section 10.1; Figure 10.2.3), has a relatively high pK_a (~7.8), precluding its use for continuous measurement of enzymatic activity.

Carboxyumbelliferyl Galactoside and the FluoReporter[®] *lacZ*/Galactosidase Quantitation Kit

Hydrolysis of 3-carboxyumbelliferyl β -D-galactopyranoside (CUG) by β -galactosidase yields 7-hydroxycoumarin-3-carboxylic acid (H185, Section 10.1). 7-Hydroxycoumarin has a pK_a below the pH at which the turnover rate is optimal, facilitating the use of CUG for continuous measurements of β -galactosidase activity. Unlike most substrates for β -galactosidase, CUG is quite water-soluble and can be used over a wide range of concentrations in enzymatic activity measurements.^{46–48} Our

Table 10.1 Glycosidase enzymes and their fluorogenic and chromogenic substrates.

FluoReporter® *lacZ*/Galactosidase Quantitation Kit (F2905) provides a CUG-based method for quantitating β -galactosidase activity in ELISAs or *lacZ*-positive cell extracts. Each kit contains:

- CUG
- 7-Hydroxycoumarin-3-carboxylic acid, a reference standard
- Detailed protocols suitable for use with any fluorescence microplate reader

Sufficient reagents are provided for approximately 1000 β -galactosidase assays. We have demonstrated a practical detection limit of ~ 0.5 pg of β -galactosidase using this kit and a fluorescence microplate reader.

Fluorescent Glycosphingolipids

β -Galactosidase enzymes that act on the lipophilic sphingosyl galactosides, including galactosylceramidase (EC 3.2.1.46) and G_{M1} ganglioside β -galactosidase (EC 3.2.1.23), are particularly important in neurochemistry. The preferred substrates for these enzymes are sphingolipids derived from galactose (Section 13.3). Galactosylceramidase converts substrates such as our BODIPY® FL C_{12} -galactosylceramide (D7519) back to the ceramide. Purified G_{M1} ganglioside galactosidase removes the terminal galactose residue from lactosylceramides such as our BODIPY® FL C_5 -lactosylceramide⁴⁹ (D13951), yielding the corresponding glucosylceramide.⁵⁰ BODIPY® FL C_5 -lactosylceramide complexed with bovine serum albumin (BSA) (B34402) may also be useful for assaying G_{M1} ganglioside galactosidase. Complexing fluorescent lipids with BSA facilitates the preparation of aqueous solutions by eliminating the need for organic solvents to dissolve the lipophilic probe. The lack of a spectral shift between the substrates and the hydrolysis products in these reactions means that extraction and chromatographic separation of the products is necessary for assessment of enzyme activity.

Figure 10.2.3 Absorption and fluorescence emission spectra of 7-hydroxy-4-methylcoumarin (H189) in pH 9.0 buffer. The spectra of 6,8-difluoro-7-hydroxy-4-methylcoumarin (D6566) are essentially identical.

Modified Fluorogenic β -Galactosidase Substrates with Improved Cellular Retention

The primary problems associated with detecting *lacZ* expression in live cells using fluorogenic substrates are:

- Difficulty in loading the substrates under physiological conditions
- Leakage of the fluorescent product from live cells
- High levels of endogenous β -galactosidase activity in many cells

Our DetectaGene™ Green, ImaGene Green™ and ImaGene Red™ Kits are designed to improve the sensitivity of β -galactosidase assays by yielding products that are better retained in viable cells and, in the case of the ImaGene Green™ and ImaGene Red™ Kits, by providing substrates that can be passively loaded into live cells. The high level of endogenous β -galactosidase activity remains an obstacle when detecting low levels of *lacZ* expression.

DetectaGene™ Green *lacZ* Gene Expression Kit

The substrate in our DetectaGene™ Green *lacZ* Gene Expression Kit (D2920)—5-chloromethylfluorescein di- β -D-galactopyranoside (CMFDG)—is a galactose derivative that has been chemically modified to include a mildly thiol-reactive chloromethyl group (Figure 10.2.4). Once loaded into the cell using the Influx™ pinocytotic cell-loading reagent (I14402,

Figure 10.2.4 Sequential β -galactosidase hydrolysis and peptide conjugate formation of CMFDG, a component of the DetectaGene™ Green CMFDG *lacZ* Gene Expression Kit (D2920).

Figure 10.2.5 Live CRE BAG 2 cells loaded with the β -galactosidase substrate from the DetectaGene™ Green CMFDG *lacZ* Gene Expression Kit (D2920). The substrate was loaded into cells with the aid of the Influx™ pinocytotic cell-loading reagent (I14402), a component of the DetectaGene™ Green Kit. The cells were then stained with LysoTracker® Red DND-99 (L7528) to differentiate lysosomal from cytoplasmic localization of the green-fluorescent CMFDG product, as well as to illustrate the selective rupture of only the Influx™ reagent-induced pinocytotic vesicles. The double-exposure image was acquired using bandpass filters appropriate for fluorescein and Texas Red® dye.

Figure 10.2.6 5-(Pentafluorobenzoylamino)fluorescein di- β -D-galactopyranoside (PFB-FDG, P11948).

included in Kit D2920; Figure 10.2.5) or by microinjection, hypotonic shock or another technique (Table 14.1, Section 1), the DetectaGene™ substrate undergoes two reactions: 1) its two galactose moieties are cleaved by intracellular β -galactosidase and 2) either simultaneously or sequentially, its chloromethyl moiety reacts with glutathione and possibly other intracellular thiols to form a membrane-impermeant, peptide–fluorescent dye adduct⁵¹ (Figure 10.2.4). Because peptides do not readily cross the plasma membrane, the resulting fluorescent adduct is much better retained than is the free dye, even in cells that have been kept at 37°C. We have found that *lacZ*-positive cells loaded from medium containing 1 mM CMFDG are as fluorescent as cells loaded with 40-fold higher concentrations of FDG. Furthermore, unlike the free dye, the peptide–fluorescent dye adducts contain amine groups and can therefore be covalently linked to surrounding biomolecules by fixation with formaldehyde or glutaraldehyde. This property permits long-term storage of the labeled cells or tissue, as well as amplification of the conjugate by standard immunohistochemical techniques using our anti–fluorescein/Oregon Green® antibody (Section 7.4, Table 7.8).

The CMFDG substrate in our DetectaGene™ Green *lacZ* Gene Expression Kit was used to stain *lacZ*-expressing floor plate cells in tissue dissected from a developing mouse embryo,⁵² to identify *lacZ*-enhancer–trapped *Drosophila* neurons in culture and to detect β -galactosidase activity in hippocampus slices.⁵³ In the latter study, the fluorescence of the neurons could still be visualized 24 hours after dye loading, and the fluorescent CMFDG-loaded neurons exhibited a normal pattern and time course of axonal outgrowth and branching.⁵⁴ CMFDG also has been microinjected into primary hepatocytes, fibroblasts and glioma cells to detect β -galactosidase activity⁵⁵ and has been incorporated into an electrophysiological recording pipette to confirm the identity of neurons cotransfected with the *lacZ* gene and a second gene encoding Ca²⁺/calmodulin-dependent protein kinase II⁵⁶ (CaM kinase II).

The DetectaGene™ Green CMFDG *lacZ* Gene Expression Kit (D2920) contains:

- DetectaGene™ Green CMFDG substrate (Figure 10.2.4)
- Phenylethyl β -D-thiogalactopyranoside (PETG; also available separately as a solid, P1692), a broad-spectrum β -galactosidase inhibitor for stopping the reaction³³
- Verapamil for inhibiting product efflux^{57,58}
- Chloroquine diphosphate for inhibiting acidic hydrolysis of the substrate
- Propidium iodide for detecting dead cells
- Influx™ pinocytotic cell-loading reagent for introducing CMFDG into cells
- Detailed protocols for detecting β -galactosidase activity

When used at the recommended dilutions, sufficient reagents are provided for approximately 200 flow cytometry tests with the DetectaGene™ Green CMFDG Kit. Verapamil has been added to the DetectaGene™ Green CMFDG *lacZ* Gene Expression Kit because we have observed that cell retention of the fluorescent dye–peptide adduct can be considerably improved in many cell types by adding verapamil to the medium.⁵⁷

Figure 10.2.7 Bovine pulmonary artery endothelial cells simultaneously stained with LysoTracker® Red DND-99 (L7528), a cell-permeant, fixable lysosomal stain, and with 5-(pentafluorobenzoylamino)fluorescein di- β -D-galactopyranoside (PFB-FDG, P11948), a fluorogenic substrate for β -galactosidase. PFB-FDG is nonfluorescent until enzymatically hydrolyzed to green-fluorescent PFB-F. The center image demonstrates colocalization of the LysoTracker® Red DND-99 dye and PFB-F to the lysosomes. The left image was acquired with a bandpass filter set appropriate for fluorescein, the right image was acquired with a bandpass filter set appropriate for Texas Red® dye, and the center image was acquired with a double bandpass optical filter set appropriate for fluorescein and the Texas Red® dye.

PFB Aminofluorescein Digalactoside

5-(Pentafluorobenzoylamino)fluorescein di- β -D-galactopyranoside (PFB-FDG, P11948; Figure 10.2.6) yields the relatively lipophilic, green-fluorescent 5-(pentafluorobenzoylamino)fluorescein (PFB-F), which appears to localize to endosomal and lysosomal compartments when loaded into cells by pinocytosis (Figure 10.2.7), similar to our PFB aminofluorescein diglucoside (PFB-FDGlu, P11947). Thus, PFB-FDG is potentially useful for studying lysosomal storage diseases, including Krabbe disease, G_{M1} gangliosidosis, galactosialidosis and Morquio syndrome, which are all associated with deficient lysosomal β -galactosidase activity.⁵⁹

ImaGene Green™ and ImaGene Red™ *lacZ* Reagents and Gene Expression Kits

The fluorescein- and resorufin-based galactosidase substrates in our ImaGene Green™ and ImaGene Red™ *lacZ* Gene Expression Kits (I2904, I2906) have been covalently modified to include a 12-carbon lipophilic moiety. Unlike FDG or CMFDG, these lipophilic fluorescein- and resorufin-based substrates—abbreviated C_{12} FDG (Figure 10.2.8) and C_{12} RG (Figure 10.2.9) for the ImaGene Green™ and ImaGene Red™ substrates, respectively—can be loaded simply by adding the substrate to the aqueous medium in which the cells or organisms are growing, either at ambient temperatures or at 37°C. Once inside the cell, the substrates are cleaved by β -galactosidase, producing fluorescent products that are well retained by the cells, probably by incorporation of their lipophilic tails within the cellular membranes. Mammalian NIH 3T3 *lacZ*-positive cells grown for several days in medium containing 60 μ M C_{12} FDG appear morphologically normal, continue to undergo cell division and remain fluorescent for up to three cell divisions after replacement with substrate-free medium.^{51,60}

The C_{12} FDG substrate in our ImaGene Green™ *lacZ* Expression Kit (I2904) is superior to FDG for flow cytometric detection of β -galactosidase activity in live mammalian cells.⁶¹ Using C_{12} FDG with flow cytometric methods, researchers have:

- Analyzed senescence-associated β -galactosidase activity⁶²
- Identified endocrine cell precursors in dissociated fetal pancreatic tissue based on their high levels of endogenous acid β -galactosidase⁶³
- Measured β -galactosidase activity in single recombinant *Escherichia coli* bacteria⁶⁴
- Detected the activity of β -galactosidase fusion proteins in yeast⁶⁵
- Sorted β -galactosidase-expressing mouse sperm cells⁶⁶ and insect cells that harbor recombinant baculovirus^{67,68}

The C_{12} FDG substrate was also useful in a fluorescence microscopy study of zebrafish expressing a *lacZ* reporter gene that was under the control of a mammalian homeobox gene promoter.⁶⁹ In some cell types, C_{12} FDG produces high levels of background fluorescence that may prohibit its use in assaying low β -galactosidase expression.²²

The ImaGene Green™ C_{12} FDG or ImaGene Red™ C_{12} RG *lacZ* Gene Expression Kits contain:

- ImaGene Green™ C_{12} FDG (in Kit I2904) or ImaGene Red™ C_{12} RG (in Kit I2906)
- Phenylethyl β -D-thiogalactopyranoside (PETG; also available separately as a solid, P1692), a broad-spectrum β -galactosidase inhibitor for stopping the reaction³³
- Chloroquine diphosphate for inhibiting acidic hydrolysis of the substrate
- Detailed protocols for detecting β -galactosidase activity

Each kit provides sufficient reagents for 100–200 assays, depending on the volume used for each experiment. 5-Dodecanoylamino fluorescein di- β -D-galactopyranoside (C_{12} FDG) is available separately (D2893). We also offer 5-acetylamino fluorescein di- β -D-galactopyranoside (C_2 FDG, A22010), which has been shown to be useful for detecting *lacZ* reporter gene expression in slow-growing mycobacteria, including *Mycobacterium tuberculosis*, using a fluorescence microplate reader or a flow cytometer.⁷⁰

Figure 10.2.8 ImaGene Green™ C_{12} FDG *lacZ* substrate (I2904).

Figure 10.2.9 ImaGene Red™ C_{12} RG *lacZ* substrate (I2906).

NovaBright™ β -Galactosidase Chemiluminescent Detection Kits

The NovaBright™ β -Galactosidase Enzyme Reporter Gene Chemiluminescent Detection Kits for mammalian cells (N10563, N10564) and for yeast cells (N10565, N10566) are designed for the rapid, simple and sensitive detection of the β -galactosidase reporter enzyme directly in microwell cultures of mammalian and yeast cells, respectively. This chemiluminescence-based assay uses the Galacton-*Star*® 1,2-dioxetane substrate (Figure 10.2.10) with a luminescence enhancer to generate glow light emission kinetics. A single reagent, which provides cell lysis components, luminescent substrate and enhancer, is added directly to cells in culture medium. Light emission typically reaches maximum intensity within 60–90 minutes and remains constant for 45–90 minutes or longer, depending upon assay temperature. Light emission is measured in a variety of luminometers without the need for solution injection.

The simple assay format and glow light emission achieved with the NovaBright™ β -Galactosidase Enzyme Reporter Gene Chemiluminescent Detection Kit provide an ideal assay system for automated high-throughput screening applications, enabling simple processing and measurement of multiple microplates. The dynamic range of the assay spans five orders of magnitude, from picogram to nanogram levels, enabling detection of a wide range of reporter enzyme concentration in cells.

Each NovaBright™ β -Galactosidase Enzyme Reporter Gene Chemiluminescent Detection Kit provides:

- Galacton-*Star*® substrate concentrate
- Assay buffer for mammalian cells (200 assays, N10563; 1000 assays, N10564) and for yeast cells (200 assays, N10565; 1000 assays, N10566)
- Detailed protocols

Chemiluminescent 1,2-dioxetane substrates for β -galactosidase, including the Galacton-*Star*® substrate described here and the Galacton-Plus substrate provided in the NovaBright™ β -Galactosidase and Firefly Luciferase Dual Enzyme Reporter Gene Chemiluminescent Detection Kits (N10561, N10562; Section 10.6) provide highly sensitive enzyme detection and have been utilized extensively in reporter assays in mammalian cell and tissue extracts.

Amplex® Red Galactose/Galactose Oxidase Assay Kit

Molecular Probes® Amplex® Red reagent (10-acetyl-3,7-dihydroxyphenoxazine, A12222, A22177) is an unusually stable peroxidase substrate that we have used in coupled reactions to detect a wide variety of analytes, including both enzymes and their substrates (see Section 10.5 for a list of all of our Amplex® Red Kits and reagents). Most of the assays can be performed as continuous assays at neutral or slightly acidic pH and are particularly suitable for automation and high-throughput screening using either an absorption- or fluorescence-based microplate reader.

Rather than requiring an unnatural fluorogenic or chromogenic substrate for β -galactosidase (or α -galactosidase), our Amplex® Red reagent-based technology permits the direct quantitation of free

galactose, which is produced by a wide variety of enzymes. Even enzymes that act on polysaccharides and glycolipids but are difficult to assay using known chromogenic substrates can, in some cases, be detected and their activity quantitated using the Amplex® Red reagent in combination with galactose oxidase and horseradish peroxidase. Unlike glucose oxidase, galactose oxidase produces H₂O₂ from either free galactose or from polysaccharides—including glycoproteins in solution and on cell surfaces—and from certain glycolipids in which galactose is the terminal residue (Figure 10.2.11). Because the galactose oxidase-catalyzed reaction does not require prior cleavage of the glycoside to free galactose by a galactosidase, appropriate control reactions must be used to ascertain whether the rate-limiting step is the galactosidase- or galactose oxidase-mediated reaction.

The Amplex® Red Galactose/Galactose Oxidase Assay Kit (A22179) provides an ultrasensitive fluorescence-based method for detecting galactose (Figure 10.2.12) and galactose oxidase (Figure 10.2.13) activity. This assay utilizes the Amplex® Red reagent to detect H₂O₂ generated by galactose oxidase-mediated oxidation of desialated galactose moieties. In the presence of horseradish peroxidase (HRP), the H₂O₂ thus produced reacts with the Amplex® Red reagent in a 1:1 stoichiometry to generate the red-fluorescent oxidation product resorufin.⁷¹ Resorufin has absorption and fluorescence emission maxima of approximately 571 nm and 585 nm, respectively, and because its extinction coefficient is high (54,000 cm⁻¹M⁻¹), the assay can be performed either fluorometrically or spectrophotometrically. The Amplex® Red Galactose/Galactose Oxidase Assay Kit provides all the reagents and a general protocol for the assay of galactose-producing enzymes or for the assay of galactose oxidase, including:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- Hydrogen peroxide (H₂O₂)
- Concentrated reaction buffer
- Galactose oxidase from *Dactylium dendroides*
- D-Galactose
- Detailed protocols

Sufficient reagents are provided for approximately 400 assays using either a fluorescence- or absorption-based microplate reader and reaction volumes of 100 μ L per assay. The Amplex® Red galactose/galactose oxidase assay is designed to accurately measure as little as 4 μ M galactose and 2 mU/mL galactose oxidase activity (Figure 10.2.12, Figure 10.2.13). Because of the high absorbance of resorufin, the spectrophotometric assay has only slightly lower sensitivity than the fluorometric assay.

Fluorogenic β -Glucuronidase Substrates

The substrate 4-methylumbelliferyl β -D-glucuronide (MUGlcU, M1490) is probably the most commonly used fluorogenic reagent for identifying *E. coli* contamination and for detecting GUS reporter gene expression in plants and plant extracts.^{72,73} However, β -glucuronidase substrates based on fluorescein may be much more sensitive and yield products that are fluorescent at physiological pH, making them useful for continuous monitoring of enzymatic activity.

Fluorescein Diglucuronide

Fluorescein di- β -D-glucuronide (FDGlcU, F2915) is colorless and nonfluorescent until it is hydrolyzed to the monoglucuronide and then to highly fluorescent fluorescein (F1300, F36915; Section 10.1). FDGlcU has been used to detect β -glucuronidase activity in plants and animals containing the GUS reporter gene^{73,74} and may also be useful for assaying lysosomal enzyme release from neutrophils.^{75,76} FDGlcU has also been used in the flow cytometry assay of individual mammalian cells expressing the *E. coli* β -glucuronidase gene.⁷⁷

PFB Aminofluorescein Diglucuronide

5-(Pentafluorobenzoylamino)fluorescein di- β -D-glucuronide (PFB-FDGlcU, P11949) yields the green-fluorescent 5-(pentafluorobenzoylamino)fluorescein (PFB-F), which appears to localize in endosomal and lysosomal compartments when PFB-FDGlcU is loaded into cells by pinocytosis, similar to PFB aminofluorescein diglucoside (PFB-FDGlu, P11947) described below. PFB-FDGlcU has been used for the quantitative analysis of β -glucuronidase activity in viable cells and for sorting high-expressing cells by flow cytometry.⁷⁸

Coumarin Glucuronides

4-Methylumbelliferyl β -D-glucuronide (MUGlcU, M1490) has been used extensively to detect *E. coli* in food,^{79,80} water,⁸¹ urine⁸² and environmental samples.⁸³ MUGlcU is stable to the conditions required for sterilization of media. A fluorogenic bioassay using MUGlcU has been developed to assess the detrimental effects of Li^+ , Al^{3+} , Cr^{6+} and Hg^{2+} on the proliferation of *E. coli*.⁸⁴ MUGlcU is also commonly used to identify plant tissue expressing the GUS reporter gene,^{85–87} including nondestructive assays that allow propagation of the transformed plant lines.^{88,89} In addition, MUGlcU has served as a sensitive substrate for lysosomal enzyme release from neutrophils.^{75,76}

ImaGene Green™ β -D-Glucuronidase Substrate

We also offer a lipophilic analog of fluorescein di- β -D-glucuronide in the ImaGene Green™ C₁₂FDGlcU GUS Gene Expression Kit (I2908). As with our similar ImaGene Green™ and ImaGene Red™ substrates for β -galactosidase, we have shown that this lipophilic β -glucuronidase substrate freely diffuses across the membranes of viable cultured tobacco leaf cells or protoplasts under physiological conditions. Furthermore, the fluorescent cleavage product is retained in the plant cell for hours to days, facilitating long-term measurements of GUS gene expression. In thin sections of transgenic tomato leaf, the ImaGene Green™ C₁₂FDGlcU GUS Gene Expression Kit provided a simple and reliable GUS assay that, coupled with confocal laser-scanning microscopy,

Figure 10.2.11 Detection scheme utilized in the Amplex® Red Galactose/Galactose Oxidase Assay Kit (A22179). Oxidation of the terminal galactose residue of a glycoprotein, glycolipid or polysaccharide results in the generation of H_2O_2 , which, in the presence of horseradish peroxidase (HRP), reacts stoichiometrically with the Amplex® Red reagent to generate the red-fluorescent oxidation product, resorufin.

Figure 10.2.10 Galacton-Star® chemiluminescent β -galactosidase substrate.

Figure 10.2.12 Detection of galactose using the Amplex® Red Galactose/Galactose Oxidase Assay Kit (A22179). Each reaction contained 50 μM Amplex® Red reagent, 0.1 U/mL HRP, 2 U/mL of galactose oxidase and the indicated amount of galactose in 1X reaction buffer. Reactions were incubated at 37°C. After 30 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. A background fluorescence of 93 units was subtracted from each data point.

Figure 10.2.13 Detection of galactose oxidase activity using the Amplex® Red Galactose/Galactose Oxidase Assay Kit (A22179). Each reaction contained 50 μM Amplex® Red reagent, 0.1 U/mL HRP, 100 μM galactose and the indicated amount of galactose oxidase in 1X reaction buffer. Reactions were incubated at 37°C. After 20 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm with fluorescence detection at 590 ± 17.5 nm.

Figure 10.2.14 Detection of glucose using the Amplex® Red Glucose/Glucose Oxidase Assay Kit (A22189). Reactions containing 50 µM Amplex® Red reagent, 0.1 U/mL HRP, 1 U/mL glucose oxidase and the indicated amount of glucose in 50 mM sodium phosphate buffer, pH 7.4, were incubated for 1 hour at room temperature. Fluorescence was then measured with a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. Background fluorescence (arbitrary units), determined for a no-glucose control reaction, has been subtracted from each value. The inset shows the sensitivity and linearity of the assay at low levels of glucose (0–15 µM).

yielded good cellular resolution.⁹⁰ The substrate has also been used to detect β -glucuronidase activity in an *Acremonium* transformant containing the GUS reporter gene.⁹¹

The ImaGene Green™ C₁₂FDGlcU GUS Gene Expression Kit contains:

- ImaGene Green™ C₁₂FDGlcU
- D-Glucaric acid-1,4-lactone, a β -glucuronidase inhibitor for stopping the reaction
- Detailed protocols for detecting β -glucuronidase activity

Each kit provides sufficient reagents for approximately 100 tests, depending on the volume used for each experiment.

Fluorogenic β -Glucosidase Substrates

β -Glucosidase, which is a marker for the endoplasmic reticulum (Section 12.4), is present in nearly all species. Its natural substrate is a glucosylceramide (Section 13.3). People with Gaucher disease have mutations in the acid β -glucosidase gene that result in abnormal lysosomal storage.⁹² Enzyme replacement therapy in Gaucher disease patients⁹³ requires sensitive and selective methods for measuring β -glucosidase activity (Table 10.1).

Fluorescein Diglycoside

As with the other fluorescein diglycosides, our fluorogenic fluorescein di- β -D-glucopyranoside (FDGlu, F2881) is likely to yield the greatest sensitivity for detecting β -glucosidase activity in both cells⁹² and emulsion droplets.⁹⁴ This substrate has been used to demonstrate the utility of *Saccharomyces cerevisiae* and *Candida albicans* exo-1,3- β -glucanase genes as reporter genes.⁹⁵ Because these reporter genes encode secreted proteins, assays for reporter gene expression do not require cell permeabilization. FDGlu has been reported to be a selective substrate for the flow cytometric assay of lysosomal glucocerebrosidase activity in a variety of cells.⁹⁶ The assay demonstrated the inordinately low glucocerebrosidase activity present in fibroblasts of Gaucher disease patients.

PFB Aminofluorescein Diglycoside

Through a collaboration with Matthew Lorincz and Leonard A. Herzenberg at Stanford University Medical School,⁹⁷ our PFB aminofluorescein diglycoside (PFB-FDGlu, P11947) has shown to be an excellent substrate for the flow cytometric discrimination of normal peripheral blood mononuclear cells (PBMC) from the PBMC of patients with Gaucher disease, a genetic deficiency in lysosomal β -glucocerebrosidase activity.⁵⁹

Figure 10.2.15 Principle of coupled enzymatic assays using our Amplex® Red reagent. Oxidation of glucose by glucose oxidase results in generation of H₂O₂, which is coupled to conversion of the Amplex® Red reagent to fluorescent resorufin by HRP. The detection scheme shown here is used in our Amplex® Red Glucose/Glucose Oxidase Assay Kit (A22189).

Amplex® Red Glucose/Glucose Oxidase Assay Kit

The Amplex® Red reagent (10-acetyl-3,7-dihydroxyphenoxazine, A12222, A22177; Section 10.5) is a colorless, stable and extremely versatile peroxidase substrate.⁹⁸ In an application similar to our use of the Amplex® Red reagent to detect galactose-producing enzymes, we have shown that it is practical to detect free glucose with high specificity at levels as low as 0.5 µg/mL using the Amplex® Red reagent in combination with excess glucose oxidase (Figure 10.2.14). Because the peroxidase- and glucose oxidase-mediated reactions can be coupled, it is potentially possible to measure the release of glucose by *any* glucosidase enzyme—for instance, α-glucosidase, β-glucosidase and glucocerebrosidase—in either a continuous or discontinuous assay (Figure 10.2.15). This assay should also be very useful for quantitation of glucose levels in foods, fermentation media and bodily fluids. The long-wavelength spectral properties of resorufin and high sensitivity of the assay result in little interference from colored components in the samples.

Our Amplex® Red Glucose/Glucose Oxidase Assay Kit (A22189) provides all the reagents required for the assay of glucose and enzymes that produce glucose. This kit is also useful for the assay of glucose oxidase activity from cell extracts. We have even shown that the Amplex® Red reagent can detect glucose liberated from native dextrans by dextranase⁹⁹ and from carboxymethylcellulose by cellulase.¹⁰⁰ The Amplex® Red Glucose/Glucose Oxidase Assay Kit contains:

- Amplex® Red reagent
- DMSO
- Horseradish peroxidase (HRP)
- Hydrogen peroxide (H₂O₂) for use as a positive control
- Concentrated reaction buffer
- Glucose oxidase
- D-glucose
- Detailed protocols

The kit provides sufficient reagents for approximately 500 assays using either a fluorescence- or absorption-based microplate reader and a reaction volume of 100 µL per assay.

Amplex® Red Neuraminidase/Sialidase Assay Kit

Neuraminidase (NA, also known as sialidase) is a very common enzyme that hydrolyzes terminal sialic acid residues on polysaccharide chains, most often exposing a galactose residue. Although NA is found in mammals, it is predominantly expressed in microorganisms such as bacteria and viruses,¹⁰¹ including the negative-stranded RNA influenza virus. NA located on the surface of the influenza virus is thought to play a key role in its invasion of target cells and subsequent replication through cleavage of target cell receptor sialic acid moieties. Anti-influenza drug design has therefore focused on the inhibition of NA.¹⁰² Various methods using chemiluminescence, absorption and fluorescence have been developed to quantitate NA in biological fluids for detecting influenza virus^{103,104} and for screening inhibitors of NA activity in drug development.^{104,105} The ultimate goal has been to develop a rapid, single-step assay that is sensitive and adaptable for a high-throughput screening format.

The Amplex® Red Neuraminidase (Sialidase) Assay Kit (A22178) provides an ultrasensitive fluorescence-based method for detecting NA activity. This assay utilizes the Amplex® Red reagent to detect H₂O₂ generated by galactose oxidase-mediated oxidation of desialated galactose, the end result of NA action. In the presence of horseradish peroxidase (HRP), the H₂O₂ thus produced reacts with a 1:1 stoichiometry with the Amplex® Red reagent to generate the red-fluorescent oxidation product, resorufin.⁷¹ Resorufin has absorption and fluorescence emission maxima of approximately 571 nm and 585 nm, respectively, and because the extinction coefficient is high (54,000 cm⁻¹M⁻¹), the assay can be performed either fluorometrically or spectrophotometrically. In a purified system with fetuin as the substrate, NA levels as low as 0.2 mU/mL have been detected with the Amplex® Red Neuraminidase (Sialidase) Assay Kit (Figure 10.2.16). NA activity can also be detected in biological samples such as serum (Figure 10.2.17).

Figure 10.2.16 Detection of neuraminidase activity using the Amplex® Red Neuraminidase (Sialidase) Assay Kit (A22178). Each reaction contained 50 µM Amplex® Red reagent, 0.1 U/mL HRP, 2 U/mL galactose oxidase, 250 µg/mL fetuin and the indicated amount of neuraminidase in 1X reaction buffer. Reactions were incubated at 37°C. After 30 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. A background fluorescence of 70 fluorescence units was subtracted from each data point. The inset shows the sensitivity and linearity of the assay at low levels of neuraminidase (0–0.8 mU/mL).

Figure 10.2.17 Detection of neuraminidase activity in serum using the Amplex® Red Neuraminidase (Sialidase) Assay Kit (A22178). Each reaction contained 50 µM Amplex® Red reagent, 0.1 U/mL HRP, 2 U/mL galactose oxidase, 250 µg/mL fetuin and the indicated amount of serum in 1X reaction buffer. Reactions were incubated at 37°C. After 60 minutes, fluorescence was measured in a fluorescence microplate reader using excitation at 530 ± 12.5 nm and fluorescence detection at 590 ± 17.5 nm. A background fluorescence of 112 units was subtracted from each data point.

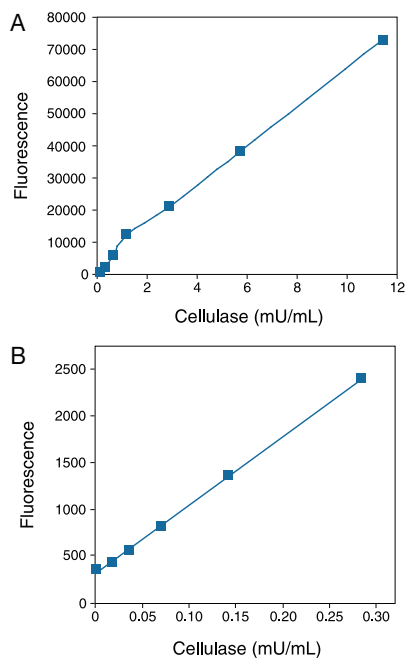

Figure 10.2.18 Sample standard curves obtained with the EnzChek® cellulase substrate. **A)** Cellulase from *Trichoderma reesei* was assayed with EnzChek® cellulase substrate (E33953) in 100 mM sodium acetate (pH 5.0) digestion buffer using cellulase activities from 0.018 to 11.4 mU/mL. **B)** This standard curve shows the same experiment at cellulase activities from 0.018 to 0.285 mU/mL. Samples were incubated for 30 minutes at room temperature and fluorescence was measured in a fluorescence microplate reader using excitation/emission wavelengths of 360/460 nm. Background fluorescence has not been subtracted.

Figure 10.2.19 Assay of α -amylase from *Bacillus* sp. using the EnzChek® Ultra Amylase Assay Kit. Reactions contained 200 μ g/mL DQ™ starch and the indicated amount of α -amylase in 100 mM MOPS (pH 6.9). After incubating at room temperature for 30 minutes, the fluorescence was measured in a microplate reader using excitation at 485 \pm 12 nm and fluorescence detection at 520 \pm 12 nm. The fluorescence of the blank sample (without enzyme) was subtracted from each value.

The Amplex® Red Neuraminidase/Sialidase Assay Kit contents include:

- Amplex® Red reagent
- Dimethylsulfoxide (DMSO)
- Horseradish peroxidase (HRP)
- Hydrogen peroxide (H₂O₂)
- Concentrated reaction buffer
- Galactose oxidase from *Dactylium dendroides*
- Fetuin from fetal calf serum
- Neuraminidase from *Clostridium perfringens*
- Detailed protocols

Each kit provides sufficient reagents for approximately 400 assays using either a fluorescence- or absorption-based microplate reader and reaction volumes of 100 μ L per assay.

EnzChek® Cellulase Substrate

The EnzChek® cellulase substrate (E33953) was developed for simple and rapid fluorescence-based quantitation of cellulase (EC 3.2.1.4). This cellulase assay can be completed in 30 minutes or less using a simple mix-incubate-read format. In contrast to other more complex, multistep assays, the EnzChek® cellulase assay is ideal for high-throughput screening, with a detection limit as low as 40 μ U/mL using a fluorescence microplate reader (Figure 10.2.18).

In the presence of cellulase, the EnzChek® cellulase substrate exhibits an increase in absorption at 360 nm, which is proportional to the amount of enzyme present and can be used to effectively quantitate enzyme activity using an absorption-based microplate reader or spectrophotometer. In addition, cellulase activity can be assayed using the Amplex® Red Glucose/Glucose Oxidase Assay Kit (A22189), as described above.¹⁰⁰

EnzChek® Ultra Amylase Assay

α -Amylase is a hydrolytic enzyme that catalyzes the conversion of starch to a mixture of glucose, maltose, maltotriose and dextrins. The levels of α -amylase in various fluids of the human body are of clinical importance in the diagnosis of disease states, including pancreatitis and diabetes.^{106–109} Plant and microbial α -amylases are important enzymes for industrial applications ranging from the manufacture of baked goods and dairy products to the production of ethanol and paper.

The EnzChek® Ultra Amylase Assay Kit (E33651) provides a fast, sensitive and convenient solution-based assay for measuring amylase activity¹¹⁰ or for screening amylase inhibitors in a high-throughput format. This EnzChek® Kit contains DQ™ starch, a starch derivative that is labeled with BODIPY® FL dye to such a degree that the fluorescence is quenched. Amylase-catalyzed hydrolysis of this substrate relieves the quenching, yielding brightly fluorescent BODIPY® FL dye-labeled fragments. The accompanying increase in fluorescence is proportional to amylase activity and can be monitored with a fluorescence microplate reader or fluorometer, using standard fluorescein filters. In tests using α -amylase from *Bacillus* sp. and 200 μ g/mL of the DQ™ starch substrate (30-minute incubation at room temperature), the EnzChek® Ultra Amylase Assay Kit could be used to detect α -amylase activity down to a final concentration of 0.002 U/mL, where one unit is defined as the amount of enzyme required to liberate 1 mg of maltose from starch in 3 minutes at 20°C, pH 6.9 (Figure 10.2.19).

The EnzChek® Ultra Amylase Assay Kit provides:

- DQ™ starch—a heavily labeled, highly quenched BODIPY® FL conjugate of starch from corn
- Concentrated reaction buffer
- Substrate solvent
- BODIPY® FL propionic acid in dimethylsulfoxide (DMSO), for use as a fluorescence standard
- Detailed protocols

Each kit provides sufficient reagents for 500 assays using 100 μ L assay volumes in a 96-well microplate assay format.

EnzChek® Xylanase Assay Kit

The hydrolysis of xylosidic linkages in hemicellulose polysaccharides by xylanase (EC 3.2.1.8) is important in a wide range of industrial processes, including baking, pulp and paper manufacturing and animal feed production. Xylanases occur in a variety of bacteria and fungi and are classified into two families—glycosyl hydrolase families 10 and 11.¹¹¹ Family 11 xylanases are more specific for xylans; family 10 xylanases also exhibit cellulase activity. Existing xylanase assay methods typically require separation or heating steps. The chromogenic substrate *o*-nitrophenyl- β -D-xylobioside can be used in a simpler homogeneous assay format; however, *o*-nitrophenol is pH sensitive ($pK_a = 7.2$) and therefore less than ideal for spectrophotometric assays of xylanases, which exhibit a wide range of pH optima (from pH 2 to 9).

The EnzChek® *Ultra* Xylanase Assay Kit (E33650) provides a quick and convenient mix-and-read assay for measuring xylanase activity or for screening xylanase inhibitors in a high-throughput format using a fluorescence microplate reader or a standard fluorometer (excitation/emission maxima $\sim 358/455$ nm).¹¹² This kit can be used for continuous detection of xylanase activity and offers broad dynamic and pH ranges (1.5 to 200 mU/mL and pH 4–10, respectively; Figure 10.2.20), high sensitivity (as low as 1.5 mU/mL) and excellent temperature tolerance. It has been tested with xylanases from *Trichoderma viride*, *T. longibrachiatum*, *Thermomyces lanuginosus*, *Aspergillus niger* and other bacterial and fungal species.

The EnzChek® *Ultra* Xylanase Assay Kit contains:

- Xylanase substrate
- Concentrated reaction buffer
- Fluorescence standard
- Detailed protocols

Each kit provides sufficient reagents for 500 assays using 100 μ L assay volumes in a 96-well microplate assay format.

EnzChek® Lysozyme Assay Kit

Lysozyme (muramidase) hydrolyzes β -1-4-glycosidic linkages between *N*-acetylmuramic acid and *N*-acetyl-D-glucosamine residues present in the mucopolysaccharide cell wall of a variety of microorganisms. Lysozyme is present in human serum, urine, tears, seminal fluid and milk. Serum and urine lysozyme levels may be elevated in acute myelomonocytic leukemia (FAB-M4), chronic myelomonocytic leukemia (CMML) and chronic myelocytic leukemia¹¹³ (CML). Increased serum lysozyme activity is also present in tuberculosis,¹¹⁴ sarcoidosis, megaloblastic anemias,¹¹⁵ acute bacterial infections, ulcerative colitis¹¹⁶ and Crohn disease.^{114,116} Elevated levels of urine and serum lysozyme occur during severe renal insufficiency, renal transplant rejection,¹¹⁷ urinary tract infections,¹¹⁸ glomerulonephritis and nephrosis.¹¹⁹

We have developed a simple and sensitive fluorescence-based EnzChek® assay that can continuously measure lysozyme activity in solution. This assay is based on a DQ™ lysozyme substrate comprising *M. lysodeikticus* cell walls that are labeled with fluorescein to such a degree that fluorescence is quenched. Lysozyme action relieves the quenching, yielding a dramatic increase in fluorescence that is proportional to lysozyme activity. This increase in fluorescence can be measured with any spectrofluorometer, mini-fluorometer or fluorescence microplate reader that can detect fluorescein (excitation/emission maxima $\sim 490/525$ nm). Our fluorescence-based EnzChek® Lysozyme Assay Kit (E22013) permits the detection of as little as 30 U/mL of lysozyme (Figure 10.2.21). One unit of lysozyme is the quantity of enzyme that produces a decrease in turbidity of 0.001 optical density units per minute at 450 nm measured at pH 7.0 (25°C) using a 0.3 mg/mL suspension of *Micrococcus lysodeikticus* cells as substrate.¹²⁰

Figure 10.2.20 The EnzChek® xylanase assay was performed at pH 4.6 under standard conditions (30-minute incubation) as described in the experimental protocol, using *Aspergillus niger* xylanase and the EnzChek® xylanase substrate. The fluorescence signal for 500 mU/mL of xylanase is equivalent to 49 μ M fluorescence standard, indicating 94% turnover of the xylanase substrate (initially 52 μ M).

Figure 10.2.21 Detection of lysozyme activity using the EnzChek® Lysozyme Assay Kit (E22013). Increasing amounts of lysozyme were incubated with the DQ™ lysozyme substrate for 60 minutes at 37°C. The fluorescence was measured in a fluorescence microplate reader using excitation/emission wavelengths of $\sim 485/530$ nm. Background fluorescence, determined for a no-enzyme control, was subtracted from each value.

The EnzChek® Lysozyme Assay Kit (E22013) contains:

- DQ™ lysozyme substrate—a heavily labeled, highly quenched fluorescein conjugate of *Micrococcus lysodeikticus*
- Reaction buffer
- Lysozyme from chicken egg white, for use as a positive control
- Detailed protocols

Each kit contains sufficient materials for approximately 400 assays of 100 µL in a fluorescence microplate reader.

Chromogenic Glycosidase Substrates

The widely used β-galactosidase substrate—5-bromo-4-chloro-3-indolyl β-D-galactopyranoside (X-Gal, B1690)—yields a dark blue precipitate at the site of enzymatic activity. X-Gal is useful for numerous histochemical and molecular biology applications, including detection of *lacZ* activity in cells and tissues. In contrast to β-glucuronidase as a gene marker, β-galactosidase can be fixed in cells and tissues with glutaraldehyde without loss of activity and detected with high resolution with X-Gal.¹²¹

The chromogenic substrate 5-bromo-4-chloro-3-indolyl β-D-glucuronic acid (X-GlcU, B1691) forms a dark blue precipitate. X-GlcU is routinely used to detect GUS expression in transformed plant cells and tissues.^{10,122–128} X-GlcU can also be used to detect *E. coli* contamination in food and water.^{129,130}

Auxiliary Products for Glycosidase Research

Phenylethyl β-D-Thiogalactopyranoside (PETG)

Phenylethyl β-D-thiogalactopyranoside (PETG, P1692) is a cell-permeant inhibitor of β-galactosidase activity.^{33,131} We provide PETG in our FluoReporter®, DetectaGene™ Green, ImaGene Green™ and ImaGene Red™ *lacZ* Gene Expression Kits for stopping the enzymatic reaction.

Streptavidin Conjugate of β-Galactosidase

We also offer the streptavidin conjugate of β-galactosidase (S931), a reagent used in a variety of ELISAs.¹³² β-D-Galactosidase streptavidin reportedly provided enhanced sensitivity over that obtained with the avidin conjugate of horseradish peroxidase in the detection of a variety of mammalian interleukins and their receptors by ELISA.¹³³ This reagent has also been used in fluorometric-reverse (IgE-capture)¹³⁴ and fluorescence-sandwich¹³⁵ ELISAs.

Rabbit Anti-β-Galactosidase Antibody

We offer a polyclonal antibody to the widely used reporter gene product, β-galactosidase. Our rabbit anti-β-galactosidase antibody (A11132) is raised against *E. coli*-derived β-galactosidase and demonstrates high selectivity for the enzyme. Whether it is being used as a reporter gene or to generate fusion proteins, anti-β-galactosidase provides an easy tool for detecting the enzyme. The antibody is suited to a variety of techniques, including immunoblotting, ELISA, immunoprecipitation and most immunological methods. β-Galactosidase has been used as a tag for quantitative detection of molecules expressed on a cell surface in unfixed, live cells, using anti-β-galactosidase and a β-galactosidase substrate for detection.¹³⁶ This novel "cell-ELISA" technique is reported to be applicable to adherent cells and nonadherent cells and to have utility for large-scale screening for expression of cell-surface molecules and of hybridomas for production of antibodies to cell-surface epitopes.

Rabbit Anti-β-Glucuronidase Antibody

In combination with a fluorophore- or enzyme-labeled anti-rabbit IgG secondary antibody (Section 7.2, Table 7.1), our anti-β-glucuronidase antibody (A5790) can be used to detect the GUS enzyme in transformed plant tissue^{10,137,138} and in transfected animal cells¹³⁹ using western blotting or immunohistochemical techniques. Furthermore, this antibody, which is raised in rabbits against *E. coli*-type X-A β-glucuronidase, can be immobilized in microplate wells in order to capture the GUS enzyme from cell lysates.¹⁴⁰ The enzymatic activity can subsequently be determined using any of our fluorogenic or chromogenic β-glucuronidase substrates.¹⁴¹

Related Products for Carbohydrate Research

We offer an extensive assortment of reagents for detection and analysis of carbohydrates that are described in other sections of this *Handbook*. These products include:

- Hydrazine, hydroxylamine and aromatic amine reagents for derivatization and analysis of reducing sugars and periodate-oxidized carbohydrates by electrophoretic methods (Section 3.3, Table 3.2)
- Lectins and fluorescent lectin conjugates (Section 7.7, Table 7.10)
- Pro-Q® Glycoprotein Blot and Gel Stain Kits (Section 9.4)
- Pro-Q® Emerald 300 Lipopolysaccharide Gel Stain Kit (P20495, Section 3.3)
- Fluorescent lipopolysaccharides (Section 16.1, Table 16.1)
- Fluorescent glycolipids, including BODIPY® FL C₅-ganglioside G_{M1} (B13950, Section 13.3)
- Fluorescent and biotinylated dextrans (Section 14.5, Table 14.4)
- NBD-glucosamine derivatives for glucose-transport studies (N13195, N23106; Section 15.2)
- Fluorescein insulin (I13269, Section 16.1)

For definitions of the contents of this data table, see "Using *The Molecular Probes® Handbook*" in the introductory pages.

Notes

- Enzymatic cleavage of this substrate yields a 5-acylaminofluorescein derivative with spectroscopic properties similar to D109.
- Enzymatic cleavage of this substrate yields a water-insoluble, blue-colored indigo dye (Abs ~615 nm).
- Em for BODIPY® FL sphingolipids shifts to ~620 nm when high concentrations of the probe (>5 mol %) are incorporated in lipid mixtures. (*J Cell Biol* (1991) 113:1267)
- Enzymatic cleavage of this product yields a fluorescent ceramide or glycosylceramide with unchanged spectral properties.
- This product is a lipid complexed with bovine serum albumin (BSA). Spectroscopic data are for the free lipid in MeOH.
- This product is packaged as a solution in 1:1 (v/v) DMSO/H₂O.
- Enzymatic cleavage of this substrate yields 5-chloromethylfluorescein, with spectroscopic properties similar to C1904.
- Data represent the substrate component of this kit.
- Fluorescence of the unhydrolyzed substrate is very weak.
- F1179 is soluble at 1 mM in water, but it is best to prepare a stock solution in DMSO.
- This product is supplied as a ready-made solution in the solvent indicated under "Soluble."
- This product is packaged as a solution in 7:3 (v/v) DMSO/EtOH.
- Enzymatic cleavage of this substrate yields 2-dodecylresorufin, Abs = 578 nm (EC = 69,000 cm⁻¹M⁻¹), Em = 597 nm in MeOH.

PRODUCT LIST 10.2 DETECTING GLYCOSIDASES

Cat. No.	Product	Quantity
A22010	5-acetylaminofluorescein di- β -D-galactopyranoside (C ₂ FDG)	5 mg
A22179	Amplex® Red Galactose/Galactose Oxidase Assay Kit *400 assays*	1 kit
A22189	Amplex® Red Glucose/Glucose Oxidase Assay Kit *500 assays*	1 kit
A22178	Amplex® Red Neuraminidase (Sialidase) Assay Kit *400 assays*	1 kit
A11132	anti- β -galactosidase, rabbit IgG fraction *2 mg/mL*	0.5 mL
A5790	anti- β -glucuronidase, rabbit IgG fraction *2 mg/mL*	0.5 mL
B34402	BODIPY® FL C ₅ -lactosylceramide complexed to BSA	1 mg
B1690	5-bromo-4-chloro-3-indolyl β -D-galactopyranoside (X-Gal)	1 g
B1691	5-bromo-4-chloro-3-indolyl β -D-glucuronide, cyclohexylammonium salt (X-GlcU, CHA)	100 mg
D2920	DetectaGene™ Green CMFDG <i>lacZ</i> Gene Expression Kit	1 kit
D6488	9H-(1,3-dichloro-9,9-dimethylacridin-2-one-7-yl) β -D-galactopyranoside (DDAO galactoside)	5 mg
D7519	N-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-dodecanoyl)sphingosyl 1- β -D-galactopyranoside (BODIPY® FL C ₁₂ -galactocerebroside)	25 μ g
D13951	N-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-s-indacene-3-pentanoyl)sphingosyl 1- β -D-lactoside (BODIPY® FL C ₅ -lactosylceramide)	25 μ g
D2893	5-dodecanoylaminofluorescein di- β -D-galactopyranoside (C ₁₂ FDG)	5 mg
E33953	EnzChek® cellulase substrate *blue fluorescent, 339/452*	1 mg
E22013	EnzChek® Lysozyme Assay Kit *400 assays*	1 kit
E33651	EnzChek® Ultra Amylase Assay Kit *500 assays*	1 kit
E33650	EnzChek® Ultra Xylanase Assay Kit *500 assays*	1 kit
F1930	FluoReporter® <i>lacZ</i> Flow Cytometry Kit *50 assays*	1 kit
F2905	FluoReporter® <i>lacZ</i> /Galactosidase Quantitation Kit *1000 assays*	1 kit
F1179	fluorescein di- β -D-galactopyranoside (FDG)	5 mg
F2881	fluorescein di- β -D-glucopyranoside (FDGlu)	5 mg
F2915	fluorescein di- β -D-glucuronide (FDGlcU)	5 mg
I2904	ImaGene Green™ C ₁₂ FDG <i>lacZ</i> Gene Expression Kit	1 kit
I2908	ImaGene Green™ C ₁₂ FDGlcU GUS Gene Expression Kit	1 kit
I2906	ImaGene Red™ C ₁₂ RG <i>lacZ</i> Gene Expression Kit	1 kit
M1489MP	4-methylumbelliferyl β -D-galactopyranoside (MUG)	1 g
M1490	4-methylumbelliferyl β -D-glucuronide (MUGlcU)	100 mg
N10563	NovaBright™ β -galactosidase Enzyme Reporter Gene Chemiluminescent Detection Kit *for mammalian cells* *200 assays*	1 kit
N10564	NovaBright™ β -galactosidase Enzyme Reporter Gene Chemiluminescent Detection Kit *for mammalian cells* *1000 assays*	1 kit
N10565	NovaBright™ β -galactosidase Enzyme Reporter Gene Chemiluminescent Detection Kit *for yeast cells* *200 assays*	1 kit
N10566	NovaBright™ β -galactosidase Enzyme Reporter Gene Chemiluminescent Detection Kit *for yeast cells* *1000 assays*	1 kit
P11948	5-(pentafluorobenzoylamino)fluorescein di- β -D-galactopyranoside (PFB-FDG)	5 mg
P11947	5-(pentafluorobenzoylamino)fluorescein di- β -D-glucopyranoside (PFB-FDGlu)	5 mg
P11949	5-(pentafluorobenzoylamino)fluorescein di- β -D-glucuronide (PFB-FDGlcU)	5 mg
P1692	phenylethyl β -D-thiogalactopyranoside (PETG)	10 mg
R1159	resorufin β -D-galactopyranoside	25 mg
S931	streptavidin, β -galactosidase conjugate	1 mg

10.3 Detecting Enzymes That Metabolize Phosphates and Polyphosphates

Cells utilize a wide variety of phosphate and polyphosphate esters as enzyme substrates, second messengers, membrane structural components and vital energy reservoirs. This section includes an assortment of reagents and methods for detecting the metabolism of phosphate esters. Our diverse array of fluorogenic, chemiluminescent and chromogenic substrates include substrates for phosphatases, as well as reagents to measure the activity of enzymes such as ATPases, GTPases, DNA and RNA polymerases and paraoxonase. Unlike phosphatases, which hydrolyze phosphate esters, kinases use ATP to phosphorylate their target. Our Antibody Beacon™ Tyrosine Kinase Assay Kit (A35725, described below) provides a general and high-throughput solution assay for measuring the activity of tyrosine kinases using unlabeled peptides. In addition to these reagents, we offer several nucleotide analogs and substrates for phosphodiesterases and phospholipases that are described in Section 17.3 and Section 17.4, respectively.

By far the largest group of chromogenic and fluorogenic substrates for phosphate-ester metabolizing enzymes are those for simple phosphatases such as alkaline and acid phosphatase, both of which hydrolyze phosphate monoesters to an alcohol and inorganic phosphate. Conjugates of calf intestinal alkaline phosphatase are extensively used as secondary detection reagents in ELISAs,¹ immunohistochemical techniques² and Southern, northern and western blot analyses. In addition, phosphatases serve as enzyme markers, allowing researchers to identify primordial germ cells,³ to distinguish subpopulations of bone marrow stromal cells⁴ and to investigate *in vitro* differentiation in carcinoma cell lines.⁵⁻⁷ *PALP-1*, the gene for human placental alkaline phosphatase, has been used as a eukaryotic reporter gene that is superior to *lacZ* for lineage studies in murine retina.^{8,9} This gene has also been engineered to produce a secreted alkaline phosphatase (SEAP), allowing quantitation of gene expression without disrupting the cells.¹⁰

Phosphatase Substrates Yielding Soluble Fluorescent Products

Fluorescein Diphosphate

First described in 1963,¹¹ fluorescein diphosphate (FDP, F2999) is perhaps the most sensitive fluorogenic phosphatase substrate available. The colorless and nonfluorescent FDP reagent is hydrolyzed to fluorescein (F1300, F36915; Section 10.1), which exhibits superior spectral properties (EC ~90,000 cm⁻¹M⁻¹, quantum yield ~0.92). We have succeeded in preparing a highly purified FDP and find it to be an excellent substrate for alkaline phosphatase in ELISAs, providing detection limits at least 50 times lower than those obtained with the chromogenic 4-nitrophenyl phosphate.¹² The relatively high pH required to monitor alkaline phosphatase activity is advantageous because it also enhances fluorescein's fluorescence. FDP has been used for a diverse set of applications, including:

- Assaying alkaline phosphatase in a microfluidic device¹³
- Assaying diarrhetic shellfish toxins in a microplate assay¹⁴
- Detecting alkaline phosphatase immobilized on microspheres in an optical sensor array¹⁵
- Measuring endogenous phosphatase in an assay for cell adhesion and migration that is reported to be as sensitive as ⁵¹Cr-release assays¹⁶
- Quantitating the effect of inhibitors on tyrosine phosphatases¹⁷⁻¹⁹

Dimethylacridinone (DDAO) Phosphate

Our phosphatase substrate DDAO phosphate (9H-(1,3-dichloro-9,9-dimethylacridin-2-one-7-yl) phosphate, D6487; Figure 10.3.1) yields a hydrolysis product that is efficiently excited by the 633 nm spectral line of the He-Ne laser to produce bright red fluorescence with absorption/emission maxima of ~646/659 nm (Figure 10.3.2). Although the substrate itself is fluorescent, the difference between the substrate's excitation maximum and that of the phenolic hydrolysis product is over 200 nm (Figure 10.3.3), allowing the two species to be easily distinguished. Like other DDAO-based substrates, DDAO phosphate has good water solubility, a low *K_M* and a high turnover

Figure 10.3.1 9H-(1,3-dichloro-9,9-dimethylacridin-2-one-7-yl) phosphate, diammonium salt (DDAO phosphate, D6487).

Figure 10.3.2 Normalized absorption and fluorescence emission spectra of DDAO, which is formed by alkaline phosphatase-mediated hydrolysis of DDAO phosphate (D6487).

Figure 10.3.3 Absorption spectra of 1) DDAO galactoside (D6488) and 2) DDAO (H6482) at equal concentrations in pH 9 aqueous buffer. These spectra show the large spectral shift accompanying enzymatic cleavage of DDAO-based substrates. DDAO phosphate (D6487) has very similar spectra to DDAO galactoside.

rate, making it particularly useful for both fluorescence- and absorption-based microplate assays.²⁰

Methylumbelliferyl Phosphate (MUP) and Difluorinated Methylumbelliferyl Phosphate (DiFMUP)

We offer 4-methylumbelliferyl phosphate (MUP, M6491), a widely used fluorogenic substrate for alkaline phosphatase detection. MUP has been used for a variety of ELISA protocols²¹ in which the relatively high pH optimum of alkaline phosphatase permits continuous detection of the rate of formation of 4-methylumbelliferone (7-hydroxy-4-methylcoumarin, H189, Section 10.1). MUP has also been used to count cells based on their alkaline phosphatase activity,²² to detect PCR amplification products^{23,24} and to identify and characterize bacteria.^{25,26}

We also offer 6,8-difluoro-4-methylumbelliferyl phosphate (DiFMUP, D6567, D22065; Figure 10.3.4), which exhibits extraordinary spectral properties that are advantageous for the assay of both acid and alkaline phosphatase activity and is probably the best general substrate available for measuring the activity of the protein phosphatases that are important for high-throughput screening applications under physiological conditions.²⁷ The hydrolysis product of DiFMUP—6,8-difluoro-4-methylumbelliferone (6,8-difluoro-7-hydroxy-4-methylcoumarin, D6566; Section 10.1)—exhibits both a lower pK_a (4.9 versus 7.8, Figure 10.3.5) and a higher fluorescence quantum yield (0.89 versus 0.63) than the hydrolysis product of MUP.²⁸ The low pK_a of its hydrolysis product makes DiFMUP a sensitive substrate for the continuous assay of acid phosphatases (Figure 10.3.6, Figure 10.3.7), which is not possible with MUP because its fluorescence must be measured at alkaline pH (pH >9) if the conventional detection configuration (excitation/emission = 360/460 nm) is used. Furthermore, with its high fluorescence

Figure 10.3.4 6,8-Difluoro-4-methylumbelliferyl phosphate (DiFMUP, D6567).

Figure 10.3.5 Comparison of the pH-dependent fluorescence changes produced by attachment of electron-withdrawing fluorine atoms to a hydroxycoumarin. 7-Hydroxy-4-methylcoumarin-3-acetic acid (○, H1428) and 6,8-difluoro-7-hydroxy-4-methylcoumarin (●, D6566) demonstrate the decrease of the pK_a from ~7.4 to ~6.2. Fluorescence intensities were measured for equal concentrations of the two dyes using excitation/emission at 360/450 nm.

Figure 10.3.6 Comparison of DiFMUP (D6567, D22065) with MUP (M6491) for the detection of acid phosphatase activity at pH 5.5. Increasing amounts of prostatic acid phosphatase from human semen were reacted with 100 μ M DiFMUP, the substrate in the EnzChek® Acid Phosphatase Assay Kit (E12020), or 100 μ M MUP, in 100 mM sodium acetate, pH 5.5, at room temperature. Fluorescence was measured after 60 minutes in a fluorescence microplate reader using excitation at 360 \pm 20 nm and emission detection at 460 \pm 20 nm.

Figure 10.3.7 Time course of the reaction of prostatic acid phosphatase with DiFMUP (D6567, D22065) and MUP (M6491). Prostatic acid phosphatase from human semen (0.002 units) was reacted with 100 μ M DiFMUP or 100 μ M MUP in 100 mM sodium acetate, pH 5.5, at room temperature. Fluorescence was measured at the indicated times in a fluorescence microplate reader using excitation at 360 \pm 20 nm and emission detection at 460 \pm 20 nm.

quantum yield, DiFMUP increases the sensitivity of both acid and alkaline phosphatase measurements. As with our fluorinated fluorescein derivatives (Oregon Green® dyes, Section 1.5), fluorination renders the methylumbelliferone fluorophore much less susceptible to photobleaching, yet does not significantly affect the extinction coefficient or excitation/emission maxima. DiFMUP is available as a single 5 mg vial (D6567) or as a set of 10 vials, each containing 10 mg of the substrate (D22065) for high-throughput screening applications. DiFMUP is also used in our EnzChek® Phosphatase Detection Kit (E12020), our RediPlate™ 96 EnzChek® Tyrosine Phosphatase Assay Kits (R22067) and our RediPlate™ 96 EnzChek® Serine/Threonine Phosphatase Assay Kit (R33700), which are described below with our other phosphatase assay kits.

Coumarin-Based Probe for Detection of Inorganic Phosphate

When conjugated to a mutant phosphate-binding protein, 7-diethylamino-3-(((2-maleimidyl)ethyl)amino)carbonyl)coumarin (MDCC, D10253; Section 2.3) has proven useful for direct, real-time measurement of inorganic phosphate release during enzymatic reactions.^{29–33} A similar (7-diethylamino-3-(((2-iodoacetamido)ethyl)amino)carbonyl) coumarin (IDCC) conjugate of a mutant nucleoside diphosphate kinase has been used as a fluorescent sensor of the phosphorylation state of the kinase and to monitor purine nucleoside diphosphate concentrations in real time.³⁴

ELF® 97 Phosphate: A Phosphatase Substrate That Yields a Fluorescent Precipitate

ELF® 97 phosphate (E6588, E6589) yields a fluorescent precipitate at the site of phosphatase activity (Figure 10.3.8)—a process we call Enzyme-Labeled Fluorescence (ELF®). Upon enzymatic cleavage (Figure 10.3.9), this weakly blue-fluorescent substrate yields an extremely photostable green-fluorescent precipitate that is up to 40 times brighter than the signal achieved when using either directly labeled fluorescent hybridization probes or fluorescent secondary detection methods in comparable applications.^{35–37} A particularly prominent application of ELF® 97 phosphate is the detection of tartrate-resistant acid

phosphatase (TRAP) activity, a marker of osteoclast differentiation from hematopoietic stem cells^{38–41} (HSC). Using ELF[®] 97 phosphate and confocal laser-scanning microscopy, researchers have developed a semiautomated method for analyzing the position within a regenerating newt limb of transfected cells expressing the secreted alkaline phosphatase reporter gene.⁴²

Kits based on our ELF[®] 97 phosphate include:

- ELF[®] 97 mRNA *In Situ* Hybridization Kits (E6604, E6605)
- ELF[®] 97 Cytological Labeling Kit (E6603)
- ELF[®] 97 Immunohistochemistry Kit (E6600)
- ELF[®] 97 Endogenous Phosphatase Detection Kit (E6601)

These kits and their contents are described in detail in Section 6.3. ELF[®] 97 phosphate is also available separately as a 5 mM solution in water containing sodium azide (E6589) or in a 0.2 μm–filtered solution (E6588). Filtration of ELF[®] 97 phosphate through an ELF[®] spin filter (E6606) is recommended before use. The ELF[®] 97 alcohol (Figure 10.3.10) is available as a concentrated solution in DMSO (E6578, Section 10.1).

BODIPY[®] FL ATP-γ-S and BODIPY[®] FL GTP-γ-S Thioesters: Substrates for the Fhit Nucleotide-Binding Protein

BODIPY[®] FL ATP-γ-S (A22184) and BODIPY[®] FL GTP-γ-S (G22183) thioesters are important substrates for Fhit (Figure 10.3.11), a member of the histidine triad superfamily of nucleotide-binding proteins that binds and cleaves diadenosine polyphosphates.^{43–45} Fhit, one of the most

Figure 10.3.9 Principle of enzyme-mediated formation of the fluorescent ELF[®] 97 alcohol precipitate from the ELF[®] 97 phosphatase substrate.

Figure 10.3.10 The normalized fluorescence excitation and emission spectra of the ELF[®] 97 alcohol precipitate (E6578), which is generated by enzymatic cleavage of the soluble ELF[®] 97 phosphatase substrate (E6588, E6589).

Figure 10.3.8 A transverse section of fixed zebrafish retina probed with FRet 43, a monoclonal antibody that binds to double cone cells, and developed for visualization with enzyme-mediated immunohistochemical techniques using our ELF[®] 97 Immunohistochemistry Kit (E6600). The yellow-green–fluorescent double cones stained with the ELF[®] 97 alcohol precipitate are oriented so that their outer segments are at the left of the stained configuration and the synaptic pedicles are at the right. This section has been counterstained with tetramethylrhodamine wheat germ agglutinin (W849), which makes the rod outer segments (bottom left) and the inner plexiform layer and ganglion cell axons (top right) appear bright red. Wheat germ agglutinin also binds in the region occupied by the cone outer segments and synaptic pedicles, which appear bright yellow because they are double-labeled with both the ELF[®] 97 alcohol precipitate and tetramethylrhodamine. Although this section has also been counterstained with Hoechst 33342 (H1399, H3570, H21492), the blue-stained nuclei are barely visible in this photomicrograph. However, the double cones' inner fibers traverse the region occupied by the Hoechst 33342 dye–stained rod nuclei, and thus appear light blue. The inner segments, myoids and nuclei of these double-cone cells are labeled only with the ELF[®] 97 alcohol precipitate, giving them a characteristic green appearance. The image was obtained by triple-exposure through optical filters appropriate for DAPI, tetramethylrhodamine and the ELF[®] precipitate. Used with permission from (J Histochem Cytochem (1995) 43:77).

Figure 10.3.11 Principle of fluorescence-based detection of the diadenosine triphosphate hydrolase activity of Fhit using BODIPY[®] FL GTP-γ-S thioester (G22183) as a substrate analog.

frequently inactivated proteins in lung cancer, functions as a tumor suppressor by inducing apoptosis.^{44,46,47} In addition to their use for screening potential Fhit inhibitors, these BODIPY® FL nucleotides should also be important for studying other nucleotide-binding proteins because they bind to ATP- or GTP-binding sites but are not metabolized (Section 17.3). As with other fluorescent nucleotides, the fluorescence polarization properties of the bound nucleotide should differ from that of the free nucleotide. The fluorescence of BODIPY® FL GTP- γ -S thioester is quenched ~90% relative to that of the free dye (Figure 10.3.12) but is recovered upon binding to at least some G-proteins.^{48,49}

Chemiluminescent Phosphatase Substrates

NovaBright™ Secreted Placental Alkaline Phosphatase (SEAP) Enzyme Reporter Gene Chemiluminescent Detection System

The NovaBright™ Secreted Placental Alkaline Phosphatase (SEAP) Enzyme Reporter Gene Chemiluminescent Detection System is a chemiluminescent reporter gene assay designed for the rapid and sensitive detection of secreted placental alkaline phosphatase (SEAP) in cell culture media. SEAP, a truncated form of human placental alkaline phosphatase (PLAP), is commonly used as a reporter protein that is secreted into the cell culture media and detected by testing aliquots of media, leaving cells intact for further experimentation. Detection of nonsecreted placental alkaline phosphatase is also possible using the NovaBright™ SEAP Enzyme Reporter Gene Chemiluminescent Detection System.

The NovaBright™ SEAP Enzyme Reporter Gene Chemiluminescent Detection System employs the CSPD® chemiluminescent substrate and Emerald luminescence enhancer to achieve sensitive SEAP detection with a wide dynamic range.^{50,51} In this NovaBright™ assay, SEAP activity is measured 48–72 hours after cell transfection by first incubating the cell culture medium or cell lysate with a buffer that selectively inhibits nonplacental alkaline phosphatase (serum and endogenous cellular alkaline phosphatases), and then with CSPD®-containing reaction buffer until maximum light emission is reached (approximately 20 minutes). The light emission kinetics provide a persistent glow signal

that enables measurement over a wide time interval. Light signal output is measured in a luminometer, without the need for automated injection capability. The NovaBright™ SEAP Enzyme Reporter Gene Chemiluminescent Detection System has been used to detect SEAP activity in cell culture media and to quantitate nonsecreted placental alkaline phosphatase in both cell and tissue extracts.

Chemiluminescent reporter assays for secreted placental alkaline phosphatase may be conducted in cells that have endogenous nonplacental alkaline phosphatase activity. Endogenous nonplacental enzyme activity is significantly reduced with a combination of heat inactivation and differential inhibitors that do not significantly inhibit the transfected placental alkaline phosphatase. It is important to determine the level of endogenous enzyme in media of nontransfected cells in order to establish assay background. Certain cell lines, such as HeLa and others derived from cervical cancers, may express placental alkaline phosphatase, which will likely produce high assay backgrounds when shed into the media, and therefore we do not recommend the use of secreted alkaline phosphatase as a reporter system in these cell lines.

Each NovaBright™ SEAP Enzyme Reporter Gene Chemiluminescent Detection System provides:

- CSPD® substrate
- Purified human placental alkaline phosphatase
- Dilution buffer
- Assay buffer, containing a mixture of nonplacental alkaline phosphatase inhibitors
- Reaction buffer, containing the Emerald luminescence enhancer
- Detailed protocols

Sufficient reagents are supplied for 400 (N10559) or 1200 (N10560) microplate assays based on the protocol provided.

NovaBright™ Secreted Placental Alkaline Phosphatase (SEAP) Enzyme Reporter Gene Chemiluminescent Detection System 2.0

The next-generation NovaBright™ SEAP Enzyme Reporter Gene Chemiluminescent Detection System 2.0 employs CSPD® chemiluminescent substrate and an advanced Emerald-III™ luminescence enhancer that produces higher signal intensity and higher assay signal/noise performance than the original assay system. In addition, all the reagents in the new assay system are provided ready-to-use without the need for any reagent preparation steps, allowing fewer assay steps and a shorter assay duration. Depending on the expression system, secreted placental alkaline phosphatase can be measured in as little as 6 hours after cell transfection.

In this assay, cell culture medium is incubated first with an assay buffer that contains selective inhibitors of nonplacental alkaline phosphatase (serum and endogenous cellular alkaline phosphatases) and then with the reaction buffer containing CSPD® substrate and Emerald-III™ light emission enhancer until maximum light signal is reached in approximately 20 minutes. The light emission kinetics provide a persistent glow signal, with light emission half-life of approximately 2.5 hours, enabling measurement over a wide time interval. Light emission is measured in a luminometer without the need for automated injection capability. As with the original system, we do not recommend the use of this assay in cell lines such as HeLa and others derived from cervical cancers, that may express placental alkaline phosphatase.

Figure 10.3.12 Fluorescence emission spectra of 1) free BODIPY® FL dye in phosphate-buffered saline, pH 7.2; 2) BODIPY® FL ATP (A12410); and 3) BODIPY® FL GTP (G12411). Samples were prepared with equal absorbance at the excitation wavelength (488 nm). The areas under the curves are therefore proportional to the relative fluorescence quantum yields, clearly showing the quenching effect caused by interaction of the BODIPY® FL fluorophore with the guanine base of GTP.

Each NovaBright™ SEAP Enzyme Reporter Gene Chemiluminescent Detection System 2.0 provides:

- Reaction buffer, containing CSPD® substrate and Emerald-III™ luminescence enhancer
- Purified human placental alkaline phosphatase
- Assay buffer, containing a mixture of nonplacental alkaline phosphatase inhibitors
- Detailed protocols

Sufficient reagents are supplied for 192 (N10577) or 960 (N10578) microplate assays based on the protocol provided.

Chemiluminescent Alkaline Phosphatase ELISA Sampler Kit

The Chemiluminescent Alkaline Phosphatase ELISA Kits employ CSPD® or CDP-Star® 1,2-dioxetane substrates for alkaline phosphatase with Sapphire™-II or Emerald-II™ enhancer in a system designed for rapid and ultrasensitive analyte detection in enzyme-linked immunoassays.⁵² Maximum light emission from alkaline phosphatase-activated CSPD® or CDP-Star® substrate is reached in 5 to 60 minutes, depending on the temperature and the substrate chosen. Enzymatic dephosphorylation of substrate occurs at a constant rate proportional to enzyme concentration; the resulting phenolate anion decomposes with a finite half-life (Figure 10.3.13). Light emission can be quantitated with a variety of luminometers without the need for solution injection.

Enzyme-linked immunosorbent assays (ELISAs) can be formatted in several configurations on a variety of solid supports including microplate wells, tubes, polystyrene beads or ferrite particles. The high sensitivity obtained with 1,2-dioxetane substrates is demonstrated in a sandwich immunoassay format that employs a biotinylated detector antibody and streptavidin alkaline phosphatase conjugate for quantitating recombinant human IL-6 (rhIL-6). The results obtained with CSPD® substrate/Sapphire™-II enhancer (Figure 10.3.14) show a significant improvement in signal-to-noise performance at all concentrations of rhIL-6 and a much wider assay dynamic range compared to those obtained with the fluorescent substrate 4-methylumbelliferyl phosphate (MUP, M6491), and the colorimetric substrate *p*-nitrophenyl phosphate⁵² (pNPP).

We offer four different Chemiluminescent Alkaline Phosphatase ELISA Kits, as well as a Chemiluminescent Alkaline Phosphatase ELISA Sampler Kit. Each kit provides concentrated assay buffer and blocking reagent, as well as one of the following substrate/enhancer solutions:

- CSPD® substrate/Sapphire™-II enhancer (in Kit #1, C10552)
- CSPD® substrate/Emerald-II™ enhancer (in Kit #2, C10553)
- CDP-Star® substrate/Sapphire™-II enhancer (in Kit #3, C10554)
- CDP-Star® substrate/Emerald-II™ enhancer (in Kit #4, C10555)

The Chemiluminescent Alkaline Phosphatase ELISA Sampler Kit (C10556) provides assay buffer, blocking reagent and sample sizes of all four substrate/enhancer solutions. All five kits provide sufficient reagents for 1000 assays based on the provided protocol.

Figure 10.3.13 Mechanism of phosphatase-dependent chemiluminescence generation by CDP-Star® substrate. Luminescence emission is shifted to 461 nm or 542 nm, respectively, by the Sapphire™-II and Emerald-II™ enhancers.

Figure 10.3.14 Comparison of detection sensitivities for the ELISA quantitation of recombinant human IL-6 (rhIL-6) using the chemiluminescent phosphatase substrate/enhancer in the Chemiluminescent Alkaline Phosphatase ELISA Kit #1 (CSPD® substrate/Sapphire™-II enhancer in C10552), the fluorescent phosphatase substrate 4-methylumbelliferyl phosphate (MUP, M6491) and the colorimetric phosphatase substrate *p*-nitrophenyl phosphate (pNPP).

Figure 10.3.16 Endogenous phosphatase activity in a zebrafish ovary cross-section, stained with the BCIP (B6492) and NBT (N6495) reagents. These reagents are also available in the NBT/BCIP Reagent Kit (N6547).

Chromogenic Phosphatase Substrate

NBT/BCIP Reagent Kit

5-Bromo-4-chloro-3-indolyl phosphate (BCIP) is commonly used with a number of different chromogens in various histological and molecular biology techniques. Hydrolysis of this indolyl phosphate, followed by oxidation, produces a blue-colored precipitate at the site of enzymatic activity. For convenience, we offer the NBT/BCIP Reagent Kit (N6547), which provides 1 g samples of BCIP as well as its co-precipitant NBT.

NBT: A Co-Precipitant for the BCIP Reaction
